The films of the knees show wide metaphyses, marked vacuolization, and a large spur-like mass springing from the inner aspect of both femora, about the level of the adductor tubercle There was a wide metaphysis and marked vacuolization of the

upper end of the fibula, with a small spur-like projection on the upper aspect of the metaphysis of both tibiae

There was marked widening and lack of

Fig 25 Case 7 Posterior view, showing the multiple lesions

tubulation of the lower metaphysis of the tibiae, and sessile, spur-like formations Similar evidences of deformity were noted in the metatarsals

The right forearm showed a marked bowing of both radius and ulna with shortening of the ulna

At the time that these films were made, the mass about the right ankle was beginning to interfere with function and the patient was advised to submit to operation

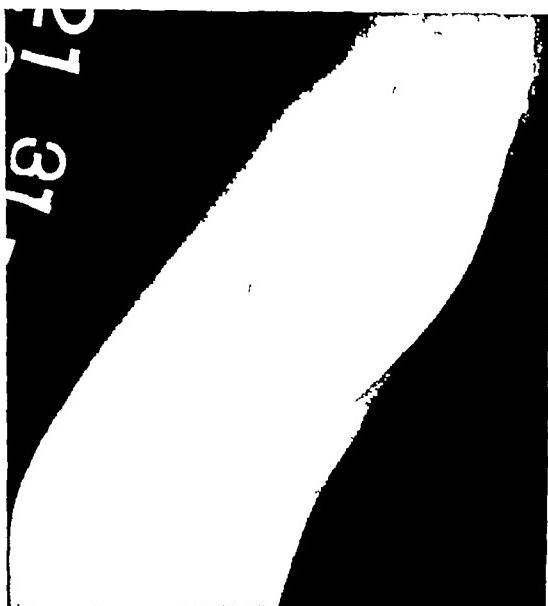

Fig. 26 Case 7 Dyschondroplasia. The film shows marked bowing of both radius and ulna with shortening of the latter.

She was seen again in January, 1931, and at that time the following notes were made:

Growth is stunted, the patient is only five feet tall.

Both upper extremities seem to be short, especially the forearms.

On the outer side of the right arm there is a large mass which extends down for about three inches. This mass is hard and nodular, and the skin which is freely movable over it, is not glossy.

On the left side of the median line, approximately at the level of the sixth dorsal vertebra, there is a mass about one inch in diameter which seems to spring from one of the ribs. Like other lesions, it is fixed, nodular, and has a bony hardness.

On the angle of the scapula, on the left side, there is a similar nodular mass. None of the masses is painful.

On the crest of the left ilium there is a mass about three inches by two inches. This lesion has all the characteristics mentioned before except that it is very much larger than the others.

On both sides of the left leg below the knee there are similar masses. There is a scar on the outer side of the left knee indicating the site of a previous operation. On the inner side of the left knee, there is a bony lesion.

The mass on the outer side of the right leg which extends into the popliteal space is one of the largest that she has.

In front of the right ankle there is a large lesion which is causing limitation of motion.

In June, 1931, the following operation was performed. Incision about three inches in length was made over the anterior inner aspect of the right leg, just above the ankle. The muscles were retracted and a hard, bony mass with multiple bosses on its surface was then seen. With a Campbell gouge and mallet, the bony growth was cut away from the tibia. Incision was made over the ulnar side of the right forearm and a mass similar to the one on the leg was removed in a like manner.

On Sept. 2, 1931, the patient returned for examination and the following notes were made:

The contour of the right leg is markedly improved, in fact, the anterior aspect of the lower third of the leg is perfectly straight. She is able to stand on her toes and at the present time there is no limitation of motion in either ankle.

The deformity about both shoulders, and the crest of the ilium is such that I have advised operative intervention in these regions.

Up to the present time I have removed seven of the masses because they were interfering with function.

Comments.—In making the diagnosis, multiple cartilaginous epiphyseal enchondromas, I was conforming with the commonly accepted term. It becomes immediately apparent, as one looks at the films of this patient's skeleton, particularly the humeri, femora, and tibiae, that these outgrowths, which like spurs interfere with

joint function, represent but a small part of the disturbance in growth and development of the pathologic process I use the expression "pathologic," not in the sense of disease but in the sense that there is a lack of

theory based on disturbance of the endocrine system, but no detailed satisfactory explanation, so far as I know, had before appeared Dissociation phenomena due to a complete retardation of the process of tubulation re-

Fig 27 Case 7 A large mass in the region of the right tuberosity and upper third of the left humerus

harmony among the various processes which have to do with normal bone growth

The fact that these lesions are multiple shows their relationship to something which has to do with abnormal development

These lesions are benign in the sense that they do not endanger life, but malignant in the sense that they are disabling and deforming We take them off if they begin to interfere with function We must not attempt to do too much during the early period of growth because of the danger of early bony union of the metaphysis and epiphysis which would interfere with growth in length of the skeleton Except with the pedunculated masses, no attempt to interfere surgically is advisable

All ideas of which I had knowledge, prior to the appearance of Murk Jansen's epoch-making study, did not seem to explain satisfactorily the wide metaphyses His explanation clearly accounts for every phenomenon which one sees in such cases It is true that John Hunter had paved the way and that Sir Arthur Keith had developed a

sult in a wide metaphysis, and partial retardation of tubulation causes exostoses

This last statement is verified by the last case of the series

Case 8 Miss B, 20 years old Diagnosis was dyschondroplasia. History—Ten years earlier she had noticed a small, hard mass about 0.5 inch in diameter on the right scapula A little later she noticed similar small bony masses on the inner aspect of the left thigh and the left leg just above the ankle Four years later she noticed a growth on the left side of the chest under the breast One year later a mass appeared on the inner aspect of the right leg just below the knee During the five years previous to examination, the patient had noted similar masses develop on various bones of her body The growth of all of the masses has been slow and painless

She was prompted to consult a doctor because of the large size of the mass on the inner aspect of the left thigh just above the knee which had begun to interfere with function

Fig 28 Case 7 A large mass springing from the posterior iliac crest and bilateral coxa vara. There was evidence of retardation of tubulation of the femora

Fig 29 Case 7 Note the large masses springing from both femora, and the wide metaphysis at the upper end of the fibulae, with spur-like masses on the inner aspect of both tibiae.

Physical Examination — Examination made on Nov 3, 1931, revealed the patient to be fairly well developed, about five feet tall. There was nothing unusual about the face and certainly no loss of symmetry. The shoulders were apparently symmetrical and the contour was not altered. There was a fullness in the infraclavicular spaces on both sides. The breasts were symmetrical. There was nothing unusual in the appearance of the chest or abdomen. Looking at the back we noted an irregular nodular appearance about the spine of the right scapula.

The lower extremities were asymmetrical in that the left thigh was less well developed than the right. There was a large prominent conical mass on the inner aspect of the left thigh just above the knee. The skin covering this was not altered in color. There was a prominent mass on the inner aspect of the left ankle.

On palpation over the right scapula, in the region of the spine particularly we found a nodular mass which seemed to spring from the region of the body of the spine of the scapula and the vertebral border.

There were nodular masses on the upper

outer portions of both humeri. The coracoid process seemed unduly large and nodular. The left forearm was shorter than the right. There was a nodular, prominent, hard mass on the dorsal and volar aspects of the radius at the lower end.

Under the outer upper quadrant of the left breast there was a hard, nodular mass which seemed to spring from about the third or fourth or the fourth or fifth rib.

Below the anterior crest of the ilium on both sides there was a hard, nodular mass which was not adherent to the skin and which was not tender. On the inner aspect of the right femur about the level of the abductor tubercle, there was a hard, sessile mass from approximately 2 5 inches to 3 inches in the transverse axis and 2 inches in the long axis of the body. This sessile growth seemed to spring from the lower metaphysis of the femur. The mass on the inner aspect of the left leg seemed to spring from the lower metaphysis of the tibia. There was a small mass on the inner aspect of the right tibia.

On the dorsum of the hand, over the metacarpals and phalanges, there were small, nodular, sessile masses.

Fig 30 Case 7. There was marked widening of the lower metaphyses and tibiae, with spur-like formations, there was also deformity in the metatarsals.

None of the masses described was adherent to the skin, nor was any one of them movable. No pain was associated with any of these masses, and, with the exception of the one on the inner aspect of the left femur, none was so located as to disturb the patient a very great deal.

The diagnosis was dyschondroplasia (Figs 31-39).

X-ray films were made of the entire skeleton. The films of the chest show involvement of ribs, both scapulae and both humeri. Below the glenoid fossa and near the angle of the scapulae, there were distinct irregular elevated lesions. The head of the right humerus was larger than the left. The upper three inches of the diaphysis of the right humerus was broader than the left. There was, apparently, an attempt at proper

tubulation of the upper portion of the shaft of the right humerus, as evidenced by a line suggesting a portion of the normal cortex, but this was covered by a large, less dense area of bone. If one had not seen other evidences of disturbance, he would have been inclined to think that a fracture had occurred in this region at some time in the past. The upper portion of the left humerus showed a marked vacuolization and there was a fusiform enlargement of the upper portion of the middle third of the shaft. There was no evidence of disturbance at the lower end of either humerus.

There were a number of exostoses on the ribs, particularly on the left side there was a large pedunculated mass which was much less dense than the surrounding bone. This sprang from the fourth rib. On the le-

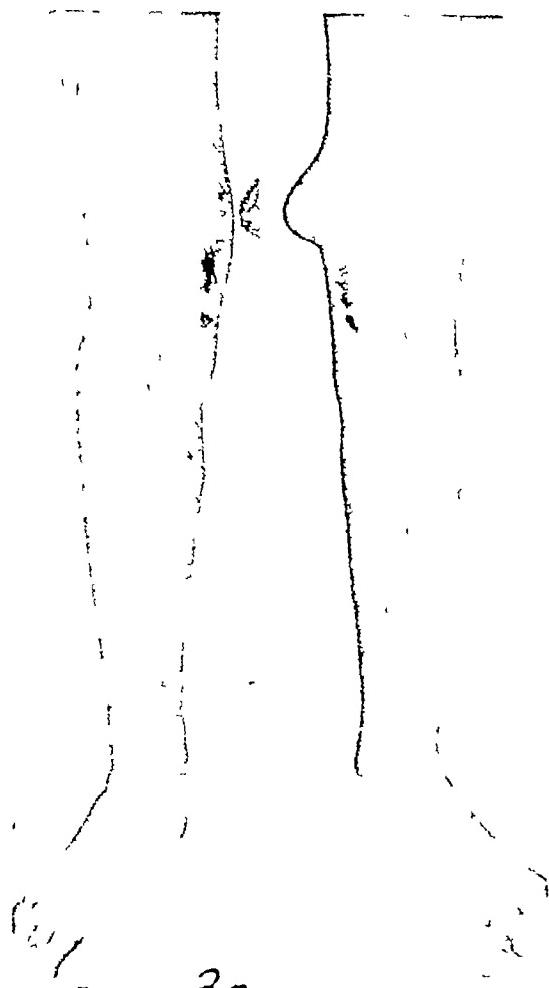

Fig. 31 Case 8 Dyschondroplasia. Physical examination showed a large mass on the inner aspect of the left femur and one on the inner aspect of the left ankle.

there was a smaller mass springing from the fifth rib

When comparing the films of the two hands and forearms, one noticed that the right hand was much larger than the left. All of the metacarpal bones and phalanges were larger on the right than on the left. There were exostoses on the phalanges, as well as the metacarpals on the right hand. The right radius was about 0.75 inch longer than the left and there were spur-like projections which sprang from the lateral aspect of both radii and ulnae. There was

bowing of both radii and ulnae on the right side. The lower end of the left radius showed a wide metaphysis and a small spur-like projection on the ulnar aspect, as well as a spur-like projection about the middle third of the shaft on the outer side of the radius. The ulna was shorter than the radius by about 0.5 inch. There was a wide metaphysis and a deformed lower end. The lower epiphysis was fused to the metaphysis in an oblique direction.

Examination of the films of the pelvis showed sessile growths springing from the crest of the ilium on both sides, and broad, flat, pubic arches which looked as though the patient barely escaped the additional defect of exstrophy of the bladder. There was a bilateral coxa vara. The neck of the femur, particularly on the left side, was extremely broad, in fact, it was almost as broad as the distance between the tips of the greater and lesser trochanters.

There was a very wide metaphysis of the lower end of the right femur with a horny projection at the lower end of the diaphysis. There was a wide metaphysis at the upper end of the tibia and a spur-like projection on the mesial aspect. The metaphysis of the upper end of the fibula, the head was distorted and there was, apparently, a large sessile growth between the tibia and fibula.

On the left side, the lower metaphysis of the femur was wide, on the mesial aspect of this metaphysis there were two pedunculated growths or exostoses. The density of one of these was irregular and vacuolated. The metaphyses for the upper end of the tibia and fibula were likewise very wide.

Examination of both knees showed wide fusiform lower metaphyses of the fibulae. The metaphysis for the lower end of the tibia did not seem to be as wide as that of the fibula.

Operation was suggested for the removal of the large mass in the inner aspect of the left femur and the one springing from the fourth rib on the left side. The patient was

advised to have others removed at a later date

Operation—Operation was performed on Nov 4, 1931. An incision was made over the large mass on the inner aspect of the femur. The muscles were found to be very thin at the apex of the mass. The muscle tissue was retracted from the tumor and its base was separated from the metaphysis by a sharp Campbell gouge. The rough edges were removed with a rongeur. Bone wax was used to control bleeding. The muscles were approximated and the skin closed.

At the same operation, we removed a small growth from beneath the left breast, which we found originated from the fourth rib. The pedicle was separated from the rib with a Campbell gouge. After bleeding was controlled, the tissue planes were approximated and the skin closed with interrupted dermal suture material.

The patient made an uneventful recovery from this operation.

This case provides additional evidence for the belief that the retardation phenomena which are responsible for the complete and partial retardation of tubulation must have occurred either in the developmental period or have been the result of a disturbance of the germ plasm.

CONCLUSIONS

1 Skeletal deformities and defects are due to retarded development at a particular period.

2 Fanciful theories making amniotic bands responsible for deformities should be discarded.

3 Congenital deformities are in many cases recessive and not dominant.

4 The theory of primogeniture is no longer tenable.

5 Clinical observations in cases of a three-phalanged thumb indicate that the

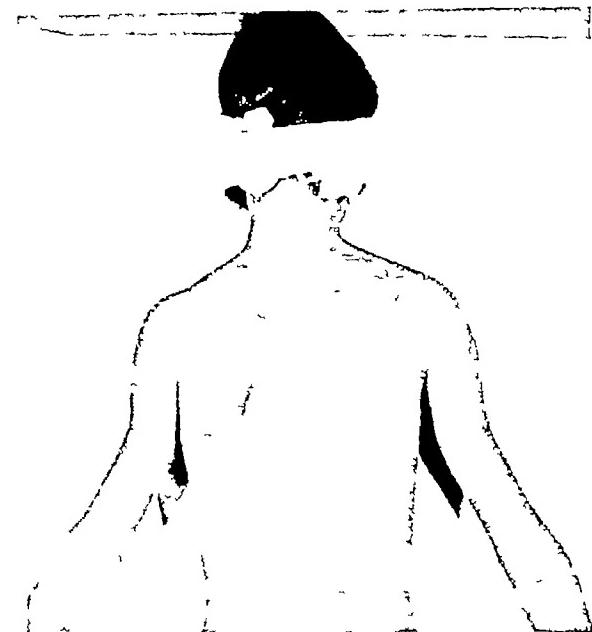

Fig. 32 Case 8 There was involvement of both scapulae and humeri

Fig. 33 Case 8 Involvement of the ribs, scapula, and humerus

metacarpal had disappeared in the process of evolution. What is ordinarily considered the first metacarpal is in all probability a first phalanx. This view is strengthened by the fact that the epiphysis of the so-called first metacarpal is at the proximal end—the position occupied by the epiphysis of the

NOTE ON INTERNATIONAL COMPARISON OF X-RAY STANDARDS

By LAURISTON S TAYLOR, Bureau of Standards, WASHINGTON, D C

A RECENT paper¹ gave a description of comparisons of the Bureau of Standards X-ray ionization standard with that of the National Physical Laboratory, Physikalisch-technische Reichsanstalt, and Le Service d'Etalonnage de l'Hôpital St Antoine. In these comparisons it was necessary in all cases to make corrections for the absorption of X-rays in air, for which absorption coefficients were obtained by extrapolation from available data. These coefficients are, as pointed out, uncertain. Unfortunately, corrections for this paper, suggested by Dr Kaye, were received after it was too late to insert them. He informs us that their recent determinations of the air absorption correction under the conditions used in the comparisons give values somewhat different from those used in the published paper. For 110 KV unfiltered radiation Dr Kaye finds a correction of 2.2 per cent as against 1.5 per cent used in the published paper. For 143 KV, 1.4 mm copper, his correction agreed with the published value. Applying the first correction raises the values of the NPL determination by approximately 0.7 per cent.

a rumor that the plaintiff had caused a roentgenogram to be taken, that there was no opportunity to verify the rumor until after the verdict was received, that afterward the defendants ascertained that the plaintiff had gone to a roentgenologist, who took a roentgenogram of her spinal column and ribs which showed that there had never been any injury to the spine and ribs, and that the roentgenologist informed her that she had not sustained any injury to her spine or ribs. The defendants contended that a new trial should have been granted because (1) the plaintiff was guilty of misconduct in suppressing and concealing the roentgenogram, and because (2) the roentgenoscopy constituted newly discovered evidence which the defendants could not with reasonable diligence have discovered and produced at the trial. But the evidence about the rib and spine affected the amount of the verdict rather than the right to a verdict. The roentgenoscopy was not made until six months after the date of the injury. The roentgenogram was not made a part of the record or exhibited to the trial judge. There was no affidavit by the roentgenologist, notwithstanding the fact that the plaintiff testified as a witness in her own behalf, and by doing so consented that the physician might testify as a witness. While the court does not intend to decide whether the trial judge could have compelled the plaintiff to submit to an examination on the application of the defendants, yet the court may with propriety note the fact that the plaintiff was not requested to permit physicians chosen by the defendants to examine her condition, and, so far as the question of her injury was concerned the defendants were apparently willing to rest their whole case on the testimony of one physician and of one of the nurses at the hospital. The plaintiff was a witness in her own behalf, and she was cross-examined. The defendants had ample opportunity to inquire as to whether or not any other physician had examined her and

whether a roentgenogram had been taken, and yet no such inquiries were made. In view of the fact that the defendants did not take full advantage of the opportunities offered by cross-examination, and in view of the other facts shown by the record, the court does not think it would be justified in reversing the trial court and holding that he should have allowed a new trial on the ground of newly discovered evidence. Nor does the court think that it could fairly be said that the plaintiff was guilty of suppressing evidence. She knew whether she suffered any pain, and she also knew where the seat of the pain was. So overwhelming was the evidence that it might be said to have conclusively established that she suffered pain in the side. The physician who examined her on the evening of the accident stated that he did not discover any broken rib or twisted spine. The physician who called on her five days afterward and from that time on acted as her attending physician testified that her rib was broken and that her spine was twisted. The roentgenogram was not taken until six months after the accident, and, for aught that appeared in the record, the broken rib, if there was one, might have completely united, leaving no evidence of a former break. The court was not advised as to whether medical men would say that a break either sometimes or always leaves evidence of the break which a roentgenogram will invariably picture, nor does it know how serious the break must be in order to leave permanent evidence of the fracture. If the plaintiff's rib was broken, it might be that it was a slight break, and no evidence of the fracture remained when the roentgenogram was taken. The plaintiff was not bound to believe the opinion of the physician who took the roentgenogram six months after the accident, but, knowing that she actually suffered pain, and having been told by her attending physician that her rib was in truth broken, she had a right to believe as she undoubtedly did that her rib

HOW WE MAY REDUCE THE NUMBER OF MALPRACTICE SUITS

By I S TROSTLER, MD, FACR, FACP, CHICAGO

If we can materially reduce the number of malpractice suits filed, we will, as a matter of course, reduce the number to be contested in the courts and the number of verdicts with judgments to be paid, and so, in an indirect and roundabout manner, reduce the premium rates of our malpractice insurance.

From even a casual observation, it is quite clearly evident that malpractice suits are greatly increasing in number and frequency. While the direct cause of this is not clearly patent, much of the increase is correctly attributed to what may well be called malicious tongue wagging. Any one who comes much in contact or has any considerable experience with malpractice suits, knows that too freely discussing the merits and demerits of fellow-practitioners and competitors, with or in the hearing of patients, tends markedly toward the instigation of malpractice suits. In no other profession is this practice so prevalent as it is among physicians. It is practically unheard-of in the various irregular healing cults, but it seems to be on the increase in the regular medical profession. This condition can and should be remedied by organized medicine, by prompt and radical action against these tongue-wagging and innuendo-uttering physicians. If a few suits for slander were filed against the men who instigate the malpractice suits, it would cause some of them to think a second time before making disparaging remarks about their confreres or competitors. Such action would go far toward curbing the malicious gossip of many who are far too ready to say and do things that tend to disparage the actions and practices of their fellow-practitioners. Let us make an example of the physicians who maliciously talk about other physicians' ability, practices,

or conduct of their practice. Make them prove what they allege or pay for their libel. Let us broadcast that we are going to do that and warn them of what we propose to do.

Another important consideration in the prevention of adverse decisions and verdicts against physicians is that practically no malpractice suits can be won without expert testimony that the acts complained of are irregular, wrongful, and constitute conditions recognizable as malpractice. If it were impossible to secure this expert medical testimony, not many malpractice suits could be or would be successful and the legal profession would not be so ready to take the cases and so frequently able to prosecute them to a successful termination.

Here is another potent and powerful means of reducing the number of suits filed and verdicts rendered against our brethren. Let us make it unpopular for any physician to instigate suits or to lend aid by furnishing expert testimony in prosecution of these suits, in that way lessening their frequency and consequently reducing our insurance premiums. *Operæ pretium est.*

REPORTS OF CASES OF INTEREST TO RADIOLOGISTS

DISCOVERIES AS TO ROENTGENOGRAM NOT GROUND FOR NEW TRIAL

(Caldwell *vs* Hoskins *et al* (Ore.),
186 Pac R. 50)

The Supreme Court of Oregon, in affirming a judgment in favor of the plaintiff for damages for personal injuries, says that the defendants filed a motion for a new trial based on affidavits to the effect that a few minutes before the jury returned the verdict the attorneys for the defendants learned of

verdict was for \$2,500. The defendant claimed that it was excessive. The trial occurred a year after the injury. After the injury developed the plaintiff wandered from doctor to doctor for several months. Finally she went to the hospital. She was there six months. The pain had been considerable. At the time of the trial, so her claim was, she was unable to work. The sore was still open and of considerable extent. One physician said it was uncertain whether it would be permanent. The verdict was not excessive.

STANDARDS FOR TREATMENT WITH
ROENTGEN RAYS

(*Hunter vs Burroughs (Va.)*, 96
S E R 360)

The Supreme Court of Appeals of Virginia, in a lengthy opinion, affirms a judgment in favor of plaintiff Burroughs for damages alleged to have been occasioned to him by the alleged malpractice of the defendant, a physician, in the treatment with roentgen rays of eczema with which the legs and ankles of the plaintiff were affected. The Court says that it should be borne in mind that the case involved two standards of professional skill and care by which the evidence as to the competency and the conduct of the defendant was to be measured, one standard having reference to the technic or mechanical operation of the roentgen-ray apparatus, and the other standard having reference to the possession and use of the professional skill and care incumbent on the defendant with respect to the diagnosis and treatment of the disease of the plaintiff in matters other than the mere mechanical operation of the apparatus.

The two standards mentioned both involved in this case, the highly specialized art of the treatment of the disease of the plaintiff by roentgen rays, and so far as they did so expert testimony before the jury

fixing such standards was essential to the support of the verdict of the jury, since otherwise the jury, to the extent of the questions involving such specialized art, would have had no standard in mind by which to measure the other facts proved in the case. Now, as to the mechanical standard of skill and care, there was no expert evidence in the case except the testimony of the defendant and of other expert witnesses for the defendant, but there was sufficient evidence in the case, when measured by the mechanical standard fixed by the testimony of the defendant, to support the verdict of the jury. It is deemed sufficient to mention only the following details of such evidence. There was evidence in the case to the effect that the defendant did not keep an accurate record of the roentgen-ray treatment or any record of the exact "dose" of roentgen rays applied in the several treatments therewith, that if only the standard "dose" had been applied, it was extremely improbable that any bad result would have been caused. The cross-examination of the defendant tended to show that his memory of the "dose" applied by him in the several treatments was not to be relied on. There were inconsistent statements made by the defendant at different times as to his opinion of the causes of the bad result, and there was other evidence to support a conclusion of the jury that the "dose" in fact applied was not in accordance with the mechanical standard fixed by the expert testimony of the defendant himself. It was true that such testimony did not show that the bad result might not have happened without fault of the defendant, but there was sufficient of such evidence, the credibility and weight of which was for the jury, tending to show that the bad result was more probably due to lack of skill or negligence of the defendant as charged. This degree of proof is all that is required of a plaintiff in a civil case. He is not required to exclude by his proof the possibility of the result complained of hav-

was broken, and she was under no obligation to call the roentgenologist as a witness merely because his opinion, based on an examination made six months after the injury, differed from the opinion of her attending physician

A CELEBRATED CASE LIABILITY FOR ROENTGENOGRAPHIC BURN—"RES IPSA LOQUITUR"—CARE REQUIRED

(*Holt vs Ten Broeck (Minn.)*, 159 N W R 1073)

The Supreme Court of Minnesota affirms a judgment for \$2,500 damages in favor of the plaintiff for injury from a burn alleged to have been caused by the negligence of the defendant in taking a roentgenogram. The court says that, in February, 1915, the plaintiff was under treatment for some trouble in her hip supposed to be a fracture or a dislocation. Her attending physician desired a roentgenogram. The defendant, a regularly licensed physician, took it. A few weeks afterward a sore developed on the plaintiff's hip which it was claimed was the result of a roentgenographic burn. The evidence was sufficient to sustain a finding that the roentgen ray caused the sore. The testimony of the plaintiff was that there was none before. It was at the point of the exposure. There was medical testimony having a tendency to prove that it came from a roentgenographic burn. The question was for the jury. To recover damages it was necessary that the plaintiff prove negligence in the defendant. There was little direct evidence of negligence. The plaintiff claimed that during the progress of the taking the defendant made some exclamation to the effect that the machine was not working right. Her claim was that the exposure was unduly long, but her testimony did not strongly support it. A physician sufficiently qualified to give an opinion as an expert stated that a proper application of the rays would not produce the result which he found. The

evidence was that with a proper machine and with a proper use of it a burn is unusual. There was evidence that the machine was a proper one. The machine and its operation were wholly under the control of the defendant. Under such circumstances the rule of *res ipsa loquitur* (the matter speaks for itself) applies. It did not follow from this, as the plaintiff's counsel argued, that the burden shifted to the defendant of proving freedom from negligence. "*Res ipsa loquitur*, where it applies, does not convert the defendant's general issue into an affirmative defense." The language quoted was approved in a case in which this court held that the *res ipsa loquitur* rule merely permits the jury to draw an inference of negligence, and "the jury is to consider and weigh the inference, in the light of all the facts and circumstances, and give it such weight as tending to prove negligence as they deem it entitled to." It does not follow from what is here said that the *res ipsa loquitur* doctrine applies to a bad result or mishap coming from a physician's treatment. The rule does not apply in such cases. In determining negligence it can make no difference whether the one operating the roentgenographic appliance is a physician or a lay expert. The care required is ordinary care. It is the care exercised by and to be expected from one reasonably skilled in the use of the appliance. The rays were not applied for curative purposes, but to obtain information. This is the logical if not the necessary result of the holding in *Henslin vs Wheaton*, 91 Minn. 219, 97 N W R 882, that in an action against a physician for negligence in the use of a roentgenographic machine he was not entitled to have the question of his skill determined by physicians of his own school. A physician who qualified himself as an expert in the application of the roentgen ray was permitted to give his opinion, based on the result of the operation, that the application was improper. This was not error. The

satisfaction of the demand, will legally satisfy it, however large the claim may be A debt or demand is liquidated when agreed on by the parties or fixed as to the amount by the operation of law The account in this case was made up of charges for visits made by the plaintiff, as a physician in attendance on the defendant and his family, from Nov 4, 1911, to May 30, 1915, and totaled \$1,347, on which payments were credited, of \$200 in 1912, \$200 in 1913, \$300 in 1914, and \$200 in 1915 It was admitted at the trial that it was not necessary for the plaintiff to prove each of his items in detail, but that it would be conceded that he would testify to the correctness of each item The defendant contended, however, that the last payment was made by him and accepted by the plaintiff as in full of all amounts due the plaintiff In no sense could this be said to have been a liquidated account While it was true that the defendant did not dispute that the services had been rendered and that the charges made for them were reasonable, he nowhere admitted that he owed them On the contrary, when his attention was called to the account rendered just before he sent his check for the last payment, he called the plaintiff's attention to the fact that they had before settled on a compromise basis and proposed to do that here, and on the plaintiff's stating that his account was about \$400, the defendant stated that he would pay \$200 if the plaintiff would accept that in full It was true that the plaintiff denied this conversation over the telephone but that was for the jury, the defendant having distinctly testified to it It was under these circumstances that the defendant made out his check for \$200, writing on it that it was in full, transmitted it by letter calling attention to that sum and the plaintiff accepted the check and cashed it Under these circumstances the plaintiff was bound by his act and could not claim anything over and above the \$200 His recep-

tion and retention of the \$200 in full payment of his account, that not being a liquidated account, or an account stated, was conclusive on him

DOCTRINE THAT AN ORDINARY PHOTOGRAPH
IS THE BEST EVIDENCE OF WHAT IT
CONTAINS DOES NOT APPLY TO RA-
DIOGRAPHS EXPERT OPINION
THE ONLY EVIDENCE TO
BE CONSIDERED¹

Marion vs Coon Construction Co (New York), 1913, Third Department, Vol 157, App Div 95

This was an action to recover damages for personal injuries sustained by the plaintiff, who was struck by a boom while signaling the engineer controlling the operation of the derrick The jury found a verdict for the plaintiff and the defendant appealed from a judgment entered on that verdict The judgment was affirmed

One of the errors alleged by the defendant on the appeal related to the failure of the plaintiff to produce X-ray pictures concerning which expert witnesses for the plaintiff testified On this point the Court said at page 99.

A careful reading of all the medical evidence and the other evidence as to injuries will show that the plaintiff was substantially injured One of the plaintiff's witnesses, Dr Gardner, swears "I was present when the (X-ray) pictures were taken, saw them taken, saw them developed, and looked at the plates immediately after they were developed" Thus their identity and correctness were established Then the Doctor proceeds to tell what the pictures show Another physician, Dr Tinker, also tells what he thinks the plates show There was no demand made by the defendant for the production of the plates, no hint or suggestion that they were desired They were, in fact, in court, so the plaintiff states in his brief I can see no error at all in this X-ray incident *The evidence*

¹Received from Leon T LeWald M D New York City

ing been due to causes for which the defendant is not responsible

The cause of the injury being the roentgen rays was, however, but one element of fact in the case. As the jury was properly instructed, if the defendant exercised ordinary care and skill in the premises, the plaintiff was not entitled to recover damages, although the injuries complained of were caused by the roentgen-ray treatment, and the question still remained whether the defendant did or did not exercise such care and skill. The Court thinks there was sufficient evidence in the case, when measured by the general professional standard, as well as by the mechanical standard of skill and care, to support the verdict of the jury.

It was correct to say that the standard by which the duty of the defendant to make the preliminary tests and examination of the patient before subjecting him to the roentgen-ray treatment had to be tested was whether other like specialists in good standing, in the same or similar localities as the defendant, would have been guilty of the omission to make such preliminary tests and examination, which test had to be applied by measuring the evidence, as it might be introduced on the trial, by the standard fixed by the testimony of experts on the subject. Failure to warn of danger in the treatment was not necessarily negligence, unless there was an assurance of a cure.

AN IMPORTANT DECISION PHYSICIANS NOT REQUIRED TO REPORT TO DEFENDANTS

(Tutone *vs* New York Consolidated R Co (N Y), 177 N Y Supp 818, Herbert *vs* Brooklyn Heights R Co, (N Y) 177 N Y Supp 901)

The Kings County, N Y, court holds in these two personal injury cases that orders for the physical examination of the plaintiffs by physicians were erroneous in requiring that the reports of the physicians should be given to counsel for the defendants. The decisions are by two different

justices. In the Herbert case, Justice May says there is nothing in the New York statutes which directs or requires a report to be made by the examining physician. The sole object of the statute in permitting physical examinations is to reduce the likelihood of fraud being practised to a minimum, by granting the right to the defendant to compel the plaintiff merely to submit to such physical examination at the hands of the physicians, so that testimony thereof may be given on the trial. While it has been customary for physicians so appointed to make a report and deliver it to the defendant, there is no authority apparently in the law therefor. There may be no objection, perhaps, to the disclosure by the physician to the defendant of the results of his examination, but the court has no power to direct him to make such report, and therefore it follows that there can be no direction to deliver a report to the defendant, or to file a report in the office of the county clerk.

EFFECT OF RECEIVING CHECK "IN FULL OF ACCOUNT"

(Booth *vs* Dougan (Mo), 217 S W R 326)

The St Louis (Mo) Court of Appeals affirms a judgment in favor of the defendant, who was sued by a physician for a balance of \$447 claimed to be due on account after the physician had indorsed and collected through the bank a check for \$200 reading "In full of account to date," which the defendant had sent to him. The Court recognizes the rule to be that when a certain sum is due from one to another, the payment of a lesser sum is no discharge as to the remainder, notwithstanding an agreement to that effect, because the latter agreement is without consideration. But such rule, the Court says, does not apply when the amount due is disputed or unliquidated. When a claim is unliquidated, any sum, no matter how small, given and received in

CASE REPORTS AND NEW DEVICES

LYMPHOSARCOMA OF THE FEMUR

By E. A. POHLE, M.D., PH.D., and GORTON RITCHIE, M.D.
MADISON, WISCONSIN

From the Departments of Radiology and Physical Therapy and Pathology, University of Wisconsin Medical School

H E R, male, aged 30 years, fractured the left femur just above the knee on March 2, 1931, while walking in the woods. The leg was put in traction for five weeks. He stayed in the hospital for another week and was then discharged. On May 14, 1931, he refractured his leg while in bed and returned to the same hospital, where Lane

He entered the University Hospital in Madison on the Orthopedic Service on Aug 8, 1931, with the probable diagnosis of non-union of fracture of left femur with secondary osteomyelitis.

The general physical examination revealed that the patient was considerably emaciated and anemic. There were tender swollen bony masses over the head of the right radius, over several ribs, and also on the right parietal bone. There was also a draining sinus in the mid-portion of an old surgical incision on the anterior aspect of the left lower thigh. The latter was considerably swollen and very tender. Motion

Fig 1 Roentgenogram of femur

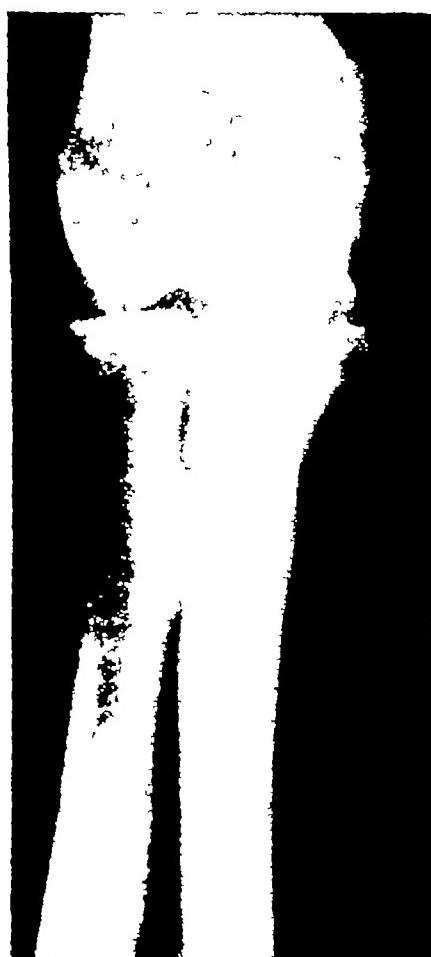

Fig 2 Roentgenogram of the right arm, showing lesion in radius

plates were inserted on May 20, 1931. One week later the wound started to drain and two drains were inserted on July 1, 1931.¹

¹We were unable to obtain roentgenograms taken before the patient came to us.

shows that nobody but an X-ray expert could tell anything from the plates, and that if they had been produced they would have done the court, jury, or the defendant's ordinary physicians no good I do not think that the doctrine that an ordinary photograph is the best evidence of what it contains should be applied to X-ray pictures They constitute an exception to the rule concerning ordinary documents and photographs, for the X-ray pictures are not, in fact, the best evidence to laymen of what they contain Generally, they are no evidence at all, signifying nothing whatever except to the expert The opinion of the expert is the best evidence of what they contain—the only evidence If there had been a demand for these pictures in court, or a request that they be submitted to the inspection of the opposing experts, and these rights had been denied the defendant, such an error would be serious But whatever harm befell the defendant, if there was any harm at all, came to it by reason of its own failure to demand what it was entitled to, and what it would unquestionably have received by the mere asking To sustain this contention of the defendant would be to tolerate worse than a technicality—a trick

PROPER TIME FOR ROENTGEN-RAY EVIDENCE

(Van Tinder *vs* Birmingham Railway,
Light & Power Co (Ala),
80 So R 858)

The Supreme Court of Alabama, in affirming a judgment in favor of the defen-

dant in this personal injury case, says that the plaintiff urged that a new trial should be granted because of newly discovered evidence resulting from a roentgen-ray examination of her back showing the nature and character of her injury and its probable cause But the Court does not think that this was a good ground for granting a new trial, for one reason, because it is not persuaded that due diligence was shown in obtaining this roentgen-ray examination The plaintiff relied, among other things on permanent injuries to her spine, and it was but fair to herself, the defendant, and the court that she should have obtained and produced the best evidence on the subject, and the reasons for resorting to a roentgen-ray examination were as important before as after the trial It is a matter of common knowledge that in cities the use of the roentgen ray for the discovery and diagnosis of internal injuries and abnormal conditions of the human body is of common occurrence True, it may incur some trouble and extra expense but the trouble and expense should be no greater before than after the trial, and the reasons and necessities for them should be as imperative for the original trial as for upsetting or overturning the verdict of a jury after it has passed on the issue to which the examination relates and which was contested on the trial

examined It was gray-white, somewhat vascular, and soft Small areas of hemorrhage were noted, but nowhere was there extensive necrosis

Unfortunately permission was not obtained for examination of the brain.

Microscopically, the tumor proved to be a lymphosarcoma (Figs 3 and 4), with many types of cell, apparently all of the lymphoid series It was felt that the primary site of the growth was in the left femur

AN IMPROVED METHOD FOR THE ORAL ADMINISTRATION OF SODIUM TETRAIODOPHENOL-PHTHALEIN FOR GALL-BLADDER VISUALIZATION

By LESTER LEVYN, M.D., and
A. H AARON, M.D.,
BUFFALO, NEW YORK

The oral administration of sodium tetraiodophenolphthalein is the method of choice among the great majority of roentgenologists Menees and Robinson (1) were the first workers whose experiments, reported in 1925, resulted in the widespread use of the dye by mouth The powdered dye was given in various types of enteric tablets and capsules, to withstand the attack of the gastric juices In 1927, we published a method of administering the dye in solution (2) Since then, numerous soluble preparations have been available, and the use of the disodium salt in powder form, in tablets, or capsules, is almost obsolete

Some of the preparations used are objectionable to patients because they are distressingly unpleasant to take, and reactions vary in degree from slight nausea to severe attacks of vomiting Even in the more pleasant preparations, patients complain of

the drinking of 200 cc or more of an astringent, acrid-tasting solution

A standardized method of oral administration of the dye is obviously most desirable With these facts in mind, we have evolved a method which has proved most satisfactory in our hands

PREPARATION OF A SINGLE DOSE

Four grams of sodium tetraiodophenolphthalein are placed in a mortar, and 0.30 cc of hydroxysuccinic acid ($\text{COO H CH}_2 \text{CH}(\text{OH}) \text{COO H}$ —malic acid) is added The hydroxysuccinic acid prevents decomposition of the dye by breaking up the unstable disodium salt into the stable monosodium salt and sodium malate Liquid petrolatum levis, in the amount of 3 cc, is next added and the mixture thoroughly triturated Two *elastic* gelatin capsules, such as various oils are dispensed in, of a capacity of 2.5 cc each, are then filled with this mixture by means of a pipette, and the aperture sealed with heat¹

The advantages of the use of these *elastic* capsules, prepared in this manner, are as follows

- 1 The capsules are absolutely devoid of taste and are easily swallowed
- 2 Nausea and vomiting are reduced to a minimum
- 3 The dye is suspended in a finely divided state, and passes through the pylorus into the duodenum upon the disintegration of the capsules, which occurs (fluoroscopic observation) from one to two hours after they are taken In many instances the capsules leave the stomach intact and are disintegrated in the small bowel

4 This method makes available a standardized procedure

5 Excellent gall-bladder visualization is obtained in children and adults

¹Owing to the fact that the filling and sealing of these capsules by hand is tedious and time-consuming, one of the chemical houses has kindly consented to manufacture them

could be felt at the site of the fracture Roentgenographic examination (Fig 1) showed an old fracture of the left femur approximately 6 inches above the knee, held by two Lane plates, without union While

AUTOPSY REPORT

The external description was similar to that recorded in the physical examination The chief interest attached to the extent and distribution of the tumor growth The left

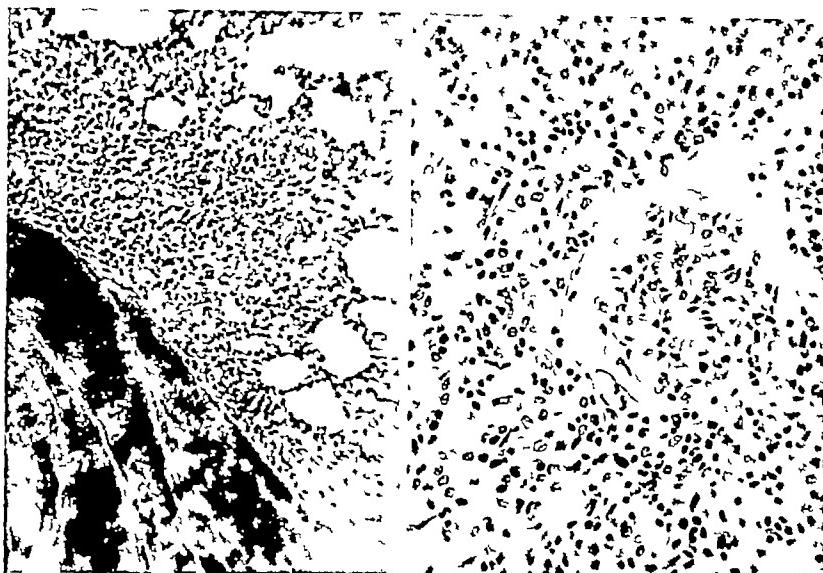

Fig 3 (*left*) Section of original tumor in left femur

Fig 4 (*right*) Tumor nodule in kidney, showing surviving glomerulus

the presence of productive bone changes suggested osteomyelitis there were also several areas of destruction which indicated in all probability a metastatic malignancy The latter impression was borne out by the fact that similar destructive lesions could be seen in the neck of the left femur, the right ilium, the right upper radius (Fig 2), right parietal bone and fifth and sixth right and eighth left ribs The only intimation as to the site of the primary lesion was found in the intravenous pyelogram, on account of which hypernephroma was suspected All laboratory examinations were essentially negative except for a marked anemia No Bence-Jones bodies were found in the urine The patient failed rapidly, developed signs of cerebral involvement on Aug 20, 1931, and died ten days later

femur was fractured at about its midpoint, and besides a considerable degree of callus formation there was extensive tumor growth in and about the bone The soft tissues were infiltrated and one nodule had appeared in the operative scar There was widespread metastasis, several ribs were involved, the growth here being fusiform in shape and having eroded the bone so completely as to cause spontaneous fractures There were flat neoplastic plaques in the subepicardial tissue Both suprarenal glands were infiltrated, and nodules were found in each kidney In the rectovesical septum there was a nodule about 4 cm in diameter No considerable lymph node enlargement was found anywhere in the body

The tumor substance presented essentially identical characteristics wherever it was

examined It was gray-white, somewhat vascular, and soft. Small areas of hemorrhage were noted, but nowhere was there extensive necrosis

Unfortunately permission was not obtained for examination of the brain

Microscopically, the tumor proved to be a lymphosarcoma (Figs 3 and 4), with many types of cell, apparently all of the lymphoid series It was felt that the primary site of the growth was in the left femur

CARCINOMA OF THE CERVIX WITH BONE METASTASIS

REPORT OF CASE

By RIEVA ROSH, M.D., Assistant Radiation Therapist From the Radiation Therapy Service, Bellevue Hospital, New York City, Ira I. Kaplan, M.D., Director

Bony metastases associated with malignancy of the breast, prostate, and thyroid gland are of frequent occurrence. While direct pelvic extension or local metastases

occur often, especially in neglected and untreated cases of carcinoma of the cervix, distant metastases from carcinoma of the cervix uteri, especially to bone, are very rare.

From the Mayo Clinic, Ford (1) reports 14 cases of bone metastases associated with carcinoma of the cervix, the tibia being involved in two cases. Albers-Schonberg reports 564 postmortem examinations of carcinoma of the cervix, 0.83 per cent of which showed metastases to long bones. Wertheimer reports 13 cases of metastases from carcinoma of the cervix, but only one case with involvement of both tibias. Jeananey (2) reports one case of metastasis to the tibia from primary squamous-cell epithelioma of the cervix, Grade 4. Monad (4) reports one case of metastasis to the sternum from a carcinoma of the cervix.

In our series of 233 cases we have had only one case showing metastasis to bone.

Fig 1 Photomicrogram showing lesion of the cervix.

Fig 2 Photomicrogram showing lesion of the tibia.

W E., widow, white, 58 years of age, entered the gynecologic service of Bellevue Hospital, July 11, 1927, complaining of vaginal bleeding which had been apparent for six months. She had had two children, normal deliveries. The menstrual history, which began at 15 years, was regular, with no pain, of eight days' duration, moderate flow. The menopause was at 43 years. The bowels were regular. Six months previous to admission the patient, having noticed a bloody discharge following a hot douche, went to a doctor, who sent her to the hospital.

Vaginal examination showed an atrophic introitus with foul bloody discharge. The cervix was situated in the axis of the vagina, and was hypertrophied, eroded, and large. The fundus was retroverted, not outlined, and appeared small. The adnexa were negative. The Wassermann reaction was negative. Biopsy of the lesion showed a plexiform epithelioma.

The patient was advised to have radiation therapy and was treated with deep X-radiation to the pelvis and radium to the uterus and cervix. She received 860 r units of high voltage X-rays to the right and left anterior and posterior pelvic areas and 5,300 mc-hrs of radon. Following treatment the cervix lesion healed completely.

Until Nov 22, 1929, the patient's general condition remained good, when she came to the clinic complaining of slight pain and swelling in the shaft of the left tibia. She gave a history of having had an injury to this leg several months previous to November, at which time the lump appeared and did not subside after applications of compresses. Gynecologic examination on Nov 22, 1929, revealed a completely healed cervix, there was no bleeding or evidence of local metastasis or recurrence. On the left tibia a small tumor mass was palpable, firmly attached to the shaft.

An X-ray film of the tibia showed a large polycystic destructive area in the mid-third

Fig 3 Roentgenogram of the lesion in the tibia

of the left tibia, 6 cm in length, occupying the full width of the shaft with some irregularity of the cortex anteriorly. In the opinion of the roentgenologist, the findings did not suggest a malignant lesion but probably an osteitis fibrosa cystica or a giant-cell tumor.

On account of the pain and the presence of tumor growth deep X-ray therapy was given to the leg. On Feb 20, 1930, the swelling appeared larger. X-ray examination revealed at this time a polycystic neoplastic mass in the mid-third of the tibia which simulated the structure of a giant-cell tumor, more so than on the previous examination. On May 20, 1930, her general condition was good, but the patient complained of pain in the left leg. Radiographic examination showed a tumor mass present in the middle of the shaft of the left tibia, with evidence of widening of the shaft at this region, cystic formation in the medulla and cortex of the bone, with trabeculation characteristic of osteitis fibrosa cystica. A node, 1 cm in diameter, was found in the left inguinal

ing built around a small copper filter pan in which the radium was later placed. It was molded to extend backwards far enough to curve up in the pharynx around the soft palate, and this curved part was split to accommodate the posterior part of the nasal septum, and the curved ends perforated with hot wire to make holes for cords, as shown in the illustration. The radium was loaded in the pan filter, covered with a rubber filter, and applied to the lesion by passing threaded catheters through each nostril, the threads being drawn forward through the mouth and attached to each of the cords of the radium pack. Application was made by pulling the cords forward through the nares until the pack was fitted snugly in place. The pack was slipped over the fingers of the operator while the cords were being drawn taut by an assistant. When the cords were taut, it was seen that the appliance hugged well the posterior extremity of the soft palate, and, as they were tightened, they drew upward the posterior surface of the palate, bringing the affected tissues in direct contact with the radium pack. It was an easy mat-

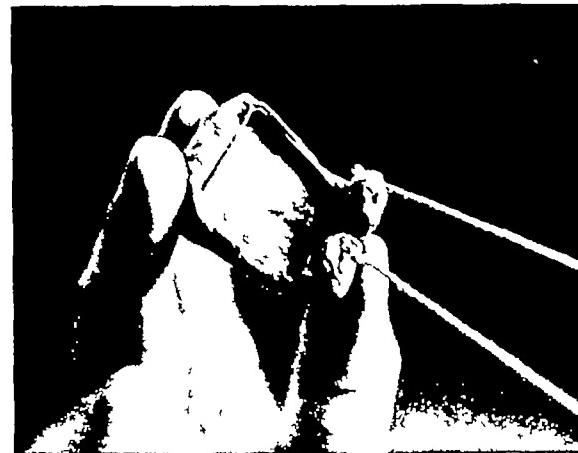

Fig 1 Radium pack for application to the under surface of the posterior part of the soft palate

ter to leave this pack in place until the desired dosage in milligram-hours was delivered. The cords were tied behind the patient's head, and, while this may be an objection to the pack, there is no possible chance for it to slip or for the patient to move it after it is in place.

Since the patient made no complaint of the presence of the pack, we feel that this appliance is not uncomfortable to wear.

area. Surgical removal of the mass was advised, to be followed by radium application.

The patient entered the hospital on June 2, 1930, and on June 6 the mass in the left tibia was excised. The pathologic findings were an extensive invasion of the bony structure of the left tibia at the mid-portion by a grayish-white, firm, soft tissue, with a necrotic center filled with mucopurulent fluid. The bone at this point was extensively infiltrated, and there was a pathologic fracture of the remaining lateral shell of the tibia.

The tumor mass was cleaned out, the bony cavity curetted and packed with gauze, a posterior molded plaster splint was applied and the patient returned to the ward in good condition.

Microscopic examination of the removed tissue showed it to be plexiform epithelioma of the same type as that previously found in the cervix.

Further radium therapy was suggested but the patient refused treatment and left the hospital on her own accord. Our social service worker followed the case at the patient's home and reported her condition as progressively becoming worse. The patient was last seen in July, 1931, at which time she was very weak, was unable to leave her bed, and the leg was considerably swollen and painful.

CONCLUSIONS

1 Metastases in the long bones are often overlooked and are attributed to inflammatory lesions.

2 In cases of carcinoma of the cervix, periodic roentgenographic study of the long bones should be done.

3 While distant metastases from carcinoma of the cervix uteri are rare, one should consider the possibility when the patient exhibits symptoms of tumor growth elsewhere in the body.

PACK FOR USE IN APPLYING RADIUM TO THE SOFT PALATE

By JOHN S. WILSON, M.D.,
Mack Wilson Hospital, MONTICELLO, ARKANSAS

Recently we were called upon to treat an elderly man who presented extensive carcinoma of the under surface of the posterior part of the soft palate. The lesion had apparently extended well into the tissues of the palate and our only hope was to give the lesion a heavy dose of well filtered radium. Attempts had been made to administer radium by having the patient hold a pack on a tongue depressor, but he would not, or could not, keep it in place.

Applications were made to the upper surface of the soft palate through two heavy catheters, each carrying 50 mg of radium, which were passed back through the nares until they emerged in the pharynx. Filtration was through monel metal needles, which contained the radium, filtered through 1 mm brass, and the catheters, which were 2 mm thick. This application gave us the dosage we felt the lesions of the upper surface should have.

The next and greater problem was to bring radium in contact with the lesion on the under surface of the palate and to keep it there sufficiently long to deliver the necessary dose. After many attempts, we improvised the little device shown in Figure 1.

The dental modeling compound of which it was made was shaped to fit the lesion, be-

cosis, notable among whom are Crottı, Virchow, Gluck, Wiens, Wever, Kaufmann, Rossle, Hart, Halsted, and others. Another reason why radiation therapy has been uniformly successful in the treatment of thyrotoxicosis is the accuracy with which it can be administered. Ingenious scientific instruments have been devised, the result of years of scientific investigation and experimentation, which accurately measure the quantity and quality of the dose prescribed by the radiologist for his patient. A unit of measurement has been accepted internationally, known as the r unit, which is understood alike in all countries. In this manner, the language of the radiologists throughout the world is the same. A competent radiologist can duplicate with little difficulty any technic in radiation therapy anywhere. The bureaus of standards of most countries are prepared to calibrate such instruments in the r unit, so that when it is said a patient has been given 300 r units, it is known definitely the quantity of radiation received by the patient. In other words, this form of therapy is standardized and accounts for the uniform results obtained by radiologists in the treatment of toxic goiter.

In a statistical study of the results obtained in the treatment of toxic goiter by means of radiation therapy, by radiologists of varying experience in goiter therapy throughout this country, 10,541 cases have been treated with a favorable percentage of cures and a low percentage of failures. Of this group, operation had previously been done upon 980. No doubt, many of these cases had been operated on by surgeons unskillful in goiter surgery. It is unfortunate that this must happen, and that it will perhaps continue for some time, but not all surgeons have attained to a uniformly high degree of skill. Others were operated on by skillful and experienced surgeons. The failures may be accounted

for on the basis of an accompanying thymic involvement, as many of these operative failures are cured by radiation therapy. In this regard, Crottı states that he routinely explores the upper mediastinum following thyroidectomy, and removes the thymus whenever it is found. It is his opinion that not only are the remote results of operation better, but that the operative course is more satisfactory.

Certain criticisms have been made against reporting goiter cases as improved. It is the belief of some that these cases, because they are not cured, must be classified as failures. We heartily agree with such criticisms when applied to surgical statistics, as the surgical and radiologic treatments are so different. In the instance of surgery, either the operation is a success or a failure, either too little or too much of the gland has been removed. Nevertheless, in radiation therapy, patients may receive a few treatments which improve their condition to such an extent that they believe themselves cured and desert before the treatment is completed. Others are advised by the referring physician to discontinue treatment, as they are considered by him as cured. In such instances they were markedly improved but not cured. Then again, patients after receiving one or two treatments, finding that they have not been cured, may fail to return. Most often, however, patients being treated by radiation therapy fall into a surgical atmosphere of persuasion, which naturally results in an operation. Many such cases were already markedly improved at the time of operation. A large number of these cases would have resulted in cures, and others, perhaps, in failures had they persisted with their treatments. It can be said in all fairness that at least one-half, or perhaps more, of the markedly improved patients, had they continued their treatment, would have been classified as cured and the others as failures. We can agree with

THE TREATMENT OF TOXIC GOITER

Because of the prevalence of toxic goiter in this country, and also because of the divergent opinions as to the best and safest method in treating this disease, a symposium appertaining to this subject was held at the last meeting of the Radiological Society of North America.

The purpose of such a symposium is primarily educational. It offers an opportunity to present the most modern advance made in the treatment of a certain disease by some particular method or methods, also—which is of importance—it correlates the results obtained by physicians of varying experience in their own specialty, and not by a few outstanding physicians with large experience, connected with some renowned medical center.

We are presenting to our readers in this issue of RADIOLOGY a symposium on the treatment of toxic goiter by radiation therapy, surgery, and internal medicine. Those physicians participating are well known to the members of their own specialties, and have acquired experience and knowledge in the treatment of this disease. For this reason, this symposium should be representative of the present-day results obtained in the treatment of toxic goiter by the methods named.

For years, the principal forms of treat-

ment used in toxic goiter were medical and surgical. Good results were being reported by surgeons. The percentage of cures was most gratifying, although the death rate was high. Improved surgical technic and greater experience in goiter surgery were the causes of a marked reduction in the mortality rate. In fact, to-day, in a few large surgical centers, where expert goiter surgeons operate, the mortality is less than 2 per cent. However, we must appreciate that this low mortality is not representative of that of the general surgeon. It is said that at present the surgical mortality following goiter operation by the general surgeon is about 10 per cent. This high mortality has given the medical profession much concern. It was hoped that some other form of treatment could be used in conjunction with surgery, or alone, which would produce a high percentage of cures with a negligible mortality. Radiation therapy is now ideally fulfilling this hope, and the results obtained by its use in carefully selected cases are far beyond the highest expectations of the medical profession.

There are several reasons why such excellent results are being obtained. One is that in treating the thyroid gland the thymus gland is also irradiated. It has been known for some time that certain changes occur in the thymus gland of patients suffering with thyrotoxicosis. Experiments have shown that after thymectomy in animals the thyroid gland tends to become hyperplastic as in Graves' disease, and likewise following thyroidectomy the thymus becomes hyperplastic. Many outstanding investigators have been emphatic in their belief that there exists a relation between hyperplasia of the thymus and thyrotoxi-

cosis, notable among whom are Crotti, Virchow, Gluck, Wiens, Wever, Kaufmann, Rossle, Hart, Halsted, and others. Another reason why radiation therapy has been uniformly successful in the treatment of thyrotoxicosis is the accuracy with which it can be administered. Ingenious scientific instruments have been devised, the result of years of scientific investigation and experimentation, which accurately measure the quantity and quality of the dose prescribed by the radiologist for his patient. A unit of measurement has been accepted internationally, known as the r unit, which is understood alike in all countries. Experiments have shown that after thymectomy in animals the thyroid gland tends to become hyperplastic as in Graves' disease, and likewise following thyroidectomy the thymus becomes hyperplastic. Many outstanding investigators have been emphatic in their belief that there exists a relation between hyperplasia of the thymus and thyrotoxi-

continuing stimulus to investigators in those subjects having a direct bearing on the advancement of clinical science

MINNESOTA RADIOLOGICAL SOCIETY

The winter meeting of the Minnesota Radiological Society was held at the University Hospital in Minneapolis on Saturday, February 13, 1932. The following program was presented

CLINICAL-PATHOLOGICAL-RADIOLOGICAL CONFERENCE

Conducted by W A O'BRIEN, M D

Assisted by B PEARSON, M D, O RANDALL, M D, and R KOUCKY, M D

1 Ewing's Sarcoma of Bone

Discussion by W Cole, M D, and C Hansen, M D

2 Multiple Myeloma, with Intestinal Obstruction

Discussion by O H Wangensteen, M D

3 Carcinoma of Breast, with Multiple Metastases

Discussion by K Stenstrom, Ph D, O Campbell, M D, and L G Rigler, M D

4 Carcinoma of Antrum, with Peripheral Metastases

Discussion by W Peyton, M D, and K Stenstrom, Ph D

Relative Value of Stereoscopic and Single Films in the Routine Examination of the Chest

Frederick B Exner, M D

Studies on the Routine Examination of the Chest in Students

Harold Diehl, M D

Anomalous Lobes of the Lungs

L G Erickson, M D

Observations on Intra-pleural Pressure in Massive Pulmonary Atelectasis

Rudolph Koucky, M D

Radiation Therapy of Neuritis

John J Eneboe, M D

Fractures of the Sesamoids

Jacob Sagel, M D

Methods of Radiation Therapy of Carcinoma of the Esophagus

The next meeting of the Minnesota Radiological Society will be held in St Paul, May 23, 1932

INDIANA ROENTGEN SOCIETY

The Indiana Roentgen Society held its fifth annual meeting in Indianapolis on the 22d of February. H P Doub, M D, of Detroit, was the speaker.

The following officers were elected
President-elect, R L Lochry, M D, of Indianapolis,
Vice-president, H W Sigmond, M D, of Crawfordsville,
Secretary and *Treasurer*, J N Collins, M D, of Indianapolis

MEDICO-LEGAL NOTE

If members of the Radiological Society who have been—or are in the fear of being

the critics that a given patient with toxic goiter, who abides by all the directions of the radiologist and receives the required number of treatments which would ordinarily constitute a cure, and is still only benefited, should be classified as a failure.

Radiation therapy in the treatment of toxic goiter has been the means of preventing a most distressing post-operative complication, namely, psychosis. This not infrequent complication is one to which a large number of patients suffering with exophthalmic goiter are susceptible. Its importance is emphasized by a prominent American goiter surgeon who says, "The incidence of post-operative psychosis is rather higher in thyroid surgery than in operative work in other regions of the body, due to the peculiar mental state of the toxic patient. Some physicians hold that individuals who develop exophthalmic goiter are mentally predisposed to the condition."

It would be unfair to say that surgery does not produce splendid results in the treatment of toxic goiter when performed by a skillful and experienced surgeon. Nor can there be a denial of the fact that there are too many failures and deaths as a result of operation by the general surgeon, who is skillful in other fields of surgery but lacks proper experience. Certain toxic goiters are best treated by surgery and such cases should be referred to surgeons by roentgenologists, on the other hand cases in which radiation therapy is indicated should be referred to radiologists. "Render unto Cæsar the things that are Cæsar's."

York City, as the recipient of the John Phillips Memorial Prize for 1932.

This prize, an annual award by the College in the sum of fifteen hundred dollars, is given to perpetuate in the College the memory of Dr. John Phillips, of Cleveland, a man of outstanding accomplishments as investigator, teacher, and physician, for many years a member of the Board of Regents of the American College of Physicians, who gave his life in saving others on the occasion of the Cleveland Clinic disaster on May 15, 1929.

The Committee on the John Phillips Memorial Prize, through its Chairman, James H. Means, M.D., of Boston, recommends the award, "To Dr. O. T. Avery for the series of studies upon the *Pneumococcus*, in which he has played a leading rôle, beginning with the discovery of the type-specific soluble capsular polysaccharides and culminating in the discovery of a bacterium producing an enzyme which splits the polysaccharides of Type 3 Pneumococcus *in vitro*, thus rendering it susceptible to phagocytosis and thereby protecting the animals infected with it."

The Sixteenth Annual Clinical Session of the College will be held in San Francisco during the week of April 4, 1932. Dr. Avery will deliver an address, "The Rôle of Specific Carbohydrates in Pneumococcus Infection and Immunity," at the Convocation on Wednesday evening, April 6. At the conclusion of Dr. Avery's address, the prize will be presented to him by S. Marx White, M.D., of Minneapolis, President of the College.

The distinction of this award is enhanced by the fact that, although it was available the previous year, it was not possible to decide on a suitable recipient. This is, therefore, the first award made. It is the hope of the officers and members of the College that this annual prize in memory of a distinguished colleague may, by recognizing merit, be a

COMMUNICATIONS

AMERICAN COLLEGE OF PHYSICIANS TO AWARD PRIZE TO
O T AVERY, M D

The American College of Physicians recently selected O. T. Avery, M.D., of the Hospital of the Rockefeller Institute of New

- 4 In large cavernous types is heavy filtration with distance preferable?
- 5 Should dosage be applied slowly over long periods of time, or are large initial doses as desirable?

Squamous-cell Carcinoma of Skin

- 1 Do you use unfiltered X-ray in these lesions?
- 2 Do you use filtered radium exclusively?
- 3 Do you regard the Regaud type of technic preferable in these lesions?
- 4 What percentage do you regard as curable by radiation?
- 5 Do you consider radium preferable to roentgen ray in these lesions?

Basal-cell Carcinoma of Skin

- 1 Do you believe it justifiable to treat these lesions with roentgen ray alone? With radium alone?
- 2 Have you had experience in treating these lesions with radium, giving large doses by using small amounts of radium heavily filtered, over a long period of time (as Regaud method)? If so, have not your results from this method been as good as published surgical results?
- 3 In large infected lesions (either squamous or basal cell) would you advise immediate electrosurgical removal? Would you follow this by post-operative radiation or would you allow the area to heal and then treat recurrences with radiation if they appeared?

INTRAO-RAL MALIGNANCIES

Lip

- 1 Do you believe practically all local malignancies on the lip are curable by radiation?
- 2 Do you believe radium preferable to X-ray for the primary lesions on the lip?

- 3 Do you use small amounts of heavily filtered radium applied over long periods of time in lip lesions?
- 4 Do you apply radiation to neck gland areas routinely in all lip malignancies? If so, do you produce a single erythema or use the saturation method?
- 5 Do you use gold implants alone in neck nodes or do you believe a combination of implantation and surgery is better?

Floor of Mouth, Cheeks, and Tongue

- 1 In these lesions are gold radon implants or heavily filtered (1 to 2 mm of platinum) surface applications preferable?
- 2 Do you consider radium alone superior to electrocoagulation in intra-oral lesions?
- 3 Would you advise a combination of these methods?
- 4 Do you take biopsy before instituting radiotherapy?
- 5 Is your radiotherapy influenced by the histological picture of the primary tumor? In other words, does the type of your treatment depend upon the pathologic findings or are all types treated with the same set-up? This refers to radiosensitivity based on the histological picture

Pharyngeal and Tonsillar Malignancies

- 1 Do you precede the local application of radium to these lesions by external high voltage X-ray to sides of neck?
- 2 Method of treatment of local lesions—gold seeds or heavily filtered surface packs?

LARYNGEAL MALIGNANCIES

Intrinsic Malignancies

- 1 Is radiation justifiable here or should total laryngectomy be done?

—harassed into answering hypothetical questions while on the witness stand as ordinary witnesses will send me a stamped addressed envelope, I will be glad to send them some really desirable and illuminating information

This offer is strictly limited to members of the Society, and then only "*Janus clausis*"

I S TROSTLER, M D

QUESTIONNAIRE FOR COMMITTEE ON RADIOLOGY, CALIFORNIA MEDICAL ASSOCIATION CAN- CER COMMISSION

The following questionnaire is being submitted to the radiological members of the California Medical Association Cancer Commission. Since radiology is playing a not inconsiderable part in the solution of the cancer question it may not be amiss to suggest to the readers of *RADIOLOGY*, everywhere, to send their replies to this inquiry to William E Costolow, M D , of Los Angeles. It is far too valuable a study to be confined to the members of one State association. Besides, it suggests itself as an interesting opportunity for a man to take measure of his methods and record his trials and successes

GENERAL

- 1 Name minimum requirements for equipment in radiation therapy for malignancies
 - (a) Roentgen ray in superficial malignancies—in deep malignancies
 - (b) Radium in superficial malignancies—in deep malignancies
- 2 What is your routine low voltage technic in superficial malignancies as to

Voltage,
Filtration,
Skin distance,
Total skin erythemas applied

- 3 What is your routine high voltage technic in more deeply situated malignancies as to

Voltage,
Filtration,
Skin distance,
Total skin erythemas applied

- 4 Do you use saturation methods (as outlined by Pfahler) or some other method in maintaining dosage in tumors over a period of time?
- 5 In high voltage technic for deeply situated tumors, do you measure your patient, plotting the tumor by cross-section anatomical charts (as Weather-wax technic) and compute the percentage of skin dose which the tumor receives?
- 6 Do you measure all your roentgen-ray dosages in r units by ionization methods?

SKIN

Keratotic Lesions

- 1 Is the Grenz ray sufficient?
- 2 Is X-ray alone the method of choice?
- 3 Should radium be used?
- 4 Are electrosurgical methods preferable?

Moles
- 1 In what types is radiation indicated?
- 2 How should melanotic moles be treated?
- 3 Have you seen any five-year cures in melanotic carcinoma?

Angiomas

- 1 Is X-ray indicated? If so, in what types?
- 2 Do you consider radium treatment the method of choice in all cases?
- 3 Should Beta rays of radium be utilized by using light filtration of radium, or should heavy filter (e.g., 1 mm platinum) be used?

- (g) Any other types
- 2 Number and percentage of palliative improvements?
 - 3 Number and percentage of five-year cures?
 - 4 Would you always advise pre-operative radiation in all bone tumors in case operation is to be performed?
 - 5 How long a time interval between radiation and operation would you advise?
 - 6 In treating bone tumors by high voltage X-ray, have you used heavy filtration (1½ to 2 mm Cu), applying moderate dosage over a long period of time by some type of saturation method?

**LYMPHOGRANULOMAS (HODGKIN'S,
LEUKEMIAS)**

- 1 Have you used heavily filtered radium packs in these cases, treating multiple areas in a short period of time?
- 2 Do you use small doses of low voltage radiation therapy in these cases, followed by high voltage later when the cases seem to be becoming radio-resistant?
- 3 Have any of your cases in this group failed to show palliation following radiation?
- 4 Have any cases of acute leukemia shown temporary improvement or palliation?
- 5 Do you believe radiation definitely prolongs life in Hodgkin's disease? In leukemia?
- 6 Approximately what prolongation of life have your cases shown over average figures given in the literature?

GENITO-URINARY—MALE AND FEMALE

Testicular Tumors

- 1 Do you advise pre-operative radiation to the primary lesion followed by complete removal?

- 2 How long an interval between completion of radiation and radical removal?
- 3 Do you believe, from your experience, that radiation is superior to any operative interference on the abdominal lymph gland metastasis?
- 4 Have you seen five-year cures following radiation of the abdominal lymph gland metastasis?
- 5 Approximately how many?

Kidney Tumors

- 1 Have you seen any five-year cures from radiation alone in kidney tumors?
- 2 Would you advise pre-operative radiation of kidney tumors? Post-operative radiation?
- 3 In inoperable kidney tumors have you observed appreciable palliative effects from radiation, as—
Lessening of pain?
Lessening of hemorrhage?
Diminution of size of growth?

Bladder Tumors

- 1 From experience, would you advise pre-operative radiation of bladder tumors by means of high voltage X-ray?
- 2 Do you consider electrocoagulation accompanied by implantation of gold radon seeds, followed by high voltage X-ray therapy, as the best technic in treating bladder malignancies?
- 3 Could you suggest another more desirable technic?
- 4 Have you seen five-year cures from radiation treatment alone in bladder tumor cases? Approximate number?
- 5 Have you seen five-year cures of bladder tumors from a combination of surgery and radiation? Approximate number?

Extrinsic Malignancies

- 1 Do you believe radiation the preferable method of treatment in these lesions?
- 2 Have you seen distinct benefit from radiation in these cases? Any cures?
- 3 Have you used the Coutard technic in these cases (heavy filter approximately 2 mm Cu, moderate doses daily over long period of time, giving large total dosage—6,000 to 8,000 r)?

CHEST

- 1 Have you seen definite five-year cures from radiation in primary carcinoma of the lung?
- 2 Have you seen a number of definite palliative results from radiation in primary carcinoma of the lung? Approximately how many?
- 3 Were all cases treated by external high voltage X-ray or did some have radium applied directly through the bronchus?

BRAIN, SPINAL CORD

- 1 Have you seen definite palliative results from radiation treatment of brain and spinal cord tumors?
- 2 In what type of tumors?
- 3 What percentage of cases showed improvement?
- 4 Any definite five-year cures?
- 5 Was high voltage X-ray therapy used exclusively, or radium?

GASTRO-INTESTINAL

Esophagus and Stomach and Intestines

- 1 Any definite palliative results from radiation? Approximately how many? What were the palliative effects? Relief of pain or retardation of growth?
- 2 Radium used alone or combined with X-ray?
- 3 Any five-year cures?

RECTAL

- 1 Do you advise preliminary colostomy before radiation?
- 2 What type of radiation
 - (a) Gold seeds
 - (b) Surface application of heavily filtered radium
 - (c) High voltage X-ray therapy, or
 - (d) A combination of these technics?
- 3 Do you precede the local application of radium with high voltage X-ray therapy?
- 4 What percentage of palliation does radiation alone give?
- 5 Does the palliation consist of—
 - (a) Prolongation of life,
 - (b) Lessening of bleeding,
 - (c) Partially destroying and retarding growth,
 - (d) Relief of pain?
- 6 Any five-year cures by radiation alone?
- 7 Number and percentage of these cures, if possible?
- 8 From experience, do you believe pre-operative external radiation, by means of high voltage X-ray, produces enough destruction of rectal carcinoma, as evidenced by palpable shrinkage of the growth, to warrant its adoption in all operable cases? Would this improvement from the external radiation be sufficient to offset the delay in operation? How soon after the radiation course would you advise operation?

BONE TUMORS

- 1 Have you seen palliative or curative results in the following bone tumors from radiation?
 - (a) Giant-cell tumors,
 - (b) Osteogenic sarcoma,
 - (c) Osteochondroma,
 - (d) Osteitis fibrosa cystica,
 - (e) Ewing's tumor,
 - (f) Metastatic bone growths,

- (g) Any other types
- 2 Number and percentage of palliative improvements?
 - 3 Number and percentage of five-year cures?
 - 4 Would you always advise pre-operative radiation in all bone tumors in case operation is to be performed?
 - 5 How long a time interval between radiation and operation would you advise?
 - 6 In treating bone tumors by high voltage X-ray, have you used heavy filtration ($1\frac{1}{2}$ to 2 mm Cu), applying moderate dosage over a long period of time by some type of saturation method?

LYMPHOGRANULOMAS (HODGKIN'S, LEUKEMIAS)

- 1 Have you used heavily filtered radium packs in these cases, treating multiple areas in a short period of time?
- 2 Do you use small doses of low voltage radiation therapy in these cases, followed by high voltage later when the cases seem to be becoming radio-resistant?
- 3 Have any of your cases in this group failed to show palliation following radiation?
- 4 Have any cases of acute leukemia shown temporary improvement or palliation?
- 5 Do you believe radiation definitely prolongs life in Hodgkin's disease? In leukemia?
- 6 Approximately what prolongation of life have your cases shown over average figures given in the literature?

GENITO-URINARY—MALE AND FEMALE

Testicular Tumors

- 1 Do you advise pre-operative radiation to the primary lesion followed by complete removal?

- 2 How long an interval between completion of radiation and radical removal?
- 3 Do you believe, from your experience, that radiation is superior to any operative interference on the abdominal lymph gland metastasis?
- 4 Have you seen five-year cures following radiation of the abdominal lymph gland metastasis?
- 5 Approximately how many?

Kidney Tumors

- 1 Have you seen any five-year cures from radiation alone in kidney tumors?
- 2 Would you advise pre-operative radiation of kidney tumors? Post-operative radiation?
- 3 In inoperable kidney tumors have you observed appreciable palliative effects from radiation, as—
Lessening of pain?
Lessening of hemorrhage?
Diminution of size of growth?

Bladder Tumors

- 1 From experience, would you advise pre-operative radiation of bladder tumors by means of high voltage X-ray?
- 2 Do you consider electrocoagulation accompanied by implantation of gold radon seeds, followed by high voltage X-ray therapy, as the best technic in treating bladder malignancies?
- 3 Could you suggest another more desirable technic?
- 4 Have you seen five-year cures from radiation treatment alone in bladder tumor cases? Approximate number?
- 5 Have you seen five-year cures of bladder tumors from a combination of surgery and radiation? Approximate number?

Prostatic Malignancies

- 1 Have you seen five-year cures of carcinoma of prostate from radiation treatment alone?
- 2 Do you consider interstitial application of radium to prostate through perineum (by means of steel radium element needles or gold seeds through needles) of distinctive palliative value in malignancies of the prostate?
- 3 Do you consider high voltage X-ray to be of definite palliative value in inoperable carcinoma of prostate? In what percentage of cases?
- 4 In recurrent post-operative carcinoma of the prostate?

MALIGNANCIES, FEMALE ORGANS*Vulval or Vaginal Malignancies*

- 1 Would you advise surgical or electro-surgical removal of these lesions, followed by radium and X-ray treatment?
- 2 Would you advise radium locally to these lesions (surface application or gold seeds) accompanied later by X-ray therapy over field and glandular areas?
- 3 Have you seen cases recurrent after operation cleared up, either temporarily or for a five-year period, by radiation methods?

Ovarian Malignancies

- 1 Is surgical removal of the primary tumor followed by high voltage X-ray therapy the proper procedure?
- 2 Do you believe attempted removal of metastatic masses logical?
- 3 Have you seen definite palliative results in treatment of metastatic ovarian carcinoma with high voltage X-ray? Approximate number?
- 4 Have you seen any five-year cures in the metastatic group just mentioned?

Uterine Malignancies

- 1 Do you believe all cases of carcinoma of cervix should be treated by radiation? Even small involvements limited entirely to cervix?
- 2 Do you advise high voltage X-ray treatment previous to local radium applications to cervix?
- 3 Do you use a more or less standardized method of application of radium (as Regaud or Stockholm method) or do you have a different technic of your own?
- 4 If you use your own technic, briefly describe
- 5 Give average dosage of radium and X-ray—average number of milligram-hours used? Do you follow a saturation method of high voltage X-ray with measurement of patient and computation of pelvic dosage delivered?
- 6 Do you believe individualization of cases as regards extent of the disease when computing dosage to be given is an important factor in improving end-results?
- 7 Should X-ray therapy always be used in conjunction with local radium applications to the cervix?
- 8 Should cases of carcinoma of fundus (where growth is apparently entirely confined to the fundus) always be treated by total hysterectomy?
- 9 Have you used radium pre-operatively in these cases? How long an interval between radiation and operation?
- 10 Have you seen carcinoma of fundus cured by radiation alone?
- 11 Would you advise the use of high voltage X-ray in conjunction with radium in all cases of carcinoma of fundus?
- 12 Should advanced uterine cases with extensive pelvic gland involvement be treated with small amounts of radiation

- for the palliative effect alone, or should an attempt be made to give full dosage?
- 13 What is the average amount of radium (describe filtration) you use intra-uterine in carcinoma of fundus?

THYROID MALIGNANCIES

- 1 Have you used interstitial radium applications in any case of thyroid malignancy?
- 2 Do you use high voltage X-ray alone or combined with distance radium packs?
- 3 Have you used a high voltage technic in these cases similar to the Coutard technic?
- 4 Have you seen five-year cures in thyroid malignancies? Approximate number?
- 5 What percentage of cases treated have shown definite palliative results? (Diminution of size of growth, relief of pain or pressure symptoms)

WITH REFERENCE TO BREAST CANCER

- 1 Is it ever justifiable to depend entirely upon radium and X-ray therapy in operable cases?
- 2 In your opinion, does pre-operative radiation increase the number of five-year cures?
- 3 Do you select cases or give pre-operative radiation for every breast lump before exploration?

WITH REFERENCE TO RADIATION TECHNIC

(A) Of Pre-operative Radiation

- 1 Do you use low voltage (120 to 140 KV, 4 to 6 mm aluminum filter, 25 to 30 cm skin distance) or
- 2 High voltage (160 to 200 KV, 0.5 to 2 mm copper filter, 50 to 80 cm skin distance) or
- 3 Radium interstitially in heavily filtered, small amounts of element or emanation,

, or heavily filtered (equivalent to 2 mm platinum) radium packs at a distance of from 3 to 6 cm?

- 4 Are doses given daily in small amounts over a period of time (as in Regaud and Coutard methods), or are they given in the space of a few days?
- 5 How long an interval do you advise between pre-operative radiation and operation?

(B) Of Post-operative Radiation

- 1 Do you use post-operative radiation routinely or only where known cancer is left?
- 2 Do you believe from your experience that post-operative radiation should always be used routinely?
- 3 Do you prefer low voltage technic (as already described) or the low voltage technic over the breast area, with high voltage technic to axillary and supra-clavicular areas?
- 4 Do you repeat your X-ray treatment cycle to the breast and gland areas in a few months, or do you wait until there is evidence of recurrence?
- 5 Do you consider the use of radium applied directly to nodular recurrences preferable to X-ray over the entire operative field? Is the radium used in the form of needles plunged around the nodule?
- 6 Has the combination of the two methods mentioned above proved more efficacious in your hands than either method singly?
- 7 From experience, do you believe recurrent nodules in field of operation should always be treated by radiation instead of surgery?
- 8 Have you seen a considerable number of cases with post-operative recurrences which have cleared up following radiation treatment, and remained so for a

five-year period? (Give percentage, if possible)

RADIUM FOR SALE

The radium described below was the property of Henry A Chapin, M D, of Jacksonville, Illinois, whose death occurred last Winter. Mrs Chapin is desirous of disposing of the radium, and the officers of the Society are glad to offer their assistance by publishing this notice.

B S No 4518, a non-corrosive alloy needle 27.6 mm long and 1.75 mm external diameter, 12.43 milligrams of radium. B S No 4515, a non-corrosive alloy needle 26.9 mm long and 1.76 mm external diameter, 12.47 milligrams of radium. These needles were purchased from Radium Chemical Company, Pittsburgh, in August, 1921. B S No 4832, monel needle 29.13 mm long and 1.48 mm external diameter, 12.45 milligrams of radium. No 4831, monel needle 28.6 mm long and 1.50 mm external diameter, 12.40 milligrams of radium, purchased from Radium Company of Colorado, Denver, Colorado, in September, 1921.

Address all communications to Mrs Grace D Chapin, Jacksonville, Illinois

BOOK REVIEWS

DIE BEHANDLUNG DER KINDERKRANKHEITEN
MIT ULTRAVIOLETT UND RÖNTGENSTRÄHLEN
By PROF DR W BIRK, Vorstand der Universitäts-Kinderklinik in Tübingen, and DR L SCHALL, Chefarzt der Kinderabteilung am Landeskrankenhaus Homburg-Saar

Volume XVII, Sonderbande zur Strahlentherapie Second enlarged and revised edition of "Strahlenbehandlung bei Kinderkrankheiten," published in 1924 Published by Urban and Schwarzenberg, Berlin, 1932 Paper, 256 pages, and 45 illustrations Price, 12 marks

The applications of radiotherapy to the treatment of diseases in children have developed to such an extent since 1924 that the authors have felt constrained to expand and revise their text-book on "Radiotherapy in Pediatrics." This revision is so radical that, in truth, a new text has resulted. The book falls naturally into two parts first, the applications of ultra-violet, and secondly, the uses of X-rays. Schall is largely responsible for the chapters on ultra-violet, and Birk for those on X-ray, but all sections have been amended where necessary by the experience of both men, so that a real joint-authorship results.

The physical aspects of both kinds of radiation are taken up in detail, apparatus is discussed briefly, dosimetry is considered from the special point of view of its peculiarities in regard to children, and then the treatment of various diseases is illustrated in detail and amplified by a wealth of clinical histories. Throughout the whole book there is a tone of conservatism.

The opinion of the authors is that there are really three groups into which the radiotherapy of children's diseases falls according to the best data available at present. There is the first group in which radiotherapy is the method of choice, and in which cure is practically certain. To it belong tuberculosis of the peritoneal cavity, tuberculosis of the mesenteric nodes, and peripheral lymph node tuberculosis. Thymic hyperplasia also falls into this group, but the authors are inclined to doubt the existence of this lesion as a frequent or important clinical entity. In the second group radiotherapy usually produces no lasting cures but is the best method of palliation for lymphogranuloma, the leukemias, and some other blood diseases. In the third group is a series of diseases in which the value of radiotherapy is debatable, such as bronchial asthma, hypertrophy of the tonsils, diseases of the cerebral nervous system, etc.

The book should be read by all radiotherapists, who will learn much which is new, interesting, and important in this specialized field, and merits serious consideration by pediatricians, to whom is presented much information of value, both in regard to indications for radiotherapy and the results to expect from it.

As is usual with the publishers, the make-up of the volume is first-class.

E T LEDDY, M D

WILHELM CONRAD RÖNTGEN AND THE HISTORY OF ROENTGEN RAYS (UND DIE GESCHICHTE DER RÖNTGENSTRÄHLEN)
By OTTO GLASSER, PH D, Cleveland Clinic Foundation, Cleveland, Ohio
With personal recollections by MARGARET BOVERI, Berlin Pages, 337, with 96 illustrations Published by Julius Springer, Berlin, 1931 Price, 27 marks, bound, 29 60 marks

Years ago I suggested to Glasser that the writing of a biography of Roentgen was a work for his hand, and now, as the spiritual father of the idea, I welcome this child into the world of literature. This book, "Wilhelm Conrad Rontgen und die Geschichte der Rontgenstrahlen," is the story of Roentgen's life and of the eventful year of 1896. It contains a contribution from the pen of Margret Boveri, daughter of Professor Theodore Boveri, a life-long and intimate friend of Roentgen's.

The book begins with the account of the discovery, as given by Roentgen to H J W Dam (sent by "McClure's Magazine" to interview him), and published in April, 1896, in "McClure's Magazine."

The incident of the book and the key as related by T S Middleton, a student at the Wurzburg University at the time Roentgen made his discovery, finds no credence in Glasser's estimation. Glasser discounts it completely. But why might it not have occurred? There is the episode of Archimedes rushing out of his bathtub crying, "Eureka!", there is the story of Newton and

the apple, of Einstein, to whom the pivotal idea of the relativity theory came in a dream when he had almost decided to abandon it. Perhaps the explanation of the key image on the photographic plates did lead him to search further. Who knows? Professor Goodspeed, of Philadelphia, had noted in 1890 strange images on photographic plates, exposed to Crookes' tubes, five years before Roentgen's discovery, and had left these mysterious markings unexplained, but Roentgen, as he assured MacKenzie Davidson, did not wonder, but investigated. Perhaps the incident did not occur. What do the Italians say, "Se non è vero, è ben trovato"?

Glasser gives in detail the story of Roentgen's life and of his scientific achievements. Margret Boveri then picks up the tale and tells of his youth, his university life, his reaction to war, politics, science, and art and the last sorrowful years of his life. There are many of Roentgen's letters which enable one to look into his mind and judge the motivating ideas of his life. He believed in truth and sought for it, in every phase of his experience, in his scientific work, and in his daily life. He believed in his fellowmen and tried to serve them. But how he hated bigotry and religious intolerance and what a contempt he had for unfounded scientific generalizations!

It is fashionable in the literary world, at the present time, to write biography, but biographies which are in reality fiction or, at any rate, belong to the rapidly increasing class of publications known as novelized biographies. The method in this form of literature is to omit all deeds or events in the subject's career not susceptible to emphasis, but to magnify everything that can be made sensational.

Here is a life, however, which needs no novelization to make it interesting. It has all the essential elements of drama. Here

is a modest, methodical, painstaking physicist living in the peace of the library and laboratory, leading the orderly regulated life of a teacher of physics in a small German university, who suddenly discovers a curious phenomenon, a phenomenon so strange and so startling as to be almost unbelievable, a phenomenon which proves to be of such tremendous import as to shake the world of physics to its very foundation. He announces the discovery, and an astonished world grasps at once the import of it and showers him with honors and approbation, yet he remains as before, a modest, retiring, simple, unassuming student of Nature, happy in the circle of his friends and family, desiring all for science and but little for himself. Then comes the war and its aftermath, engulfing him in its tragedy and making of him, in the end, a sad and lonely figure.

Glasser's description of the reaction of the daily press to the discovery is full and complete and contains an account of the discovery as reported in the scientific journals, and the description of the first magazine dealing with roentgenology, the "Archives of Skiagraphy," published in 1896. Then follow Roentgen's first two papers, the beginnings of fluoroscopy, the early application of X-rays in medicine, the early diagnostic X-ray literature, the first observations on the therapeutic use of the X-ray, the development of the X-ray tube and energizing apparatus intensifying screens, the beginning revolutionary changes in the world of physics, the use of the X-ray in the arts, the discovery as viewed by the comic press, and letters from pioneer workers recounting their early experience with the newly discovered ray. The book closes with the third contribution of Roentgen in May, 1897, "Further Observations on the Characteristics of the X-ray."

Many interesting illustrations taken from early publications on the X-rays and numer-

ous pictures of Roentgen and his family and friends add to the value of this work. It is apparent that Glasser does not like the bust the sculptor Hildebrand made of Roentgen, for he does not show a picture of it. His friend Boveri thought it admirable for he writes to Roentgen "I find the likeness and expression wonderful and think that this bust belongs to Hildebrand's best work. One sees in it clearly a labor of love and joy. How marvelously the brow is modelled! The attitude of the head and the expression of the eyes are beyond criticism."

I think this extraordinary work is the very epitome of spiritual grandeur and beauty. It is certainly superior to all the studied photographs of Roentgen extant, most of which are reproduced in the book.

The volume is filled to the brim with facts gathered through great industry and effort. It is an extraordinary piece of research work of its kind. Unfortunately, it lacks an index. Rather pedantic and sophomoric in its literary style, it is nevertheless written with great sincerity and a burning enthusiasm, which a worker in this field finds difficult to avoid, knowing the great import of the discovery and the revolutionary changes it has wrought.

From the extraordinarily complete data some one will some day write a fascinating story of the events which transpired in the world of physics in the year 1896, after the discovery which Roentgen made on that fateful Friday evening of November 8, 1895, and of which he said to Boveri a few days later, "I have discovered something interesting, but I do not yet know whether my observations are correct."

l'Académie de Médecine Published by Masson et Cie, Paris, 1931 Pages 266 and 71 plates Price, 40 francs

This is one of several works which constitute the library on phthisiology published under the editorship of the author himself. The book is an attempt to bring together and to analyze the extensive body of knowledge relating to pulmonary tuberculosis, which has accumulated during recent years as a result of numerous developments in roentgenology, bacteriology and serology, experimental and social medicine, surgery and chemotherapy. In no sense a treatise or text-book, it is, primarily, the expression of the personal studies and experience of the author, who, by reason of his position as a teacher, his extensive clinical experience, and his previous writings, is known as one of the leading authorities in the field. Throughout the work, one is impressed by breadth and soundness of judgment, and by the critical sense with which the clinical, pathologic, and roentgenologic factors are evaluated and correlated. The book is well printed and contains many half-tone reproductions of roentgenograms which are well selected to illustrate the features described.

The twelve chapters deal with present ideas on the development of pulmonary tuberculosis, the onset of primary infection at different ages, the onset of recurring tuberculosis in the intercleido-hilar, parahilar, basilar, parietal, and apical portions of the lungs, the correlation of roentgenologic images or signs of tuberculosis in the different localizations previously mentioned, the lobar variety of onset, onset by diffuse miliary extension, the so-called typhobacillary form of onset, the arrest of primary infection and of recurring infection, as well as a discussion of tuberculosis as it affects, or is affected by, marriage.

To any one interested in pulmonary tuberculosis, either from the clinical or roentgenologic standpoint, this work must be of decided interest and value.

PHYSICS AND ELECTRICITY (PHYSIK UND ELEKTRIZITÄTSLEHRE) By DR. ROBERT JAEGER, Regierungsrat bei der Physikal-Technik Reichsanstalt, Berlin. With an In-

trodition by Oberregierungs- und Ober-medizinalrat DR. WALTER LUSTIG, Berlin. A handbook for the doctor and technician of laboratory technic and roentgenologic methods, edited by DR. WALTER LUSTIG. Volume V, 175 pages (paper volume), with 289 illustrations. Published by Fischer's Medizinische Buchhandlung, Leipzig, 1931. Price, 9.80 marks.

It is a very difficult task indeed to write a brief text-book on physics for readers who are not familiar with calculus, particularly with differential equations and integration. The author will find himself compelled either to sacrifice to a certain degree the accuracy aspired to by the full-fledged physicist or to write "over the heads" of his students. After reading the book of Jaeger I must confess that he has succeeded remarkably in satisfying both requirements. In 168 pages the fundamentals of mechanics, of solid bodies, liquids and gases, acoustics, heat, optics and electricity are outlined and illustrated by simple diagrams. Practical references in the various chapters as, for instance, to the mechanics of joints, the clinical thermometer, sphygmomanometer, the microscope, medical lamps, electrocardiogram, ionization instruments, and diathermy apparatus render the book most suitable to the novice in medicine or the apprentice in the X-ray and clinical laboratory. The last two chapters deal with practical problems in electricity which should be of interest to anyone working in an X-ray laboratory.

The author, who is a member of the staff of the German Bureau of Standards in Berlin, has presented us with a brief but concise book for the beginner in physics, which is recommended particularly to teachers of X-ray and laboratory courses as a helpful guide in arranging their class work.

GYNECOLOGICAL ROENTGENOLOGY A roentgen atlas of the female generative organs, with special reference to uterosalpingography, an outline of gynecology in its relation to roentgenology, and a chapter on radium therapy. By JULIUS JARCHO, M.D.,

F A C S , attending gynecologist and obstetrician, Sydenham Hospital, New York
Pages 650, illustrations 273, and 5 colored plates (cloth volume) Published by Paul B Hoeber, New York 1931 Price \$20 00

This book is particularly interesting as the first attempt, in this country at least, to compile and co-ordinate all the work that has been done in gynecologic roentgenology. It is the more significant since the advent of uterosalpingography and its combination with pneumonography. The author has quite thoroughly gone over the literature, which is represented in an adequate bibliography. He presents a rather lengthy, although interesting, historical sketch of the entire field, presenting in detail—perhaps too much—the steps that were taken before the present stage of progress was reached. A few additional drawings or cuts would have demonstrated the older apparatus to more advantage than a lengthy and rather difficult description.

There is an excellent discussion of the Rubin test, both in the original and in the most recent modifications. The test is evaluated against the intra-uterine iodized oil instillation, both as to its demonstration of tubal patency or non-patency, and the determination of the point of obstruction when such is present. The author favors the newer procedure, citing examples of tubes impervious to gas and patent to iodized oil, and discusses the relative reliability of diagnosing a point of tubal stricture by reference of pain, as against actual visualization.

The technic of uterosalpingography is presented in some detail, with sketches of the necessary apparatus. Again, more drawings or cuts could be used to advantage. There is a reasonable conception of indications and contra-indications to this and the other procedures, with a special effort to allay the fears of ultraconservative operators. The book contains a very interesting and fairly complete series of uterosalpingographs, with their interpretations and also the clinical findings. This is the more valuable because of a well written chapter on the physiology of the uterus and tubes as brought out by iodized oil and serial examination. The combined method

receives approbation but hardly adequate treatment. Very few illustrations of pathologic conditions, as exhibited by this method, are shown. The author discusses the method of Béclère, placing a lead wire about the limits of a palpable tumor before radiographic examination, to outline the tumor on the films. Besides the restriction of this method to tumors of considerable size, or convenient location, the element of possible faulty projection of the shadow of the wire relative to that of the intra-abdominal structures enters. The combined method (pneumoperitoneum plus iodized oil instillation) appears, by all odds, to be more simple, accurate, and graphic.

The therapeutic value of intra-uterine insufflation by gas and instillation of iodized oil is presented in detail, together with representative case studies. There is also a short discussion of radiation in gynecology.

The reviewer feels that in the section devoted to the description of roentgenographic technic, this could be handled to better advantage by a less verbose description and a few cuts to illustrate, rather than a description of the patient and the relation of the incident ray to the organ to be rayed, which, at best, is both obscure and faulty. The chapter on equipment might be revamped to advantage. However, the book is extremely interesting, well written and edited, and gives a good summary of the roentgen diagnosis of lesions of the female pelvis, with reasonable conclusions.

The reviewer, however, would like to call attention to the composition of the book which, at this day should be taken into consideration, namely, the unusually large type such as is used in grade school primers, and which is quite uncalled for, making the book at least half again as large as need be. Nowhere are there higher priced volumes than roentgen publications, and the price of this volume is no exception.

PRECIS DE PHYSIOTHERAPIE ET DE PETITE CHIRURGIE DERMATOLOGIQUES By JEAN MEYER and JEAN SAIDMAN, with the collaboration of ROBERT GIRAudeau Preface by H GOUGEROT Professor of Dermato-

syphilography at the Faculty of Medicine of Paris, Doctor at Saint Louis Hospital Published by Gaston Doin & Cie, Paris, 1931 Pages 200, figures, 24 Price, 38 francs

This book is an exhaustive treatise, but is intended to help general practitioners in dealing with certain skin affections and in knowing the forms of treatment best adapted to certain cases. Moreover, the book is not an evaluation of methods employed by other workers, but is strictly confined to a brief description of the methods employed by the authors themselves. Among the therapeutic agencies considered are high frequency currents, including surgical diathermy, ultra-violet irradiation in its different forms, infra-red rays, roentgen rays, radium, cryotherapy, and hot air. Much more attention is given to the use of high frequency currents and ultra-violet rays than to any other method. For instance, the general considerations on radium are covered in three pages. The section dealing with the general aspects of roentgen-ray treatment is somewhat more adequate. In connection with radiodermatitis, no mention is made of late lesions occurring from six months to three or more years after irradiation. The authors also fail to mention the fact that secondary infection plays such an important rôle in the slow healing of radiodermatitic ulcers. They seem to favor ultra-violet irradiation for keloids, although it is well known that roentgen rays or radium are more effective. The same is true of furuncle and other infections of the skin. As a general guide the book is useful, but with reference to certain conditions, such as those mentioned, the therapeutic recommendations can hardly be said to represent the soundest opinion. Also, the descriptions of the technic of treatment given in relation to many conditions are altogether too brief.

ROENTGEN STEREOSCOPY IN PULMONARY DISEASES (RONTGENSTEREOSKOPIE BEI LUNGENKRANKHEITEN) By DR W KREMER, Dirigierender Arzt an den Beelitzer Heilstalten und Leiter des Tuberkulosekranken-

hauses, and DR W LUEDKE, Assistenzarzt am Tuberkulosekrankenhaus der Beelitzer Heilstalten No 40, Tuberkulose-Bibliothek, Beihefte zur Zeitschrift für Tuberkulose herausgegeben von Prof Dr Lydia Rabinowitsch Paper-bound volume, 35 pages, with 23 illustrations, 8 of which are colored. Published by Johann Ambrosius Barth, Leipzig, 1931 Price, 375 marks

Dr Kremer and Dr Luedke go to great pains and unusual lengths to establish the *rationale* of pulmonary stereoröntgenography. They show that stereoscopic procedure has advantages and disadvantages. Of the latter, they mention (1) the inability of many persons, especially physicians, to see stereoscopically, (2) the lack of artistic plasticity in stereoscopy because of the lack of colors, shades, air perspective, etc., and (3) the technical difficulties, especially the short exposure technic. As for the advantages, they mention the value of stereoscopy.

- 1 For diagnostic purposes in differentiation
 - (a) between intra- and extra-thoracic pathology, especially of gland shadows,
 - (b) of rib pathology (osteomas) and intrapleural pathology (cavities),
 - (c) between pleural and intrapleural processes (Cova's "tortoise-shell pleuritis," cavities, and annular shadows),
 - (d) of vascular and hilus shadows
- 2 For use in operative intervention
 - (a) as to localization of foreign bodies,
 - (b) for Jacobaeus' operation,
 - (c) for localization of cavities for thoracoplasty,
 - (d) for abscess operations

The remainder of the pamphlet is devoted to the evaluation of various types of apparatus and a discussion of the history and applicability of the anaglyphic process. There are eight illustrations of chest pathology and the accompanying anaglyphic duplicates, which are shown to support their contentions.

The first main point made by the authors—the necessity and value of pulmonary stereoröntgenography—is one which was recognized in this country long ago. The second

F A C S , attending gynecologist and obstetrician, Sydenham Hospital, New York Pages 650, illustrations 273, and 5 colored plates (cloth volume) Published by Paul B Hoeber, New York 1931 Price \$20.00

This book is particularly interesting as the first attempt, in this country at least, to compile and co-ordinate all the work that has been done in gynecologic roentgenology. Nowhere are there higher priced volumes than roentgen publications, and the price of this volume is no exception.

PRECIS DE PHYSIOTHERAPIE ET DE PETITE CHIRURGIE DERMATOLOGIQUES By JEAN MEYER and JEAN SAIDMAN, with the collaboration of ROBERT GIRAUDEAU Preface by H. GOUGEROT Professor of Dermato-

The roentgen cataract has its form similar to that seen in the glassblowers' cataract. It may appear as early as four months, but more often it makes its development two to three years after the treatment. One case has been reported as late as eight years. The smallest recorded dose which has resulted in a cataract was 110 per cent of the skin erythema dose. However, patients who are suffering from skin diseases, such as lupus, eczema, and other similar lesions are especially sensitive, as well as patients who are poorly nourished. A larger total dosage of roentgen therapy can be received by the orbit without the production of cataract, provided the doses are partitioned. For instance, 1,200 roentgens given over four weeks are required to produce a typical roentgen cataract in experimental work on animals, whereas 1,000 roentgens will produce the same damage if given in one treatment. The main precaution to observe is that epilation must not occur.

JAMES T CASE, M.D.

PULMONARY SYPHILIS IN ADULTS (DIE LUNGENSYPHILIS DES ERWACHSENEN) By DR L DÜNNER, ärztlicher Direktor, DR F LEESER, Röntgenologe, and DR H BLUME, Assistenzarzt am städtischen Hospital Buch-West in Berlin No 41, Tuberkulose-Bibliothek, Beihefte zur Zeitschrift für Tuberkulose herausgegeben von Prof Dr Lydia Rabenowitsch. Paper-bound volume, 52 pages, with 37 illustrations. Published by Johann Ambrosius Barth, Leipzig, 1931. Price, 6 marks.

The monograph of fifty-two pages by Dr Dunner, Dr Leeser, and Dr Blume on pulmonary syphilis is characterized by an intense caution. A careful and evidently exhaustive review of the literature as well as the study of cases in their own experience makes them highly circumspect in giving a positive diagnosis of lung syphilis. The book is divided into a number of sections or chapters, the titles of which show the encyclopedic approach followed in the presentation. Under the heading of "Generalizations concerning Syphilis," the authors mention the work of Rothschild, in which he claimed to have diagnosed syphilis in the secondary stage and even some cases

during the incubation period. They feel that tertiary syphilis only is demonstrable. They stress the prevalence of confusion in the differential diagnosis of pulmonary syphilis and other chronic diseases. A statistical review of the number of cases proved at autopsy shows great divergence. They attribute this either to geographic discrepancies or to the inexperience of the examining pathologist. Skill in the pathologic diagnosis of lung syphilis would account for the findings of Rossle, who demonstrated twenty-five cases from autopsy material seen by him during his service in Jena. These were cases which had not been suspected clinically. After discussing history, symptomatology, diagnostic means, and pathology in general terms the authors indicate that the material which is to follow will prove that, after all, there are but two dependable diagnostic points, namely, the persistent failure to demonstrate tubercle bacilli in the sputum, and the localization of the lung process in the middle or lower lobes, especially on the right side. They add that a third point may be admissible also in certain types of cases, namely, the success of a specific cure in the treatment of true gummas.

The next chapter deals with "Diagnosis" in regard to (a) history and common symptoms, (b) physical findings, (c) sputum findings ("There is no specific sputum for syphilis"), (d) serological reactions for syphilis, (e) other syphilitic changes, and (f) roentgen findings—three types (1) the chronic interstitial pneumonic form, (2) the rare isolated gummas, and (3) the miliary gummatous form. The conclusions from reviewing these phases of the situation are that the previously mentioned points are the only decisive ones for diagnosis although the roentgenogram is a necessary adjunct in all doubtful cases and as a means of following the progress of therapy.

The third main chapter heading is "Prognosis and Therapy." The authors say that they will speak in this article less of prognosis and therapy and more of symptoms and diagnosis. They advocate mild and harmless treatment which may be gradually fortified and increased. Their reason for this is the great possibility of a mistaken diagnosis, and

main point of their thesis—the necessity for short exposure technic—was established routinely in this country long since, and it is no longer mentioned. As for the various types of apparatus described, all of them are of purely local German manufacture, and none of them offers any noteworthy features for the roentgen laboratory which is provided with any standard American equipment.

The only real departure in the book is the use of the anaglyphic principle in pulmonary stereoroentgenography, and it is doubtful whether the value of the process the authors advocate is substantiated by the argument or the examples they show. The style is abstruse and complicated, and the article is not graced in its execution with any factors which would predispose the reader in favor of the procedure which the writers promulgate.

W WALTER WASSON, M D

ROENTGEN DIAGNOSIS OF THE VISCERA BY TABLES AND DRAWINGS (RÖNTGENDIAGNOSTIK DER ERKRANKUNGEN INNERER ORGANE IN TABellen UND SKIZZEN) By DR. EMMERICH MARKOVITS, Head of the Roentgen Laboratory of the State Asylum in Budapest, and collaborator of the Central Roentgen Institute of Allgemeines Krankenhaus in Vienna. With an Introduction by the late Hofrat Prof Dr GUIDO HOLZKNECHT, Director of the Central Roentgen Institute of the Allgemeines Krankenhaus, Vienna. Second, revised edition, with 429 illustrations, and 224 pages. Published by Georg Thieme, Leipzig, 1931. Price, 17.50 marks.

This new edition of Markovits' work has included the findings of intravenous pyelography, the methods of bringing out the relief of the gastric and intestinal mucosa, discussion on polyposis, diverticula, and new material on cholecystography and hysteroscopy.

The peculiar value of this work lies in the numerous tables of differential diagnostic points in regard to nearly every lesion of the respiratory, gastro-intestinal, biliary, urinary, and genital tracts. The numerous line drawings illustrate the various diagnostic points

better, perhaps, than the more expensive half-tone reproductions of roentgenograms. These drawings are such as one might make on the blackboard to illustrate class lectures. This method of drawings and comparative tables permits one to cover the entire field of roentgenologic diagnostics of internal medicine within the covers of a relatively small volume. Familiarity with this work cannot fail to enhance very greatly the percentage of correct diagnoses in any roentgen laboratory. All radiologists, readers of German, will do well to acquire a copy of this valuable treatise.

JAMES T CASE, M D

ROENTGEN DIAGNOSIS AND THERAPY IN DISEASES OF THE EYE (DIE RÖNTGENDIAGNOSTIK UND -THERAPIE IN DER AUGENHEILKUNDE) Radiologische Praktika, Band 19. By DR. WOLFGANG HOFFMANN, Chief Physician of the Ophthalmological Clinic, University of Königsberg; 1 Pr. Pages, 72, and illustrations, 20. Published by Georg Thieme, Leipzig, 1932. Price, 8.70 marks.

This is a small but very timely volume, for, in addition to the 24 pages devoted to roentgen diagnosis in diseases of the eye, the remainder of the 72 pages in this work is devoted to roentgen therapy, beginning with damage which may be suffered from the roentgen rays. These roentgen-ray damages to the eye are considered under two headings. First, those which may appear shortly after the irradiation, second, late-appearing damage, such as cataracts and glaucoma. There follows an appropriate chapter on protection of the eye during roentgen irradiation, and then a detailed consideration of the application of X-rays in the treatment of tuberculosis of the eyes and their surroundings, chronic inflammation of the eyeball other than tuberculosis, chronic inflammation of the lids, especially blepharitis, granulosis, and spring catarrh, acute inflammation, glaucoma and epiphora tumors. Ten pages are devoted to the literature.

Of special interest, and as a timely warning there is an excellent section devoted to cataracts and glaucoma as late roentgen damages.

the consequent ill effects which would accrue to a diseased heart condition if strenuous anti-syphilitic treatment were instituted at the beginning of the illness.

The fourth chapter deals with the "Pathological Anatomy." Dr Dünner, Dr Leeser, and Dr Blume distinguish two types (1) the interstitial pneumonic form, and (2) the gummatous. According to localization, they list three groups:

1. Gummatous changes with coarse radiating cicatrices, in the upper and lower lobes.

2. The interstitial form with finer cicatrices in the hilus region.

(a) In the lower lobes.

(b) Especially probable in the right middle and lower lobes.

3. Bronchiectasis on a syphilitic base, in the middle and lower lobes.

Also, they have compiled an excellent diagrammatic chart which portrays, in graphic and readily accessible form, the similar and dissimilar characteristic findings of pulmonary syphilis and tuberculosis.

After citing twelve cases, of which four were positive syphilis, four were probable syphilis, three were doubtful, and one was tuberculosis with a questionable syphilitic complication, the authors conclude with certain questions prompted by the critical analysis of these cases. They do not attempt to answer the questions, and the reader is left with the impression that they believe:

(1) That pulmonary syphilis *per se* is truly a rare disease.

(2) That the diagnostic methods at our disposal are valuable but not conclusive, because of the similarity between the case history, common symptoms, physical findings,

sputum examination, and serological reaction for syphilis and other chronic pulmonary diseases.

(3) That there are but two factors which can be considered positive indicators of lung syphilis—(a) failure to demonstrate tubercle bacilli in repeated sputum examinations, (b) the localization of the process in the middle and lower lobes, especially of the right lung.

(4) That there is a third point which may be considered as confirmatory in the diagnosis of pulmonary syphilis, namely, the success of a specific cure in the treatment of true gummas.

(5) That even the careful consideration of the collected clinical and recorded findings and tests can lead only to a presumptive diagnosis.

(6) That the positive diagnosis must come from the examination of necropsy material by a pathologist experienced in discerning this particular disease.

(7) That tuberculosis and syphilis may exist simultaneously in different sections of the same pair of lungs.

On the whole, the authors seem to be constantly advising the utmost care and precision in the analysis and evaluation of diagnostic and therapeutic measures as well as persistent skepticism even in the face of what may seem to be an absolutely positive diagnosis of pulmonary syphilis. The style is direct and straightforward, and there is no equivocation in the statements of their opinions. The especially facile German in which it is written makes the original publication pleasant and enlightening to even the American reader possessed of but a textbook knowledge of the language.

W WALTER WASSON, M.D.

of the expanded tendons, soon becomes the site of a fibrosis. When the condition progresses so far that there is an exudate within the joint this gravitates to the anterior-inferior aspects of the capsule, where it becomes organized and forms adhesions. Unless these adhesions are broken up it is futile to spend time and money on physiotherapy.

Where arthritis exists, it is rational to consider the process infective, and to do a reasonable removal of foci. Later, when the joint is quiescent and showing some increased range of motion, adhesions may be broken up. Where tipping about the joint margins is excessive or the degeneration of osteo-arthritis is present, only fixation in a favorable angle can be accomplished.

L J CARTER, M.D.

Roentgenotherapy of Chronic Arthritis H O Röhr Strahlentherapie, Oct 24, 1931, XLII, 425-436

The author first discusses briefly the literature on roentgenotherapy in arthritis. He usually applies from 20 to 30 per cent H.E.D. (180 K.V., 0.5 mm Cu + 1 mm Al, 4 ma) at a distance of 30 centimeters. Since it seems advisable to irradiate also the tissue surrounding the joint, large fields of 10 X 15 sq cm are used even for small joints. For large joints two fields are used in order to cover the surrounding tissue. Exposures are given at intervals of from three to four days.

A total of forty patients suffering from chronic arthritis were irradiated. Half of those had primary or secondary chronic arthritis, the other half, arthritis deformans, gout, and septic arthritis. In most cases irradiation was started after all other methods of treatment had failed. The most striking feature was a relief from pain following the first exposure. Swelling decreased and motility was improved. Then follows a brief discussion of the possible mechanism of the effect of roentgenotherapy in arthritis.

THE BLADDER

Reticulolymphosarcoma of Bladder R. Dupont and V. Mistachi Presse Méd., June 24, 1931, XXXIX, 937, 938 (Reprinted from "Cancer Review" by permission.)

In a woman, 32 years of age, who complained of repeated hematuria, pain in the right lower quadrant, and loss of weight, vaginal palpation revealed a right paramedial induration, the urine drawn off containing blood and pus. At operation a bi-lobed infiltrating tumor was found occupying a large part of the right lateral wall of the bladder. This was

removed successfully by partial cystectomy. The recovery was uneventful, the patient being in good health a year later.

Lerou diagnosed the tumor histologically as a lymphosarcoma in which the stroma consisted of reticular cells. The authors add that since these sarcomas are radiosensitive, they would have used deep X-ray therapy, had it been possible to make a histologic diagnosis first, and that this will be resorted to should there be recurrence.

F CAVERS, D.Sc.

The Roentgen Ray and Radium in the Diagnosis and Treatment of Carcinoma of the Bladder G. E Pfahler Surg, Gynec and Obst., November, 1931, LIII, 680-690

The author believes additional information is obtained by combining a pneumocystographic study with the cystoscopic examination. In carcinoma of the bladder it is valuable in demonstrating the size, position, outline, and degree of infiltration.

The technic for pneumocystograms is to make an anterior and a posterior film of the bladder region before any air is injected. Any opaque calculus present will be shown, also any localized collection of gas in the rectum or colon which may hinder the interpretation of the subsequent pneumocystograms. Any residual urine should be withdrawn—the usual sterile methods being used—for a soft tumor surrounded by fluid may not be demonstrated. Either the film made anteriorly or posteriorly will show the tumor surrounded by air, even though occasionally one is unsuccessful in removing all the urine.

After the urine has been withdrawn, an atomizer bulb is attached to the catheter by using a tapering glass connecting rod, then by gentle compression with the thumb and index finger, air is pumped into the bladder until the patient complains of bladder distention or until one can feel the distention of the bladder by palpation or outline it by percussion. The catheter is then clamped with hemostatic forceps and both are strapped to the thigh with adhesive plaster. All of these procedures are performed as quickly as possible, with the patient on the Bucky diaphragm, and the tube and film in position, thus minimizing the delay and distress from bladder distention. If the injections are made slowly and due attention is paid to the patient's complaint of pressure, no harm results.

One or more 8 X 10 films are made posteriorly, directing the rays in line with the axis of the pelvis. Then one or more films are made anteriorly, the patient being carefully turned upon the abdomen and the rays directed obliquely, anteriorly, and upward. There should be some variation in the exposures. With the patient again in the supine position, the clamp is released and the air is quickly

THE APPENDIX

The Active Motility and the Emptying Mechanism of the Appendix Vermiformis Ernst Schmidlein Fortschr a. d. Geb. d. Rontgenstr., August, 1931, XLIV, 141-162

Observations on 21 appendices were made, from 7 to 9 hours *p.c.*, some under the influence of saline cathartics, all under the pharmacologic influences of 0.01 mg pilocarpin, and 1 or 2 mg of atropin at intervals of from 20 to 40 minutes. Conclusions were chiefly drawn from a comparison of from 4 to 8 exposures made at irregular intervals and some from occasional fluoroscopy. Experiments covered not more than 40 minutes. The author is aware of the possibility that the visible appendiceal shadow may not represent the entire length of the organ.

(*Abstractors Note*)—It seems that the time of observation is much too short and that terms like "spasm at the appendico-cecal junction" should better be replaced by "contraction", "stagnation" in the terminal portion also is easily misleading as it might give the impression of a pathologic phenomenon, the German term "Beutelung" ("pocketing" in English) might be less conspicuous.)

Motility of the organ is chiefly the result of changes in tone of the muscle coats. The proximal portion shows the expressions of changes in tone, peristalsis (at times reversed), and contractions. The distal portion is motorically inert and pockets contents regularly. Changes in muscle tone produce elongation and shortening, with apparent segmentation. Tortuosity and stagnation are of no functional pathognomonic significance.

HANS A. JARRE, M.D.

ARTHRITIS

Traumatic Disability of the Shoulder George A. Ramsay Canadian Med. Assn. Jour., November, 1931, XXV, 566-571

Shoulder function may be seriously disabled by the common traumas of accident or by occupational over-use. That such cases need careful attention is seen in the records of insurance companies and workmen's compensation boards where shoulder injuries are found to account for an average period of disability greater than other traumas. In one large group of cases of shoulder disability not due to fracture, one-eighth recovered fully in three months, while nearly one-half had partial permanent disability and another eighth had permanent incapacity. The contribution of the X-ray examination was to the effect that one-half had no evident bone lesions, and that in cases in which such did exist

they were found more frequently in the acromio-clavicular joint than elsewhere. When osteoarthritis occurs in the shoulder following injury it is prone to become progressive, more so than in any other joint. If our previous concepts of management are insufficient, then we must face a situation that warrants our best efforts to arrive at a better rationale in treatment.

Shoulder disabilities would seem to fall within certain groups (1) Frank trauma, with subsequent limitation of function, (*a*) burns causing a skin cicatrix, (*b*) fractures and dislocations (2) Unseen traumas, with latent disability, (*a*) tendonitis, (*b*) neuritis, (*c*) cartilage injury, including recurrent dislocation, (*d*) adhesions, (*e*) periarthritis and arthritis.

Evident bone injury most frequently involves the upper third of the humerus, i.e., the surgical and the anatomical neck, the tuberosities, and especially the facet of the supraspinatus on the greater tuberosity. In these conditions we should avoid such fixative appliances as will keep the arm applied to the body in the abducted internal rotated position. Further, the shoulder should not be neglected in the treatment of fractures of the clavicle, the lower humerus, the elbow, or the forearm. No splint should be applied in such a way as to cause a drag on the shoulder girdle. It should be remembered that the shoulder joint, with its shallow socket and large humeral head, is held in place largely by muscular action, the capsule playing a minor role in this respect. Any position or type of fixation that places any continued strain on these muscular supports will cause future loss of function and produce future discomfort.

Special attention is drawn to the avulsion of the facet of attachment of the supraspinatus muscle on the greater tuberosity, or to the rupture of the tendon of the muscle itself. So-called sprains of the shoulder joint are not due to a rupture of the capsule as in many other joints, for the capsule of the shoulder is so lax that it is almost impossible to rupture it. The injury is most often that to the supraspinatus muscle described above. The author gives detailed technic for the elicitation of this injury.

By far the larger group of cases of shoulder disability are those in which a definite anatomical lesion is not determinable, and in which the terms, synovitis, periarthritis, strain, or bursitis are very loosely applied. In general, we may say that there are injuries to the soft parts, with coincident synovitis, the acute lesion being usually sprain of muscle or tendon while the more chronic lesion may be termed a periarthritis.

Muscle strain results in the formation of exudates, with subsequent adhesions about the tendinous extremity of that muscle. As this progresses it involves the capsule. The capsule, being the fusion

author denies that true osteochondritic processes (Perthes) is a cause of such deformities, but admits that such disease may occur occasionally without relation to the former dislocation He assumes, furthermore, that some of Freund's deformities may be explained by incongruities between the acetabula and the femoral heads, necessitating structural transformations A reply from Freund is added to this paper, in which he maintains his stand

HANS A JARRE, M D

The Roentgenologic Diagnosis of Bone Tumors
Franz Polgar Rontgenpraxis, Nov 1, 1931, III,
963-972

The roentgenologic examination of bone tumors, especially if done in serials, is more important than even a biopsy The removal of a small piece of tissue from bone tumors is not always harmless, and histologic examination of such small specimens does not always decide between the benign or malignant type The differentiation of these two on roentgenograms is often possible only if a series of films, taken at intervals, is studied.

Benign tumors are most often centrally located They do not infiltrate the surrounding bone, but may grow expansively The structure of the surrounding bone in benign lesions is more uniform, and the outline of the tumor is more definite The malignant tumors raise the periosteum, are not definitely circumscribed, and lead to dense ossification of the bone or soft tissues Rather frequently the benign giant-cell tumor is mistaken for a sarcoma, and sometimes a solitary osteolytic bone metastasis has been believed to be a sarcoma.

The osteogenic sarcoma is the most malignant and the most frequent bone tumor Ray-like arrangement of periosteal bone proliferation is the most dependable roentgen sign, elevation of the periosteum being important, also Occasionally a diagnosis cannot be made roentgenologically, especially if the case be early In 72 per cent, the lower extremities are attacked, the age is usually found to be in the second decennium Pain, especially at night, is clinically a very early symptom The prognosis is poor In Ewing's statistics only 6 per cent remained alive after five years Early amputation with pre- or post-operative irradiation seems advisable, roentgenotherapy alone offering only palliation

The extrperiosteal fibrosarcoma is a rare tumor, which shows in a roentgenogram only a soft tissue tumor, sometimes with erosion of the neighboring bone The prognosis after surgery is better than in an osteogenic sarcoma Irradiation has no effect

The "Ewing Sarcoma" (endothelial myeloma) represents about 10 per cent of all bone tumors and is found in young individuals The diaphysis of long

bones is often involved, especially the fibula and tibia, sometimes it is found in the small bones of the extremities or in the skull and vertebrae This tumor is the only type which metastasizes to other bones The roentgenogram shows frequently an onion-like layer periosteal bone growth, often with areas of destruction in the bone A soft-tissue tumor may often be seen This tumor is very radiosensitive. The prognosis for a permanent cure is poor, as most cases are diagnosed in a late stage

The multiple myeloma is typified by multiple, small, round, circumscribed areas of bone destruction New bone formation is absent A diffuse osteoporosis accompanies the picture in many cases Skull, ribs, pelvis, and long bones are attacked Lung metastases are not found, contrary to the case of other sarcomas

The benign giant-cell tumor (or osteogranuloma) is the most frequently occurring benign tumor It probably represents an overproduction of granulomatous tissue, occurring after a medullary hematoma or another trauma It must not be mistaken for an osteitis fibrosa cystica The roentgenologic film is very characteristic, and difficult only in flat bones The tumor is usually centrally located and expands the surrounding bone symmetrically, cystic areas of different size may be present In advanced cases the tumor breaks through the bone into the soft tissues Usually a few thin bone trabeculae remain visible in the tumor A periosteal bone-growth is absent The prognosis is always favorable Bloodgood could not find in his review a single occurrence of sarcomatous degeneration Surgical curettage is followed by recurrence in from 20 to 30 per cent of the cases Roentgenotherapy is the treatment of choice, as recurrences have not been reported The tumor shows a definite increase in size after the treatment and begins to decrease only after about two months Complete ossification can be looked for in about one year Many cases of this benign tumor have been operated on with the diagnosis of a sarcoma and many bones have been needlessly amputated

Chondromas and osteomas are considered congenital anomalies rather than tumors Chondromas grow expansively and often show typical calcification They are always bounded by a sharp line

Metastatic bone tumors are diagnosed by their multiplicity, their characteristic localization, and by the knowledge of a primary tumor The hypernephroma and carcinoma of the thyroid may cause solitary metastasis

Hodgkin's disease, lymphosarcomatosis, actinomycosis, and the echinococcus disease may simulate malignant tumors, when they attack bones

H W HEFKE, M D

Osteogenic Sarcoma Developing in Osteitis Deformans (Paget's Disease of the Bone) A. Ochsner

expelled compression may be used to aid in removing all of the air. The author has made several hundred such examinations with no damaging effects.

IRRADIATION TREATMENT

The author is not satisfied with the results of either surgical excision or irradiation, but points out that irradiation is used almost entirely in "inoperable" cases. He gives most complete tables showing the various methods of radiotherapy. Radium may be used alone in the form of capsules, needles, or seeds (glass or gold), or deep roentgenotherapy may be used alone, also in conjunction with electrocoagulation, before or after. The method of suprapubic cystotomy, electrocoagulation, and radium needles has been abandoned by the author, but that of electrocoagulation followed by highly filtered radium capsules packed into the bladder against the base of the tumor is favored.

Tables are also given of combined surgery and radiation treatment, electrocoagulation and radiation therapy, and of irradiation only.

D S CHILDS, M D

BONE (THERAPY)

Technic of Treatment of Fracture Re-dressing without Removal of Plaster of Paris Bandage. Mauritz Parsson. *Acta Orthopedica Scandinavica*, 1931, 166-201

In treatment of fractures of the long bones, a *dislocatio ad arum* not infrequently occurs, either immediately after application of the plaster of Paris bandage or a few weeks later. In such cases, instead of removal of the bandage, with re-dressing and application of a fresh bandage, the author advocates the following procedure. After roentgen examination in two perpendicular planes, generally the frontal and sagittal, the following measures are taken:

(1) Measurement on the roentgenograms of the angle between the axis of the lower fragment and the prolongation of the axis of the upper fragment (here termed the "angle of deviation")

(2) A horizontal cut is made by saw in the bandage at the level of the fracture, through the entire bandage, with preservation of a bridge from 4 to 5 cm broad, on the side toward which the vertex of the angle between the fragments seems to point.

(3) Breaking of the plaster of Paris bandage with the enclosed member until the cut made by the saw is open at the desired angle, and then insertion into the cut of a plug of suitable size and shape.

(4) Roentgen control

(5) Stiffening of the bandage with starch and plaster of Paris dressings.

In the fourteen cases recorded by the author the desired end was achieved and the angle of deviation was done away with, or nearly so. Five cases are reported in detail, with roentgenograms taken before and after the interference.

Further, a method, with figures and formulae, is explained which renders it possible, exclusively by means of the two angles of deviation ascertained by roentgenograms in two perpendicular planes, to determine mathematically both the angle of deviation proper and the plane in which the angle of deviation lies in relation to the frontal and sagittal planes of the patient.

W W WHITELOCK, Ph D

BONE DISEASES (DIAGNOSIS)

A Clinical and Radiologic Study of a Case of Dyschondroplasia. Giorgina Giacomini. Riv di radiol e fisica med., December, 1931, IV, 206-222.

This case illustrates the following important radiologic points. Dyschondroplastic changes may be symmetrical and extend throughout most of the cartilaginous bones; in addition, there may exist cartilaginous exostoses and chondromatous outgrowths; these chondromatous changes may be encountered not only in the skeleton but also in any organ containing cartilage.

The case report has several excellent radiographs and is supplemented by an extensive bibliography.

E. T. LENNY, M D

Deformities of the Femoral Head Following Non-surgical Reduction of Congenital Dislocations of the Hip. Max Lange. Fortschr a. d. Geb d. Röntgenstr., August, 1931, XLIV, 227-231.

This paper is a reply to a publication by Freund, abstracted in a previous issue. The author contends that "late deformities of such hips are seen the more frequent the larger number of former old congenital hip luxations." Such late deformities never occur in femoral heads which originally were well formed and developed normally. Consequently, there is no danger of late deformities in cases in which an anatomic, perfect cure is obtained with reduction (concluded from study of cases from Munich, Dresden, Zwickau), covering a 10 to 15 year period.

One must differentiate between early and late deformities of such femoral heads, the former developing during the first year following the reduction, the latter occurring independently years later. Early deformities continue to undergo changes for many years, as these joints of lessened functional capacity will not tolerate normal use. They not infrequently terminate with arthritis deformans. The

publication of Kienbock and Preiser, concerning malacia of the os naviculare and lunatum, and has aroused wide interest. Three cases are reported, which could be observed during several years. They showed at the onset, as outstanding roentgenologic signs, small isolated cavities in the carpal bones. Two of these could be considered definitely tuberculous, as the patients had other bone or joint pathology which followed a clinical and roentgenologic course, compatible with the assumption of such infection. The third patient was considered tuberculous as no other possible explanation could be detected, and the lesion showed regenerative changes in the time of observation and during X-ray treatment.

The difficulty in differentiation between Kienbock-Preiser's malacia, localized osteitis fibrosa (Konjetzny-Kappis), structural anomalies, projective simulation of disease, osteomyelitis, and enchondroma is stressed, and the remarks concerning malacia are of interest.

HANS A JARRE, M D

Periosteal Thickening in Paget's Disease as Well as in Recklinghausen's Disease H Meyer-Borstel Röntgenpraxis, Sept 15, 1931, III, 830-833

The absence of periosteal proliferation is one of the diagnostic signs of generalized osteitis fibrosa (Recklinghausen) in Schmorl's opinion, while a Paget's disease shows the presence of it. The author shows in two cases the presence of well-defined periosteal thickening and proliferation. Generally Recklinghausen's disease does not give evidence of it, but in chronic cases (as in the one shown by the author) it may be definitely present.

H W HEFKE, M D

BONE DISEASES (THERAPY)

Solitary Cysts of the Long Bones F Jacoby Arch f Klin Chir, 1931, CLXIII, 386-406 (Reprinted from "Cancer Review" by permission)

The author describes ten cases, seen during the past three years, of single long-bone cysts, excluding parasitic cysts and those arising in malignant tumors and thus dealing only with localized cystic osteitis fibrosa, cystic benign tumors (fibromas, chondromas, giant-called brown tumors) and cysts of undetermined origin. Of the ten patients, eight were from 3 to 16 years of age, the others 25 and 40, respectively. In seven there was pathologic fracture.

Curettage of the cyst cavity is the treatment of choice, with suitable splints the fractures healed well, and in all cases (except one lost sight of) normal function of the extremity followed operation.

The author emphasizes the need for biopsy since X-ray examination does not suffice to distinguish among a cyst, chondroma, fibroma, osteitis fibrosa, brown tumor, and malignant central sarcoma.

The author does not think that trauma often plays a primary part in the etiology of bone cysts, though it may secondarily affect an already cystic bone by causing fracture or setting up infection. In his ten cases, there was primary trauma in one case and secondary trauma in four.

F CAVERS, D Sc.

Osteosarcoma of the Femur Treated by Radiotherapy M Delaye Lyon Chir, May-June, 1931, XXVIII, 338, 339 (Reprinted from "Cancer Review" by permission)

A 24 year-old soldier had been complaining for four weeks of swelling at the lower end of his left thigh. A radiograph showed a typical osteogenic sarcoma, with marked destruction of the cortex. A large skin incision was made and the tumor freely exposed. Deep X-rays were then delivered directly to the growth, a total dose of 6,000 r without a filter being given in one sitting. The tumor now shows considerable reduction in size. A further report of this case will be of considerable interest as the radiation technic employed is entirely new.

P J KERLEY, M B

CANCER (DIAGNOSIS)

Studies on the Blood of Persons with Carcinoma G Creuzberg, F Dannmeyer, O Hartleb, E L Lederer, L v Noël, J Schubert, H Seel, and L Treplin Strahlentherapie, Nov 14, 1931, XLII, 609-709

This paper deals with studies of the cancer problem carried out by a group of physicians, physicists, chemists, and biologists. Their co-operative plan comprises the following problems: Physicobiologic considerations of the cancer problem, chemical studies on the serum of patients with carcinoma (the "cancer index" and other characteristic factors regarding the cancer diagnosis), spectrometric studies on the blood serum of patients with carcinoma (the "cancer curve"), colloid chemical studies on the serum of man, particularly cases with carcinoma (the "protective index"), animal experiments, and last, clinical remarks concerning the blood studies on patients with carcinoma.

It is utterly impossible to attempt in an abstract to do justice to the tremendous material collected by the authors. Suffice it to say that very definite relations between fatty acids, cholesterol, and acidity of the blood in the serum of healthy persons and

and I M Gage. Surg Clin N America, August, 1930, X, 851-868 (Reprinted from "Cancer Review" by permission)

The authors found in the available literature thirty-one cases of Paget's sarcoma or osteogenic sarcoma arising on osteitis deformans, every one of the patients died within a short time after the appearance of malignancy.

They describe a case occurring in a man, 61 years of age, with a history suggesting Paget's disease of the right tibia and the skull for about ten years. A year before admission to the hospital he fell and hurt the right knee, and after this noticed gradual swelling and increasingly severe pain. X-ray examination revealed typical Paget's disease in both femora, tibiae, and ilia and in the skull. In the right tibia there coexisted with this a periosteal sarcoma invading the muscles. The limb was amputated, but death occurred seven weeks after operation. At necropsy there were found metastases to lungs, liver, and mesenteric and mediastinal lymph glands. Despite the very bad prognosis of sarcoma superposed on Paget's disease, the authors regard amputation as justifiable in order to relieve the severe pain.

F CAVERS D Sc.

Osteochondromatosis of the Joints R. Kienböck.
Rontgenpraxis, Oct 1, 1931, III, 895-899

Osteochondromatosis is a tumor disease of the joints, in which osteomas as well as chondromas are present. There are different types of this disease some with multiple osteomas and one or several chondromas, and another type with a single exostosis and multiple cartilaginous bodies. The author describes some cases.

H W HEFKE, MD

Osteochondromatosis of the Knee Joint Paul C Colonna Surg, Gynec and Obst., November, 1931, LIII, 698-703

This rare pathologic process is seen most often in early or middle adult life, though no age-period is exempt. Pedunculated and loose cartilaginous bodies are formed from the synovial membrane of joints, the knee being most commonly affected. These bodies are thought to represent an overstimulation of a normal process and to begin to grow from the outer fibrous layer of the joint capsule and push their way toward the joint cavity. They grow to different sizes before being cast free into the joint. (The type of injury is the probable deciding factor in the portion of the joint first involved.) The exact cause has not been proved, but a review of many cases gave a history of trauma to the joint, either direct or from irritation produced

by wrenching or twisting. Occasional sharp pain followed as well as increased limitation of movement or a feeling of weakness about the joint.

There are at least two types of osteochondromatosis (1) Those cases in which one or more, usually multiple, loose bodies are free within the joint. These may be of varying sizes—large ones are sometimes three-fourths of an inch in diameter—oblong or round with glistening white, cartilaginous surfaces, often pitted and presenting numerous bosses. Their tendency is to wander about though they often gravitate backward during movement and produce few symptoms. The absence of any area of calcification is noted. (2) The bodies in great quantities were found both free and attached. This type more nearly resembles a neoplastic process, and the earlier cases pass unnoticed on the roentgenogram. In one case reported the whole interior of the joint appeared studded with literally thousands of small, glistening, pearly white bodies about the size of seed pearls. Many of these bodies were attached to the synovial membrane by tiny stalks, others were free within the joint, and many had fused together, this being the only case with a distinctly rancid odor.

In the fourth case report given by the author, the only symptoms present were those caused by mechanical blocking, there being no increase in the joint fluid or local heat or redness. The roentgenogram is regarded as the deciding factor in diagnosis. The treatment is surgical.

D S CHILDS, MD

Joint Osteochondromatosis, with Formation of a Sarcoma. Heinrich Reimann and Robert Kienböck. Röntgenpraxis, Oct 15, 1931, III, 942-944

Osteomatosis, chondromatosis, and osteochondromatosis of joints are in general benign affections and do not develop malignant changes. That a sarcoma may rarely develop on the basis of these changes is shown by a case, described in detail. Roentgenologic examination of the right knee showed an osteochondromatosis of the usual type, with chondromatous and osteomatous growths, beside it there was a large tumor with irregular, cloudy areas of calcification. The inguinal glands were enlarged. After amputation the pathologic diagnosis was osteochondroma with sarcomatous changes.

H W HEFKE, MD

Tuberculous Etiology of Roentgenologically Demonstrable Cavities in the Carpal Bones Hans Hanke Fortschr a d Geb d Röntgenstr., August, 1931, XLIV, 188-197

This paper contributes to the discussion on lesions of the carpal bones in adults which began with the

showed displacement of the esophagus to the right and deformation of the duodenal bulb, suggesting the presence of a tumor lying behind the stomach and compressing the duodenum. Neither in the liver nor other part of the abdomen was there evidence of echinococcus cysts. Exploratory laparotomy showed that a tumor was present above the left half of the diaphragm, and later an attempt was made by rib resection to remove this tumor, which proved to be a large, grey, fleshy inoperable mass found on microscopic examination to be a pulmonary carcinoma. The patient died soon after the second operation, and necropsy showed the right lung to be almost entirely replaced by a fetid, necrotic, carcinomatous mass.

F CAVERS, D Sc

Cancer Diagnosis by Spectro-photometry Editorial, British Med Jour, Aug 1, 1931, No 3682, p 196

Bendien, of Zeist, Holland, claims to have elaborated a laboratory method for diagnosis of carcinoma by blood examination. The technic consists of two parts.

The first is a flocculation method in which the serum is precipitated with various mixtures of acetic acid and sodium vanadate, this precipitate is dissolved in 2 per cent sodium bicarbonate solution, which is submitted to spectro-photometric examination. From a series of spectrograms the extinction coefficients are obtained, and it is on the basis of the curve so plotted that the diagnosis is made. Bendien's view is that cancer is a local disease which can develop only if a specific abnormality of the serum is present. He is not satisfied yet that he can obtain an accurate diagnosis in every case of carcinoma, but he claims that a positive reaction is never seen in cases of any other disease. A matter of very considerable interest is the fact that Bendien has been unable to discover any specific characters in the serum of cases of sarcoma.

WALLACE D MACKENZIE, M D

Is Cancer an Infectious Disease? C Sternberg Wien. klin. Wochenschr., Jan 23, 1931, XLIV, 97-99 (Reprinted from "Cancer Review" by permission.)

The author has published many excellent reviews on special aspects of malignant disease, and now adds another in which he deals in a trenchant manner with some recent publications in which some infective agent or other has been proclaimed to be the real *causa causans* of cancer.

He begins by recalling the fact that in the early days of bacteriology living agents were sought as the cause of malignant growths, and also that at

that time no clear distinction was drawn between infective granulomas and neoplasms—the difficulty in making such a distinction was pointed out by Virchow in his book on tumors, published about seventy years ago. From these early days down to the present time numerous bacteria, fungi, yeasts, protozoa, etc., found in tumors have been regarded as oncogenic agents, though it has been proved that many of these bacteria, etc., may be found in any tissue and that various saprophytic forms may be easily isolated from a tumor.

The author next gives more definite instances. He considers that Gye's work has been completely refuted. Most of Heidenhain's mouse tumors were obviously spontaneous growths bearing no relation to the injection of human tumor autolysates into the animals. Sternberg agrees in this with Hellner and says the experiments have been repeated in his own laboratory on 400 mice with absolutely negative results. As to Blumenthal's claim to have produced animal tumors with *Bacterium tumefaciens*, he points out that this writer now claims that this organism only sets up inflammation of a precancerous nature, from which a neoplasm may arise, but as other writers have not been able to produce tumors in this way the connection of *Bacterium tumefaciens* with animal tumors may be abandoned. The author does not believe that the Rous sarcoma itself affords any evidence for the parasitic theory of tumors. The Rous sarcoma differs too much from all other known forms of tumor for any results obtained from its study to be applied to the etiology of tumors in general.

The author's general conclusions are summarized in the following sentence: "Parasites, in the widest sense of the term, have no other rôle in the causation of malignant tumors than have injuries due to a great variety of agents of chemical and physical nature, hence it may be asserted definitely that there is no specific cancer agent and that cancer is not an infectious disease."

F CAVERS, D Sc

Cancer in Young Persons E Wildbolz Ztschr f Krebsforsch, 1931, XXXIII, 681-708 (Reprinted from "Cancer Review" by permission.)

From an analysis of the pathologic material examined in the Institute [Pathological Institute, University, Bern] from 1920 to 1929, which includes autopsies and tumors removed by operation, it is found that of 5,536 cases, 94 referred to patients under 30 years of age. Of these 94 patients, four were children. This gives a percentage of 1.79 of all malignant growths which had been examined and represents a slight diminution when compared with the period from 1906 to 1915. No evidence could be obtained from the clinical history that cancer in young persons is particularly malignant. In a few

those with carcinoma were established. This led to the creation of the "cancer index." A typical "cancer curve" was seen in the absorption studies if the wave length was plotted against the absorption coefficient of the alcohol-ether extract of the blood serum, prepared according to Noël. A colloid chemical test is also described which offers encouraging possibilities in the sero-diagnosis of carcinoma. These particular studies led to the creation of the so-called "protective index."

Animal experiments concerning the inhibiting effect of blood extracts from patients with and without carcinoma did not show definite results. A few practical remarks of the medical co-worker conclude the article. It is recommended for careful study in the original to all radiologists interested in the cancer problem.

ERNST A. POHLE, M.D., Ph.D.

Carcinomatous Degeneration of Polyp of the Stomach. Report of Eight Personal Cases with Review of Twenty-four Recorded by Others T. G. Miller, E. L. Elsason, and V. W. M. Wright. Arch. Int. Med., November, 1930, XLVI, 841-878. (Reprinted from "Cancer Review" by permission.)

Besides reviewing twenty-four cases found in the available literature, the authors describe eight cases of their own occurring in a series of 200 operations for cancer of the stomach. They conclude that carcinomatous polypi usually arise in benign adenomatous polypi. Quoting from the authors, "most of the patients showing such malignant change are males (80 per cent), and the age incidence is the same as for mural gastric cancer (83 per cent over 40 years of age). The symptoms are those of any malignant gastric lesion with, in addition, those of the two other common consequences of gastric polypi—intermittent pyloric constriction and hemorrhage. The hemorrhage may be frank or occult, it not infrequently leads to an erroneous diagnosis of primary anemia (three of our eight personal cases). Consequently, gastric polypi should be considered in all cases of unexplained anemia. Roentgenologic study alone often makes the diagnosis of gastric polyp, and malignancy may be suspected on the basis of the clinical picture."

F. CAVERS, D.Sc.

The X-ray Diagnosis of Carcinomatous Metastases in the Lungs. M. Bagliani. Radiol. Med., February, 1931, XVIII, 214-245. (Reprinted from "Cancer Review" by permission.)

The value of radiography for the diagnosis of unsuspected pulmonary metastases is shown by a description of twelve cases. In the author's clinic carcinoma of the breast and carcinoma of the stomach are the most frequent sources of carcinomatous

metastases in the lungs. There are two well-known forms: a generalized infiltrative form, known as lymphangitis carcinomatosa, and a nodular form in which malignant nodules are distributed throughout the lungs. Lymphangitis carcinomatosa is easily recognizable on a radiograph; it runs a rapid course often with pleural as well as pulmonary involvement and does not react to deep X-ray therapy. The nodular form is more chronic. If secondary to breast carcinoma there is usually only one nodule for some time. In some cases the nodules are bunched together near the lung root and in others the nodules are distributed throughout the lower parts of the lungs. The apices are seldom the seat of malignant nodules. Slight improvement may follow deep X-ray therapy in this form of metastasis. The nodular form may be secondary to sarcoma—in such a case the nodules react promptly to X-radiation. The technic for the X-ray examination and the pathology of lung metastases are described in detail.

[It has long been held that, radiologically, metastases to the lungs are not seen in the apices even when there is advanced disease in other parts of the lungs. Improvements in technic and more detailed examination of the apices in such cases disprove this view.]

P. J. KERLEY, M.D.

The Diagnosis of a Primary Carcinoma of the Ureter from the Roentgenogram. H. Sauer. Röntgenpraxis, Oct. 15, 1931, III, 935-937.

The diagnosis of a primary carcinoma of the ureter has been made possible only by pyelograms, either by cystoscopy or by intravenous administration. The latter is often of more help because introduction of a ureteral catheter is frequently impossible. Roentgenograms of such a case are shown. They reveal a filling defect and partial obstruction.

H. W. HEFKE, M.D.

Carcinoma of the Lung of Long Duration. L. H. Ball. Jour. Coll. Surg. Australasia, November, 1930 III, 286-290. (Reprinted from "Cancer Review" by permission.)

A man, 60 years of age, was found, seven years before his death, to have pleural effusion (verified by X-ray examination), and was admitted to a sanatorium on a diagnosis of phthisis. Later he was discharged as fit for light work. In December, 1928, he was admitted to the hospital on a diagnosis of gastric carcinoma with metastases in the liver. X-ray examination showed a dense shadow over the lower two-thirds of the left lung with a thick oval line, which was interpreted as the wall of a calcified *echinococcus cyst*. Barium filling of the stomach

showed displacement of the esophagus to the right and deformation of the duodenal bulb, suggesting the presence of a tumor lying behind the stomach and compressing the duodenum. Neither in the liver nor other part of the abdomen was there evidence of echinococcus cysts. Exploratory laparotomy showed that a tumor was present above the left half of the diaphragm, and later an attempt was made by rib resection to remove this tumor, which proved to be a large, grey, fleshy inoperable mass found on microscopic examination to be a pulmonary carcinoma. The patient died soon after the second operation, and necropsy showed the right lung to be almost entirely replaced by a fetid, necrotic, carcinomatous mass.

F CAVERS, D Sc

Cancer Diagnosis by Spectro-photometry Editorial, British Med Jour, Aug 1, 1931, No 3682, p 196

Bendien, of Zeist, Holland claims to have elaborated a laboratory method for diagnosis of carcinoma by blood examination. The technic consists of two parts.

The first is a flocculation method in which the serum is precipitated with various mixtures of acetic acid and sodium vanadate, this precipitate is dissolved in 2 per cent sodium bicarbonate solution, which is submitted to spectro-photometric examination. From a series of spectrograms the extinction coefficients are obtained, and it is on the basis of the curve so plotted that the diagnosis is made. Bendien's view is that cancer is a local disease which can develop only if a specific abnormality of the serum is present. F CAVERS, D Sc.

Cancer in Young Persons E Wildbolz Ztschr f Krebsforsch, 1931, XXXIII, 681-708 (Reprinted from "Cancer Review" by permission)

From an analysis of the pathologic material examined in the Institute [Pathological Institute, University, Bern] from 1920 to 1929, which includes autopsies and tumors removed by operation, it is found that of 5,536 cases, 94 referred to patients under 30 years of age. Of these 94 patients, four were children. This gives a percentage of 1.79 of all malignant growths which had been examined and represents a slight diminution when compared with the period from 1906 to 1915. No evidence could be obtained from the clinical history that cancer in young persons is particularly malignant. In a few

patients the appearance of cancer was preceded by a trauma. The most striking example is a carcinoma of the lower eyelid which appeared in a young man, 25 years of age, two months after a piece of hot metal filing had accidentally struck the eye.

There is a good bibliography of previous work on the occurrence of cancer in young people.

W CRAMER, Ph D, D Sc

Co-existence of Calcified Retrosternal Goiter and Carcinoma of Esophagus F J Collett and R. Bertrand Lyon Med, Feb 1, 1931, CXLVII, 133-136 (Reprinted from "Cancer Review" by permission)

In a man, 69 years of age, complaining of dysphagia for the last two months, X-ray examination showed at the level of the manubrium sterni a non-homogeneous shadow extending to the aortic arch. The diagnosis was either retrosternal goiter or thyroid carcinoma, and it was decided to make a gastrostomy next day, as the patient had not been able to swallow for five days.

Death occurred during the night. Necropsy revealed a cystic and calcified left thyroid lobe and just below, but free from this, an annular ulcerated tumor of the esophagus, histologically carcinoma, just beginning to perforate into the trachea. The authors add that had esophagoscopy been done during life it would have given the correct diagnosis and supplemented the X-ray findings.

F CAVERS, D Sc.

X-ray Diagnosis of Scirrhous Carcinoma of Stomach L Turano Policlinico (Sez Med), October, 1930, XXXVII, 469-482 (Reprinted from "Cancer Review" by permission)

Six cases are described, and the author emphasizes the difficulty sometimes encountered in distinguishing between scirrhous cancer and syphilis, the X-ray investigation alone being usually insufficient. The case history is important, especially because in syphilis several years elapse before the scirrhous-like condition is reached and during this time the patient has suffered more or less severe gastric pains.

F CAVERS, D Sc

Lupus and Carcinoma A von Mallinckrodt Haupt Dermatol Ztschr, January, 1931, LX, 138-152 (Reprinted from "Cancer Review" by permission)

In this interesting paper the author first cites some statistics regarding the frequency of development of

Carcinoma upon lupus vulgaris. The lowest frequency cited (15 per cent) was given by Sequeira, almost the same (16 per cent) was observed at the Munich clinic (four cases in 249 of lupus), next, 2 per cent at the Wurzburg clinic, and 2.2 per cent at the Freiburg clinic. Higher figures were reported by Darier (4 per cent) and by Stühmer (41 cases in 832, or 5 per cent).

During ten years the author saw 906 patients with lupus, including 28 with lupus carcinoma (3.09 per cent), in all cases on the face. Clinically the majority showed the ulcerated and rapidly growing granuloma-like type of cancer, little influenced by any form of treatment. Roughly, half of the patients had had X-ray treatment, but the author agrees with Albert in believing that X-ray treatment rarely causes lupus carcinoma when it has been given carefully.

F CAVERS, D Sc.

Simultaneous Occurrence of Aortic Aneurysm and Bronchial Carcinoma Carl Mumme. München med Wochenschr, Oct 2, 1931, LXXVIII, 1704, 1705

This is a report of a case of aortic aneurysm which, on the X-ray film, showed an increasing density of the lower lobe of the left lung. The gradual increase of this density, together with bloody exudation, led to the diagnosis of a malignancy. At autopsy a bronchial carcinoma with generalized metastasis was found.

E. A. MAY, MD

CANCER (THERAPY)

A Clinical Evaluation of Various Qualities of Roentgen and Radium Rays for the Treatment of Advanced Cancer Bernard P. Widmann Am Jour Roentgenol and Rad Ther, November, 1931, XXVI, 729-733

The author first emphasizes that there is no biological proof of superiority of any particular wave length of radiation in cancer therapy. However, 200 K.V. radiation filtered with 0.5 mm copper affords greater penetration at varying depths with less danger of skin damage than 127 K.V. radiation using 6 mm aluminum. Similarly, it has now been proven by two years of practical experience that skin tolerance can be even further increased by combining two qualities of short wave length radiations such as 200 K.V. roentgen irradiation with gamma radium packs (2 mm platinum). However, end-results studied on a statistical basis of a series of 319 cases of advanced cancer treated by this method indicate that no material improvement over the intensive use of either one of these

agents (roentgen rays or radium) was achieved, although, based on clinical impressions, results from the combined method justify recommending it. By combining qualities of radiation, from 230 to 280 per cent S.E.D through a given skin area may be given by protracting treatment over a period of from four to six weeks

J E HABBE, M D

The Advantage of Bacteriologic Examination before Radiation Therapy of Uterine Cancer D den Hoed Strahlentherapie, Nov 14, 1931, XLII, 775-779

Infection represents one of the most serious complications following radium implantation in cases of carcinoma of the uterus. In order to determine the role played by the resistance of the organism in this connection, the author studied the virulence of the bacteria in the vagina by means of the Ruge and Phillip's test. A small amount of secretion from the cervical ulcer is mixed with 10 cc of sterile blood which has been defibrinated. This is then placed on an agar plate in the incubator at 37° Centigrade. Part of the blood is put in the incubator alone. After 1, 2, and 3 hours new samples are taken and new agar plates made. This gives an idea not only as to the type and number of microbes present in the ulcer but also of the bactericidal power of the blood. Patients who have hemolytic streptococci or whose blood has no bactericidal power are treated first locally as well as with vaccines before irradiation.

The author then tabulated the patients according to the reactions observed following radium implantation and compared the period before the Ruge and Phillip's test was done with the period after it had become a routine. It appeared that without the guidance of the test 32 per cent of the cases had reactions lasting from 3 to 5 days, while of those who had been properly prepared only 6 per cent showed reactions for from 3 to 5 days. The author concludes, therefore, that the Ruge and Phillip's test is most valuable in preventing undesirable reactions following intra-uterine radium therapy.

ERNST A POHLE, M D, Ph D

The Carbohydrate Metabolism in Carcinoma of the Uterus after Treatment with Roentgen Rays and Radium I Lucas Arch f Gynäkol, 1930, CXLIII, 389-411 (Reprinted from "Cancer Review" by permission)

The author estimated the blood sugar, dioxvaccine, and lactic acid content in blood, and the alkali-reserve of the plasma, in women with uterine carcinoma before and after treatment with X-rays and radium. The blood sugar showed no constant changes. The lactic acid showed only a transient increase shortly after radiation. From two to four

hours after radiation there was a transient lessening, and after twenty-four hours an increase, of the alkali-reserve. After each further radiation there was a slight increase of the alkali-reserve, but a normal CO₂-fixing power was never reached. The increase in lactic acid and the decrease in the alkali-reserve after radiation were simultaneous. A summary is given of the literature on the subject. The CO₂-fixing power in these women was between 40 and 47 c.c. per 100 c.c. plasma, while the normal range, as given by Van Slyke, is from 53 to 77 cubic centimeters.

E L KENNAWAY, M D, DSc

The Sensitiveness of Carcinoma to Radiation F Voltz. Virchow's Arch f pathol Anat, 1931, CCLXXX, 340-342 (Reprinted from "Cancer Review" by permission.)

From a series of close observations on the reaction of patients with carcinoma to radiation of a carefully standardized variety, the author concludes that the red-blond human type responds less satisfactorily than other human types. He further draws the deduction that the red-blond type is more predisposed to cancer than other human types. He, therefore, addresses an appeal to all radiation institutes and to all pathologic institutes to supply information about the age, color-type, degree of pigmentation (both in normal and irradiated areas), and other details of all patients under treatment for, or dying of, cancer. This information can be supplied on special forms to be obtained from the author.

C E DUKES, M D, M Sc

End-results in the Treatment of Carcinoma of the Cervix with Radium Lewis C Scheffey and William J Thudium Am Jour Obst. and Gynec., August, 1931, XXII, 247-254

The authors report on 150 cases seen from 1921 to 1930, at the Jefferson Hospital, 140 of which were treated by irradiation. Since 1923, no case of cancer of the cervix, early or late, has been subjected to radical operation, irradiation alone being employed. The age incidence is interesting in that 30 per cent of the cases occurred before the age of 40, the youngest patient being 22. Six per cent of the cases occurred in nulliparous women.

Schmitz' classification was employed, and 111 cases, or 76 per cent, fell under class three. Only sixteen, or 10.3 per cent, of the cases were operable. They conclude from these statistics that patients are not seeking advice at an earlier stage than formerly.

Of the three early cases treated by irradiation alone, all, or 100 per cent, have survived five years. Of the fifty-six inoperable patients seen, fifty of whom were treated, eight have survived for five

years, giving a relative five-year curability of 160 per cent and an absolute curability of 14.2 per cent

All cases, regardless of stage, gave a relative five-year curability of 20.7 per cent and an absolute curability of 18.6 per cent

COMPARATIVE FIVE-YEAR STATISTICS, IRRADIATION

| | All cases reported | Percentage of five year cures of all cases | Percentage of operable cases with percentage of five year cures of same |
|---------------------------|--------------------|--|---|
| Mayo Clinic | 1,094 | 21.8% | 21—60.8% |
| Radiumhemmet | 790 | 20.6% | 25.5—40.4% |
| Mercy Hospital | 332 | 17.5% | 21.9—53.5% |
| Woman's Hospital (N Y) | 259 | 24.3% | 25.9—57.1% |
| Rhode Island Hospital | 92 | 17.4% | 20.6—57.9% |
| Jefferson Hospital | 59 | 18.6% | 5.0—100% |

Their technic consisted of the application of radium in a cervical applicator, a total of 3,600 milligram-hours being employed at the present time. The size and filtration of the applicator are not stated. Monel needles of radium element have been occasionally introduced interstitially, directly into the carcinomatous tissue. X-rays have been employed only occasionally in the past, but following the recommendations of Healy, Ward, and a great many others, they are considering the routine employment of roentgenotherapy in addition to the radium therapy.

JACOB H VASTINE, M.D.

Skin Cancer, with Special Reference to Hospital Cases at Bern O Naegeli Schweiz med Wehnschr, Sept 6, 1930, LX, 837-842 (Reprinted from "Cancer Review" by permission)

This is an analysis of 190 cases of primary squamous-celled cancer of the skin and mouth observed from 1914 to 1928 and representing an annual average of 0.85 per cent of the total skin lesions seen during this period. Basal-celled forms were eight times more frequent than squamous, and the sex incidence was unusual in that women were nearly as often affected as men. As to age incidence, no cases were seen below the age of 20, only four below 30, the disease increased rapidly after the fifth decade and fell slightly after the seventh. In more than half the cases the upper part of the face was affected. After giving a list of fourteen precancerous skin lesions, the author says that cancer on a precancerous basis was most often associated with senile keratosis in three cases each with leukoplakia and Bowen's disease, in two cases each with tertiary syphilis, lupus vulgaris, and Paget's disease, in one case each with lupus erythematoses, X-ray dermatitis, nevus, pluriosis

As to treatment, surgery has been used in nevi and in carcinoma of the lips, tongue, and external genitalia, also in all cases of prickle-celled cancer, radiotherapy (with X-rays or mesothorium) in benign growths, in inoperable cancers, and following surgery. In X-ray treatment a single dose of from 15 to 30 units with 3 mm Al filter is given as a routine, the author states that larger doses give no better results. No cases were treated by electrocoagulation, freezing, or caustics.

F CAVERS, D.Sc.

Electrosurgery in Malignant Disease G A Wyeth Internat Jour Med, September, 1930, XLIII, 479-481 (Reprinted from "Cancer Review" by permission)

In this brief note the author assumes that tumors of low differentiation, i.e. showing embryonic features, are of unfavorable surgical prognosis but are highly radiosensitive, and that Broders' classification of tumors is correct, i.e., that the highly differentiated tumors of Grade I are relatively benign while those of Grade IV represent the opposite extreme. He states that for Grade IV cases, Cutler and Healy report 43 per cent of cures by radiotherapy while the Mayo Clinic statistics report only 9 per cent cures by surgery. Hence, biopsy is essential and should be made by diathermic methods. The author invariably uses electrosurgery for operable tumors and claims that this treatment also gives good palliative results in inoperable cases. Many tumors of Grade IV should not be immediately treated surgically, but first given radiotherapy. Above all treatment should not be schematic and one-sided.

F CAVERS, D.Sc.

Results of Radiation Therapy in Inoperable Carcinoma of the Cervix (from 1920 to 1927) E Mühlmann Strahlentherapie, Oct 24, 1931, XLII, 504-509

Before reporting the results obtained in cases of inoperable carcinoma of the cervix, observed during the years from 1920 to 1927, the author briefly reviews the patients seen from 1915 to 1920. In a brass filter of 0.5 to 1.5 mm thickness 25 mg of radium element were used. From 5,000 to 10,000 mg-hrs. were given in the cervical canal or within the growth. Some cases received, in addition, X-ray therapy which, of course, must be considered insufficient in the light of our present knowledge. The first group observed five years or longer consisted of thirty patients, five, or 16.6 per cent of whom were clinically cured. In the second group, consisting of twenty patients observed from three and one-fourth to six years, three, or 13.6 per cent, were cured. In 1920, a deep therapy apparatus was installed and the patients were treated according to the method of Seitz and Wintz. They were observed from one-half to two years following the treatment.

six out of sixteen patients, or 37.5 per cent, were clinically cured.

The method of treatment used, beginning in 1920, was changed very little. The radium available had been increased to from 50 to 75 mg., which was distributed in seven tubes placed in the cervical canal, within the cauliflower growth, or in the fornix of the vagina. Within a week 3,000 mg.-hrs., distributed over 3 or 4 sittings, were given. From eight to ten days later from 100 to 110 H.E.D. X-ray deep therapy were applied. From 1920 to 1922, the Seitz-Wintz method was used, and beginning in 1923, the large field method of Dessauer-Warnekros. In 1924, another method was introduced, using two large anterior and posterior fields and two lateral fields. A total of 238 inoperable carcinomas of the cervix were irradiated with the combined method. After five years, forty-six patients, or 19.74 per cent, remained clinically free from the disease. The author compares this figure with the cure of 16.6 per cent obtained during the period from 1915 to 1918, in thirty cases treated by radium alone. He concludes that the combined therapy has not materially improved the results obtained by radium alone, and suggests, therefore, that the protracted fractional method of Coutard be given a trial.

Advances in the Method of Treating Carcinoma of the Gastro-intestinal Tract by Roentgen Rays
Hans Holzfelder Strahlentherapie, Oct. 24, 1931
XLII, 497-503

Carcinoma of the stomach can be influenced favorably in about 50 per cent of the cases by intensive X-ray therapy. From 20 to 25 per cent of these patients do not show any evidence of tumor after completion of the treatment. The scirrhus type of carcinoma does not respond as well. The principle of the method is the use of a number of small fields of 6×8 sq cm with compression by means of a treatment cone. On the first day usually two or three fields are used, on the second day two fields, and then daily after that only one field for a period of from four to six weeks. The single dose per field is 300 r (in air), each field receiving a total of from 2,400 to 3,000 r. The technic is similar in cases with carcinoma of the rectum.

Two cases are briefly related illustrating the results which sometimes can be obtained by this procedure. One woman, 53 years of age, was operated on in October, 1928, at the Mayo Clinic. The upper three-fourths of the stomach, including all the posterior wall and part of the anterior wall, was involved with carcinoma. There were also considerable metastases to the neighboring lymph nodes as well as in the omentum. A gastro-enterostomy was not done because there was no obstruction. She started treatment under the author's supervision in Decem-

ber, 1928. She improved considerably, gained weight, and roentgen examination about one year later showed a perfectly normal stomach. In June, 1931, the patient was still well and free of recurrence.

The second case concerned a man, 59 years of age, operated on in the University clinic in Heidelberg, in June, 1929. A carcinoma the size of a fist was found to be adherent to the pancreas. Roentgenotherapy was carried out from August to November, 1930. Roentgenograms are appended showing the slow regression of the tumor until there was complete disappearance. The general condition of the patient also improved markedly. In October, 1931, he was still free from recurrence. The method employed by the author is, therefore, recommended to radiologists for trial in similar cases.

ERNST A. POHLE, M.D., Ph.D.

Multiple Epitheliomas of the Trunk Associated with Parapsoriasis W. Cürrh Dermatol Ztschr, February, 1931, LX, 256-260 (Reprinted from "Cancer Review" by permission)

A woman showed numerous epitheliomas and many patches of parapsoriasis, but nowhere was there a transition from the latter to the former; several sections of both lesions were examined. The epitheliomas cleared up after electrocoagulation followed by X-ray treatment, but the parapsoriasis was intractable to all the remedies tried. The author believes that multiple epitheliomatosis is becoming more frequent [a perusal of current dermatologic literature certainly shows an increasingly large number of case reports].

F. CAVERS, D.Sc.

Summary of Our Experience in the Use of Endothermic Methods in Cancers of the Skin and Mucous Membranes N. Puente Duany, E. Fonts, and M. C. Gomez Bull de l'Assn fran^c p l'etude du cancer, July, 1931, XX, 561-574

The authors are quite enthusiastic over the results obtained by electrocoagulation and the electric bistoury in the past three years. So successful have they been with these endothermic methods that they give them preference over radium. The advantages claimed are that radiotherapy is always longer, and besides the element of time, a larger quantity of radium is made accessible for cases requiring this substance. These endothermic methods facilitate the treatment of a greater number of patients than would be possible with radium treatment.

The electric bistoury has the advantage of bloodless operations on nevi, angiomas, fibromas, etc. The choice of method, either electrocoagulation or the electric knife, or both combined, depends on the size and character of the tumors which are divided

simply in three classes Incipient, small, and large In the first category are included spinocellular epitheliomas, melanomas, nevi, etc., not larger than a pea. In these the disease is completely localized, infiltration very discrete, and cure is practically 100 per cent In the second group are found tumors varying from a pea to a one- or two-franc piece, and in the third group, tumors of large size However, size is not always proportionate to gravity, localization, infiltration, and lymphatic invasion make these forms less accessible to endothermic methods Almost every advantage offered by radium in cutaneous tumors can be accomplished by electrocoagulation or the electric bistoury

Electrocoagulation alone is employed in cutaneous cancers of small size, also in tumors of the conjunctiva and lids, the proximity of the eyeball very often interferes with the use of radium on account of more or less irritation Electrocoagulation is also frequently resorted to in those cases in which small islets have remained undestroyed after radium therapy

Small recurrences on extensive scars of the mouth or skin are well treated with the electric knife followed by electrocoagulation Epitheliomas of the skin of the face, which have been uninfluenced by radium, yield to endothermic methods One of the principal uses of the electric bistoury is the treatment of advanced cases

HENRY BAYON, MD

Diathermocoagulation in the Surgical Treatment of Cancer F F Carranza Bol Inst Med Exp, December, 1930, VII, 1339-1357 (Reprinted from "Cancer Review" by permission)

After discussing the advantages and drawbacks of electrocoagulation, its possibilities in combination with surgery and radium, and its technic, the author gives an account of its use at the Buenos Aires Cancer Institute, in the treatment of carcinoma of the uterine cervix (100 cases), breast (29), vulva (17), and rectum (12), reporting a definite improvement in results as compared with other methods that have been used there

F CAVERS, D Sc

Radiotherapy of Cancer of the Uterine Cervix at the Anticancerous Center of a Parisian Suburb Statistics of the Years 1921 to 1926 Simone Laborde and Y-L Wickham Bull de l'Assn franç p l'étude du cancer, July, 1931, XX, 458-475

The statistics cover a period of ten years Although, inasmuch as cancer is concerned, if five years after treatment there has been no recurrence, the case is usually regarded as cured However, the authors consider that figure as too arbitrary, since

return of the disease has been observed after a much longer time. They have consequently carried their observations for ten years, from 1921 to 1926, extending them from this time to 1931, noticing, as is naturally expected, that the percentage of cures declines but slightly after five years, since, after a time, death is often the result of intercurrent disease

In these observations, cancers of the cervix alone, treated by radiation, figure, cancers of the vagina and post-operative recurrences having been eliminated Epitheliomas of the cervix have been classified in four groups, according to the different degrees of extension of the lesions

The first degree comprises lesions entirely limited to the cervix and considered operable

The second degree includes a juxta-uterine extension with uterine mobility partly preserved, this group comprises cases at the limit of operability

The third degree includes cases in which there is an invasion of the parametrium or of a part of the vaginal wall, with immobility of the uterus, consequently, they are absolutely inoperable.

The fourth degree comprises cases in which neighboring organs (vagina, bladder, rectum) are involved and for which treatment was instituted only as a palliative measure

Five tables are submitted for each year from 1921 to 1926, with the purpose of showing (1) The number of patients examined for cancer of the cervix, (2) the number of patients treated, (3) the number of patients not treated and the causes of their elimination, (4) the number of patients, living and without recurrence, in each of the categories

Following these data, their sum total is condensed in two tables, the model of which has been devised by the Sub-commission of Radiology and the Cancer Commission of the League of Nations In these two tables are enumerated the number of cases treated, the number of deaths, and the percentage of cures in each year from 1921 to 1926, and from 1926 to 1931 Also, the total percentage of cures in each of the four degrees in five years and in ten years, showing the rapid decline of cures, as would naturally be expected considering the stage of disease (80 per cent in the first degree, 50 per cent in the second, and 22 per cent in the third) Patients in the fourth stage usually survived but a few months, and in these cases treatment was expected to accomplish no more than palliation of painful symptoms

Utero-vaginal curietherapy alone has been resorted to for cancers of the first degree In cases of the second and third degrees, roentgenotherapy is associated with curietherapy, roentgenotherapy is usually applied alone in cancers of the fourth degree In the extensive forms involving the vagina, the use of radium involves the risk of hastening perforation of the vaginal walls Surgical treatment following curietherapy has been discountenanced

When extensive cervical granulations are present, even though the cervical canal is free, it is better to carry out the treatment in two stages, the destruction of the granulations which are always infected allowing intra-uterine irradiation to be carried out with less risk of infection. In these cases an interval of five or six days separates the vaginal from the intra-uterine irradiation.

The authors disapprove of the destruction of exuberant cervical granulations by the curette or by electrocoagulation, as these methods favor infection. Doses usually employed, which have proved most favorable, vary between 5,000 and 7,000 milligram-hours, larger doses often being harmful as they interfere with cicatrization.

The authors condemn short irradiations of a few hours, such as is the custom in America, nor do they approve of irradiations prolonged from twenty to twenty-five days, which, on account of frequent manipulations, might be followed by infection. They consider an average duration of from four to six days, when the irradiation can be accomplished in one stage.

An attempt is made to establish the effect of treatment according to the histologic form of cancer of the cervix, as some forms are more radiosensitive than others, and after a lengthy discussion they finally conclude that treatment is successful in proportion to the degree of invasion, regardless of the histologic type.

In conclusion, the statistics here presented demonstrate that the number of uterine cancers in the first degree which were treated by radiotherapy in this series is small. However, the authors are receiving more patients referred to them by internists and surgeons. It seems that radiotherapy is gradually superseding surgery in the treatment of cancer of the uterine cervix.

HENRY BAYON, M.D.

CHEST (DIAGNOSIS)

Three Interesting Lung Cases F. Forman. Jour Med Assn South Africa, Aug 22, 1931, V, 515-519

I. *Syphilis of the Lung*—A female, 37 years of age, was admitted to the hospital, complaining of cough with expectoration. For nine months prior to admission she had noticed cough, weight loss, night sweats, capricious appetite, and nausea and vomiting.

Physical examination showed evidence of moderate weight loss. The left side of the chest was flattened, showed restriction of movement, was dull to percussion, with increased tactile fremitus and bronchial breath sounds. There was also tachycardia and rather high temperature.

X-ray examination revealed diffuse nodular infiltration of the entire left lung, with glandular enlargement in each hilus, the appearance being con-

sidered suggestive of tuberculosis. Sputum examination was, however, repeatedly negative, while the blood Wassermann was positive. While there was no clinical evidence of syphilis, under anti-syphilitic treatment the patient made rapid improvement. X-ray study about one month after admission showed almost complete resolution of the process in the left lung, hence it was no longer felt that the lesion was tuberculosis.

While the writer recognizes the fact that the therapeutic test is not conclusive, he nevertheless considers the accumulated evidence distinctly in favor of the diagnosis of pulmonary syphilis in this case, and believes the occurrence of this form of syphilitic disease to be more frequent than is generally considered.

II. *Pulmonary Actinomycosis*—An European male, 22 years of age, was admitted to the hospital, with a swelling of the right fifth rib. He was known to have been running a temperature for the past six weeks and had a slight cough with scanty greenish-yellow sputum.

About five years prior to admission he had been ill with pain in the right chest, and cough. During this illness he had on several occasions coughed up large quantities of malodorous pus, these copious expectorations being followed shortly by almost complete recovery, except for slight cough and scanty sputum.

Examination revealed a pulse of 90, temperature of 100°, and dullness over the right base and in the mid-axillary line. There was a small swelling over the lower half of the right fifth rib in front, the swelling being firm and elastic, not red, but adherent to the underlying rib. This was incised, typically actinomycotic pus with golden granules being evacuated, and the ray fungus was demonstrated.

X-ray study on admission showed a small patch of nodular infiltration at the right base but no evidence of rib abnormality. During his stay in the hospital he developed first a left-sided pleural effusion and later a right-sided effusion, each of which cleared rather promptly. Fluid withdrawn from the right pleural cavity was clear and sterile. Sputum studies were persistently negative for tubercle bacilli, ray fungus, or any demonstrable organism. Final X-ray study some months after first admission to the hospital showed an essentially negative chest. The therapy in the meantime had been large doses of iodides and vaccine therapy. It was assumed that the chronic lung condition was actinomycotic, with apparent recovery.

III. *Amebic Abscess of the Lung*—A male, 31 years of age, was admitted to the hospital with a temperature of 102.6°, pulse of 108, and respirations of 32, his complaints being cough, with copious expectoration of pinkish, foul-smelling sputum, and diarrhea, with mucus in the stools. For a number of months prior to admission these symptoms had been present in variable degrees.

Examination showed flattening and limitation of motion of the right lower chest, dullness to percussion from the inferior angle of the scapula downward, with tubular breathing, numerous moist sounds, and diminished vocal fremitus. The liver edge was felt three inches below the costal margin and was quite tender to palpation. Sigmoidoscopic examination revealed numerous typical amebic ulcers. The diagnosis was amebiasis, amebic dysentery, amebic hepatitis, with abscess extending to involve the base of the right lung with pleural effusion.

X-ray examination revealed a moderate quantity of fluid. After this was withdrawn a lung abscess, not connected with the diaphragm, could be demonstrated.

Under antiamebic treatment (emetine yatren, and stovarsol), he made rapid and complete recovery.

J. E. HARBE, M.D.

A Report of Two Cases of Localized Pleural Effusion in Heart Failure. J. Murray Steele. Am Heart Jour., December, 1931, VII, 212-222.

The author cites the rare cases of localized pleural effusions attributable to heart failure, and adds two cases of his own, one with an effusion localized in the upper half of the right thorax, and the other with an effusion encapsulated in the right interlobar fissure.

Both patients had clinical signs of heart failure, and chest plates showed the localized effusions and enlarged hearts. After recession of the cardiac symptoms, chest studies showed the disappearance of the fluid and reduction in cardiac size. Recurrence of the heart failures showed in each instance a reaccumulation of the fluid and dilated hearts. One patient recovered from his second attack and showed once more the disappearance of the fluid and reduction in heart size, the other patient died, and autopsy revealed the dilated heart and localized pleural effusion. The fluid proved to be a transudate, confirming its origin in the heart failure.

Further, autopsy revealed on the right side a thickened pleura that had obliterated the entire pleural cavity except in the region of the effusion. This finding and a similar instance in the literature lead the author to conclude that localized pleural effusions in heart failure depend upon a pre-existing adhesive pleurisy.

NATHAN FLAX, M.D.

Roentgenologic Observation of Recurrent Perifocal Inflammatory Processes in Chronic Bronchiectasis. Gerhard Strocka. Röntgenpraxis, Sept 15, 1931, III, 839-843.

The clinical differentiation between retention of secretion in bronchiectasis and perifocal (pneumonic) lesions is very difficult. The bronchopneumonic areas are usually too small for clinical detection, a roentgenologic examination being helpful. Sometimes the complication of bronchopneumonic foci around the bronchiectasis might be the first sign of the disease. Certain cases of that nature are reported. To the author it appears questionable whether the temperature and acute sickness, supposedly caused by retention in bronchiectatic cavities, may not be due to a perifocal infection.

H. W. HEFKE, M.D.

Bronchial Neoplasms. Roentgenologic Aspects. W. F. Manges. Arch. Otolaryngol., December, 1930, XII, 732-738. (Reprinted from "Cancer Review" by permission.)

The author deals with diagnosis, emphasizing especially the importance of bronchography and of biopsy. As to treatment, he advises large doses of X-rays over several fields. He mentions two cases which are alive six and one-half and seven years after the diagnosis was made (but does not state whether or not this was histologically verified).

F. CAVERS, D.Sc.

The Borderline between Normal and Pathologic in the Chest Roentgenogram. Felix Fleischner. Röntgenpraxis, Oct 15, 1931, III, 913-926.

The many different appearances of normal and pathologic chest roentgenograms are described. Particular attention is called to borderline cases, in which it is difficult to say whether the findings should be considered pathologic or a variation of the normal. Emphasis is laid on the importance of good chest films, which should be made with as low a voltage as possible and in as short a time as possible. Many points are given which help to interpret the roentgenologic signs.

This very interesting article cannot be reviewed here in detail, but must be commended for study in the original.

H. W. HEFKE, M.D.

Encysted Empyema, with Special Plate. N. D. Patel. British Med. Jour., Dec 5, 1931, No. 3700, p. 1032.

Encysted empyemas are not very rare conditions. They are difficult to diagnose without the help of X-ray, lipiodol, exploratory needle, or artificial pneumothorax. The collection of pus, often pneumococcal, but sometimes tuberculous, may occur in one of the interlobar fissures, between the diaphragm

and the under surface of the base of the lung, between the lung and the pericardium, or in the general pleural cavity, in the pockets formed by the adhesions of the parietal and visceral layers of the pleura

A case is reported at length of a collection of pus in a rare position, namely, between the lung and the right margin of the heart

X-ray examination of the chest showed that the heart was normal in size and in position. The lungs also showed no lesions but a triangular shadow opposite the right second and third costal cartilages just above the right border of the heart. It was homogeneous, and had clearly defined margins. A diagnosis of an encysted empyema was made

WALLACE D MACKENZIE, M.D.

Destructive Processes in the Sternum. Adalbert Low-Berl Röntgenpraxis, Sept. 15, 1931, III, 817-830

The roentgenologic demonstration of the sternum is somewhat difficult, as it must be projected away from the shadow of the spine and the mediastinum. Neoplastic processes, as well as inflammatory processes, may lead to areas of destruction in the sternum. Six cases are described. One of metastases from a thyroid carcinoma, one of metastases from a breast carcinoma, another shows a diffuse invasion by tumor tissue, which probably was a sarcoma, a fourth case shows roentgenologically areas of destruction without proliferation (autopsy proved the presence of a sarcoma secondary from a retrobulbar tumor), the fifth was a case of syphilis, and the sixth, one of chronic osteomyelitis. The localization of the changes was in the manubrium in the fifth and sixth cases

H W HEFKE, M.D.

X-ray Diagnosis of Diseases of the Chest. Proc. Royal Soc Med., Sect. of Radiology, Nov 20, 1931. British Med Jour., Nov 28, 1931, No 3699, pp 990-992

In discussing pulmonary tuberculosis it was concluded that definite infiltration could be demonstrated on the X-ray film as soon as there was any clinical evidence, and that the film usually showed far more evidence of disease than was obtainable by means of physical examination

Passing on to consider lung abscess, the non entrance of lipiodol was stressed as the greatest confirmatory evidence available, as lipiodol rarely enters a lung abscess

As to benign neoplasms, it must be remembered that they were benign only in the pathologic sense. All are extra-pulmonary, the commonest being fibromas, which grow almost invariably from the

posterior thoracic wall, and very often from the head of a rib. Teratomas are anterior in position, more irritant, irregular in shape, and cause adhesions to lung tissue from which they are not easily separated. The diagnosis is made from the perfectly straightforward evidence of a film in the lateral plane, in which the growth is seen to have its origin from the mediastinum in the anterior part

The commonest malignant condition of the lungs, namely, primary bronchial carcinoma, is apparently increasing. This increase is probably due to improved methods of diagnosis in the last twenty years. Carcinoma is classified in the simplest possible way, namely, the two forms in which the disease is most often seen—the lobar, or pneumonic, and the hilar form. The former is due to a combination of growth and collapse, in the hilar form there is growth without collapse, and this might be readily converted into the lobar or pneumonic form.

The thoracic contents are always diminished by primary lung cancer. On closer study of a radiograph of lobar carcinoma it is observed that the opacity is most dense near the root, and diminished in intensity towards the periphery. There is no doubt but that carcinoma of the lung is the commonest cause of bronchial stenosis and of phrenic paralysis. The nerve is at first compressed, and later infiltrated, by the glands

A less well-known disturbance associated with carcinoma of the lung is compression or invasion of the vagus. The resulting effect is disturbance of the cardiac rhythm, not to be distinguished antemortem from malignant invasion of the heart muscle. Much more often abdominal symptoms result from vagal irritation in the thorax, the commonest being complete or partial gastrospasm, while in rarer cases there may be spasm of the lower end of the esophagus. Very rarely a lung cancer compresses the esophagus directly and gives rise to vomiting.

The visualization of large bronchial or mediastinal glands is a most valuable diagnostic point, and one of considerable significance, as it contra-indicates surgical intervention. The chief conditions simulating lobar carcinoma are tuberculous pneumonia, syphilis, and aneurysm, but it should not be forgotten that a combination of aneurysm and growth is possible.

It is doubted whether or not to-day abdominal operation for malignant growth is justifiable before an X-ray film of the chest is taken, as it is useless to operate on a malignant mass in the stomach when there is a carcinomatous growth in the chest.

WALLACE D MACKENZIE, M.D.

CHEST (THERAPY)

Contribution to the Roentgenotherapy of Actinomycosis of the Lungs. Max Lüdin Strahlentherapie, Oct 24, 1931, XLII, 466-470

Reports in the literature regarding unsatisfactory results with roentgenotherapy in actinomycosis of the lungs usually state that in spite of high doses the patient did not improve. The author describes a case of this type, with involvement of the left lower lung and fistula. Potassium iodide was not very effective. Roentgenotherapy was given through four fields over the diseased part of the lungs, each field receiving 200 r (160 KV, 8 mm. Al, 25 cm FSD, 10 X 10 sq cm field). Following this first series of X-ray therapy the patient improved considerably. The fistula closed, pain temporarily disappeared, and the general condition was much improved. Following a three months' sojourn in Switzerland, the patient received a second series and at the same time potassium iodide was given internally. He has gained 8 kilograms since the first treatment. The roentgenogram shows only thickening of the pleura. This case is undoubtedly clinically cured. Although one case does not definitely prove the efficacy of roentgenotherapy in actinomycosis of the lung, it is suggested that the same dosage be tried in similar cases.

ERNST A. PÖHLE, M.D., Ph.D.

CONTRAST MEDIA

Some Sialograms L. N. Pyrah and P. R. Allison
British Med Jour., Dec. 5, 1931, No 3700, pp 1028-1030

The lipiodol injection is made with a metal syringe and a modified lachrymal duct needle made of silver, having a blunt, slightly bulbous end. It is malleable, and the curve can be adjusted to suit any given case. The needle is fitted to the body of the syringe by a screw attachment. The syringe, needle, and lipiodol are warmed, so that there is then no difficulty in driving the lipiodol through the rather fine-bore needle.

Parotid Gland—The needle of the loaded syringe is brought up to the orifice of the duct and is steadied by the surgeon resting it upon his left thumb. It is slid into the duct for about an inch. The introduction of the needle causes a slight cutting pain, but not sufficiently intense to cause undue discomfort.

The injection is continued gently until the patient experiences a sensation of discomfort in the region of the parotid gland, this indicates that the finer ducts are filled with lipiodol. From about 0.5 to 1 c.c. is used. The needle is quickly but gently withdrawn, and the patient is immediately placed in the recumbent position on the X-ray table.

Submaxillary Gland—The needle is introduced as before, but the procedure usually presents more difficulty than in the case of the parotid duct.

The X-ray technic is as follows:

(1) *Parotid Gland*—The patient lies on his side,

and the radiographer places the head (as accurately as possible) in the lateral position, so that the two rami of the lower jaw are superimposed. The head is hyperextended so as to open up the space between the jaw and the vertebral column. The mouth is opened and is retained in this position by a cork, which is placed between the incisor teeth. With the patient in this position, the greater part of the shadow of the gland is in front of the shadow of the cervical vertebrae.

(2) *Submaxillary Gland*—A lateral radiogram is taken here. The patient's mouth is fully opened and the tongue is pressed upwards to the roof of the mouth. There is usually no shadow of bone overlying that of the gland, but in some cases the hyoid shadow may be superimposed.

The uses of sialography are listed as follows:

(1) In some cases of chronic parotitis with subacute exacerbation, sialography reveals that one essential feature in the pathology of the disease is a dilatation of the ducts and of the alveoli.

(2) A sialogram is of value in helping to decide whether a tumor in the neighborhood of a salivary gland is derived from the gland tissue or from adjoining structures. In the former case the gland may be largely destroyed and there may be a considerable filling defect on the sialogram, while in the latter case, even though the gland may be somewhat displaced, it will show normal filling.

(3) Injection of lipiodol may be of assistance in the localization of calculi.

(4) The precise position and track of a salivary fistula, more especially of the parotid gland, can be traced very easily by means of a sialogram.

WALLACE D. MACKENZIE, M.D.

A New Method for the Injection of Lipiodol
Ernest Fletcher British Med Jour., Nov. 7, 1931,
No 3696, p 846

There are two possible methods of injection—the intralaryngeal (usually called the oral route), and injection through the crico-thyroid membrane direct into the larynx.

An attempt has here been made to simplify the technic of injection through the crico-thyroid membrane and to dispense with the necessity of a general anesthetic for child cases.

The apparatus is a 20 c.c. syringe with a barrel greater in diameter and thus shorter in length than the one generally in use. The usual thumb-piece has been replaced by a lever. The piston is attached to the working arm of this lever by a rod, and into the other arm is screwed the barrel of the syringe. The rod is attached to the piston by a universal joint. A spring is inserted between the two arms of the lever to keep them constantly apart and to bring the piston up the barrel. To the end of the

barrel is attached a bayonet joint. A filling tube is provided. A special trocar-pointed needle with lateral holes fits the syringe. On this needle a shoulder may be placed, if desired, to prevent its penetrating the larynx beyond a certain point.

The injection may be made through the crico-thyroid membrane or between two of the upper rings of the trachea, and has been found more rapid, painless, and efficient than other methods previously in use for injection through the crico-thyroid membrane.

The original article gives the name of the makers of a syringe of this type.

WALLACE D MACKENZIE, MD

CYST

Paradental and Traumatic Cysts of the Jaw
O Schneider Ztschr f Stomatol, January, 1931,
XXIX, 80-96 (Reprinted from "Cancer Review" by
permission)

The cysts dealt with here are to be distinguished from the better known radicular and follicular dental cysts. The author first describes two cases of paradental cysts (in a man, 44 years of age, and a woman, 50 years of age). These resemble ordinary dental cysts in general structure, the epithelial lining is produced by reactive proliferative growth, corresponding to what is sometimes seen in gingivitis. He then deals with three cases of traumatic bone cysts of the jaw, which are devoid of epithelial lining or may contain epithelium derived secondarily from the buccal mucosa.

The author says these cysts have nothing to do with localized osteitis fibrosa but form an independent lesion arising by medullary hemorrhage. They are, therefore, commoner in the lower jaw, which has a single central artery. There is a list of fifty-one references (all German), beginning with Virchow (1876). The roentgenograms are good.

F CAVERS, D Sc

Hydatid Disease in England James F Brailsford
Brit Jour Radiol, September, 1931, IV, 440-450

In man the average frequency of hydatid cyst locations are: Liver 70 per cent, lungs 10 per cent, kidney and spleen, each 2.5 per cent, other abdominal organs 5 per cent, muscles and cellular tissues 5 per cent, brain 5 per cent, and bone 1 per cent. In the lungs the cyst may rupture into a bronchus and cure take place, however, the same accident may produce serious hemorrhage, pulmonary edema, shock, and even death. Of human infections 25 per cent show multiple cyst involvement.

Recognition of hydatid infection may first take place through roentgenologic study. Most commonly, of course, the chest findings are most suggestive

The appearance of the cyst will depend upon its condition, hence if simple and unruptured, it will be represented by an ovoid shadow, uniform in density, and with sharply defined margins, with no changes from the normal in the surrounding lung tissue. The lesion may be either single or multiple. If, however, the cyst has ruptured into a bronchus, it may be entirely empty and simulate a "pleural ring." Occasionally the cyst wall undergoes calcification. Differentiation must be made from fibroma, primary or metastatic sarcoma, dermoid cyst, pyemic abscess, and aneurysm. Hydatid cyst formation in the abdominal organs or skull is much more difficult to demonstrate and recognize, although occasionally the abdominal cysts will show calcification of their walls and the intracranial cysts may produce erosion of the inner table or displacement of the pineal gland. Positive precipitation and intradermal tests contribute greatly to the diagnosis, while the finding of hydatid membrane, scolices, or hooklets in the sputum, vomitus, or excreta is the most conclusive evidence of the disease.

J E HABBE, MD

DIATHERMY

Electrical Treatment of Neuritis and Writer's Cramp W Black Jones British Med Jour, Sept 19, 1931, No 3689, p 531

The method adopted by Davies consisted, first, of testing for the affected spot, the negative pole of a faradic current is connected with a conical-shaped electrode covered with wash-leather, the positive being a large pad, which is connected to the arm or leg. Both electrodes are moistened with saline solution. The faradic current is so regulated that it will excite pain in the diseased spot, but will not cause pain in a healthy nerve. When the spot is touched with the electrode and pain is felt, the position is marked. The second stage is that of treatment, and for this purpose the galvanic current is employed. An insulated needle is connected with the negative pole, the large pad remaining positive. A local anesthetic is next injected under the dermis, the needle is inserted, and the current is turned on, the needle is directed to the point at which the pain is most acute. The current should not exceed 6 ma., the needle is withdrawn after ten minutes.

Here the technic is modified slightly. The current generally used does not exceed 1 ma., frequently it is 0.2 milliampere. It is found that five minutes is sufficient for the treatment, frequently after four minutes the patient states that the pain is diminishing. Two spots are often treated at one sitting.

The general results of the treatment show that in cases in which one or two spots occur on a par-

ticular nerve, the action of the current gives immediate and permanent relief. If the faradic current is again applied to the spot after an interval of a few days and no pain is felt, it is concluded that the spot is cured. Thus, when a spot has been treated, no second treatment is necessary. Occasionally when a spot is found there may be felt under the skin a small nodule, which disappears with the application of the galvanic current, the nodule may be a deposit of uric acid. On the other hand, when the number of spots is multiple and when they are close together, the results are not so satisfactory and the relief is often only partial, or it may be some time before a moderate amount of success is obtained, this is assisted by the internal administration of iodine.

Illustrative cases are reported.

WALLACE D MACKENZIE, M.D.

DOSAGE

Our Experience with the Protracted Fractional Dose Method W Dieterich and I Umbach Strahlentherapie, Oct 24, 1931, XLII, 510-513

The authors tried the method of Coutard in a number of advanced tumor cases. Their technic was as follows: 219 K.V., 4 ma, 3 mm Zn, half value layer in Cu 21 mm, 40 cm FSD, 10 X 15 cm field, HED = 550 r. Each area received 185 r in one sitting, and thus dose was repeated every other day until 3,000 r had been applied. The treatment extended over a period of four weeks. Practical experience seemed to show that less filtration, for instance, 0.5 mm Zn + 1 Al leads to similar results.

It is assumed, therefore, that not the heavy filtration, but the distribution of the total dose over a long period represents the most important factor of the method. In certain patients the results were remarkable, while others did not respond at all. In view of the high cost of the treatment and also the danger of late reactions, this treatment method should be employed with great caution and only in selected cases.

ERNST A. POHLE, M.D., Ph.D.

THE ESOPHAGUS (DIAGNOSIS)

Esophageal Varicosities or Carcinoma? Klaus Pohlndt. Röntgenpraxis, Oct 1, 1931, III, 889-895

The roentgenologic differential diagnosis between a carcinoma and varicosities of the esophagus is sometimes very difficult. Multiple small filling defects may be present in both, the only differentiation of importance being the slight narrowing and fixation of a cancer as compared with varicosities. An

esophagoscopy does not always settle the question, as is shown in a case described. Absence of normal elasticity and involvement of only a small portion of the esophagus are points tending to indicate a malignant growth.

H. W. HEFFE, M.D.

Symposium on Esophagus Diverticula Frank H Lahey Laryngoscope, January, 1932, XLII, 71-75

A. C. Crump began his discussion with interesting statistics on the incidence of the common types of pathologic conditions found in the esophagus.

"On a combined admission of about 500,000 cases in 10 years in the Presbyterian and Bellevue Hospitals, there were only 665 cases of disease of this organ, a little over 0.2 per cent. Of these, over 50 per cent were carcinoma, cardiospasm, 4 per cent, stricture, 7 per cent, and diverticula, 3 per cent."

In examination of the esophagus, he believes that a fluoroscopic study should precede any instrumentation. He does not state, however, if he thinks the ordinary liquid barium mixture is satisfactory or if gelatin-barium bougies should be used in conjunction.

Crump closed his discussion with the presentation of a case of cardiospasm in a herniated stomach and doubted if "X-ray control" of the dilating instrument was helpful, even in normal stomachs, since the cardia is very variable and can be moved as much as four inches.

HILLYER RUDISILL, JR., M.D.

Preventricular Dilatation of the Esophagus (Luschka), and the Process of Emptying the Esophagus L. Huismans München med Wchnschr, Aug 28, 1931, LXXVIII, 1488, 1489

Luschka, in his publication, in 1857, distinguished between the antrum cardiacum below the diaphragm, and a dilatation above the diaphragm. Leichtenstern reported a case and the author of the present paper adds another, in which a noticeable dilatation of the distal end of the esophagus was found. The author also discusses the physiology and the function of the esophagus.

E. A. M. M.D.

Röntgenologic Diagnosis of Lesions in Esophagus A. P. Overgaard Nebraska St Med Jour, September, 1931, XVI, 350-352

The roentgen ray with barium meal is the most important procedure in diagnosing diverticula of the esophagus. They are usually located on the lateral or posterior wall of the tube. They are rare at the

lower end of the esophagus, and when found there are usually on the anterior wall and may be mistaken for partial herniation of the stomach. In addition to diverticula, deviations and deformities due to neoplasms are usually capable of early diagnosis. Late diagnosis and ineffective treatment of cancer of the esophagus are a reproach to the medical profession. Herniation of the stomach through the diaphragm often passes undiscovered and when this occurs through the esophageal orifice, roentgen-ray study is of the utmost importance. Examination in the horizontal position is necessary to detect this lesion, but it is usually necessary to examine in the erect, supine, and oblique positions.

W W WATKINS, M D

Partial Pharyngeal Paresis as a Roentgenologic Symptom in Diseases of the Esophagus G v Pannewitz Fortschr a d Geb d Röntgenstr, August, 1931, XLIV, 170-177

On fluoroscopic examination of the diseased esophagus, the author found residues of contrast medium in the valvulae epiglotticae and the sinus piriformis in 38.5 per cent of the cases. This observation was made chiefly in cases of esophageal carcinoma. A paralysis of pharyngeal muscular elements must be considered responsible for the phenomenon. In its presence a particularly careful search of the entire esophagus and chest is indicated, as it was never found without the presence of important pathology. Its absence, of course, does not rule out the existence of esophageal disease.

(*Abstractor's Note*—The closer the lesion is located to the pharynx the more regularly the disease appears to occur.)

HANS A JARRE, M D

Peptic Ulcer of the Esophagus J Richards Aurchus Am Jour Roentgenol and Rad Ther, November, 1931, XXVI, 696-703

Peptic ulcer of the esophagus is a definite disease entity, despite the paucity of case reports in the literature. Until recently the lesion was found and reported only at postmortem examinations, but with recent improvements in esophagoscopy examinations clinical diagnoses are being proved, although there is still very little in the literature concerning the roentgenologic diagnosis.

The cardinal symptoms are pain, usually near the lower end of the sternum, dysphagia, nausea and vomiting, and occasionally hemorrhage. These are most apt to be confused, therefore, with high-lying gastric ulcers. The lesion usually involves the lower third of the esophagus and is observed oftenest in middle age, the two sexes showing about equal frequency of involvement. The most significant roent-

genologic finding is the niche, with secondary signs of regional spasm and lagging of the barium mixture also being often seen.

The case herein reported was of a white male, aged 40, who had had symptoms of a burning pain in the epigastrium for a period of three years prior to examination. The diagnosis was suggested by repeated roentgen study which revealed the stomach, duodenum, and gall bladder to be normal, but showed a suggestive niche shadow near the cardia. Esophagoscopic examination confirmed the diagnosis, and repeated topical applications of 5 per cent silver nitrate through the esophagoscope for a period of two months were followed by apparent cure. Peptic ulcer of the esophagus requires differentiation from other types of ulcer, such differentiation being most largely dependent on the history of the case.

J E HABBE, M D

EXPERIMENTAL STUDIES

Radiobiologic Studies on Fertilized Sea-urchin Eggs H and M Langendorff Strahlentherapie, Nov 14, 1931, XLII, 793-799

The authors studied the radiosensitivity of sea-urchin eggs at different stages of mitosis. At intervals of five minutes following impregnation 200 r were applied. There was a maximum at five minutes, a minimum at thirty-five minutes, and a second maximum at fifty-five minutes. Fractional doses of 2 X 100 r were given at five and thirty-five minutes, thirty-five and fifty-five minutes, and nothing and fifty-five minutes after impregnation. The results confirmed the author's expectations, the mitotic stage influences also the effect of fractional exposure. The ovum is the least susceptible to irradiation during the metaphase, but very susceptible before and after that stage.

ERNST A POHLE, M D, Ph D

Experimental Study in the Biological Effect of Roentgen Rays I Effect of Roentgen Rays on the Blood Constituents of Splanchnicotomized or Vagotomized Dogs II The Mechanism of the Decreased Blood Sugar Caused by Roentgen Rays Shoji Kikuchi Tōhoku Jour Exp Med, 1931, XVII, 545-578

Irradiation of dogs causes an increased blood sugar (from 25 to 50 per cent) reaching a maximum in from three to seven hours. The size of the dose and the site are comparatively unimportant. The serum pH does not change. The serum protein is variably affected, but, like the total N, usually shows an initial increase. If the liver area is irradiated,

there is a very large increase in total N. The blood non-protein N usually shows either no increase or a slight increase, but if the liver area is irradiated, there is a very significant rise. Serum Cl decreases, the extent varying with the amount of irradiation. An initial decrease in the inorganic P is followed by a marked increase. The acetone bodies increase only if the liver area is irradiated, and then in proportion to the size of the dose. A slight increase in lactic acid is followed by a decrease. All these values return to normal within twenty-four hours. Following splanchnicotomy, irradiation causes a decreased blood sugar, and does not affect lactic acid or the total acetone bodies. Vagotomy does not appreciably change the effects of irradiation. The significance of these findings is discussed.

Lymph taken from the thoracic duct of irradiated dogs and injected into rabbits does not affect the blood sugar. If the dog's splanchnics had been sectioned before irradiation, his lymph caused a marked fall in blood sugar. Presumably, irradiation stimulates the parasympathetics in such animals, releasing pancreatic hormone into the lymph and thence into the blood, explaining the fall in blood sugar observed after the irradiation of splanchnicotomized animals.

CHEMICAL ABSTRACTS

Mice as Indicators of the Presence of Carcinogenic Nova in Factories O Teutschlaender Deutsche med Wchenschr, Dec 19, 1930, LVI, 2166, 2167 (Reprinted from "Cancer Review" by permission.)

A wild grey mouse which was caught in a briquette factory was found to have spontaneous tar cancer, probably produced by pitch dust. This leads the author to suggest that since mice are more susceptible than men to various carcinogenic substances, they might be usefully employed as test subjects in various workshops, also in the so-called cancer houses, for carcinogenic nova (tar, aniline dyes, X-rays, etc.)

F CAVERS, D Sc.

Influence of Radiation Energy on the Mineral Elements of the Blood St. Malczynski, A Borysiewicz, and T Toczycki Compt. rend. Soc. de biol., Oct 12 1931, CVIII, 165-167

The experiments were made on healthy dogs submitted to ultra-violet radiation from a quartz lamp, to the administration of ergosterin, irradiated by a quartz lamp, and to X-rays.

The results were that under the influence of ultra-violet radiation there was an increase of almost all the mineral elements, especially calcium and phosphorus, and to a lesser degree potassium and sodium.

The alterations resulting from X-rays were much less characteristic, especially regarding those of phosphorus, potassium, and sodium. The authors have observed a general tendency towards a lowering of these elements, for calcium, this lowering was more distinct and quite characteristic.

The effects of irradiated ergosterin were more or less similar to those of the quartz lamp, the differences consisting in greater intensity and longer duration from the quartz lamp. The effects produced by irradiated ergosterin rapidly subsided, the initial values very soon returning on the discontinuance of its administration.

The authors believe their experiments prove that ultra-violet radiation and irradiated ergosterin are stimulants, whereas X-rays have a rather slowing effect on the mineral metabolism of the healthy animal.

HENRY BAYON, M D

Experimental Investigations Concerning the Roentgenologic Demonstrability of Pulmonary Connective Tissue. Oskar Meller and B Menkes. Fortschr a. d Geb d Röntgenstr, August, 1931, XLIV, 197-204

This is a very instructive and important paper based on the application of modern conceptions of colloidal chemistry upon our teachings of inflammation. The lungs of young children were removed from the corpses and permitted to hydrate in 5 per cent acetic acid solution. They were roentgenographed and equally inflated under identical technical conditions. There was a marked increase in pulmonary markings during the stage of hydration. It is evident that we will have to pay more attention to the mesodermic pulmonary structures in roentgenologic interpretation.

Further studies on the effects of hydration and dehydration of colloids under the influence of H and HO ions are very important for our conceptions of inflammation and its effects.

Literature may be found under the names of Bechtold, Schade, Menschel, and Roessle. Very interesting and instructive illustrations accompany this article.

HANS A JARRE, M D

Comparative Study of the Action of X-rays on the Adult Thymus and on the Embryonic Thymus. A-P Dustin and Ch Grégoire Compt. rend. Soc. de biol., Sept 18, 1931 CVII, 1565-1567

During experiments undertaken with an altogether different purpose, in which pregnant guinea pigs were irradiated the authors' attention was attracted by reactions of the embryonic thymus, suggesting

the investigation, not as yet undertaken, of modifications of the thymus to X-rays in the different phases of its histogenesis

In pregnant females, the thymus presents a state of involution which increases with the age of the animal and as the pregnancy advances. The involuted thymus is sclerosed, poor in thymocytes, containing none but old thymocytes because the process of regeneration is retarded, consequently such organs are but slightly affected by radiation. Pyknosis being sluggish, consecutive phagocytosis is inactive, the thymus reacts under such conditions very much in the manner of the medullary region (more radioresistant) of the normal thymus.

In the fetus, pyknotic degeneration is rapid and massive under the influence of radiation and appears only in the fetus in which the thymus has undergone pseudo-lymphoid transformation. Before this stage the thymic cells are no more sensitive than the surrounding tissues. When, on the contrary, the small thymic cell is developed, it at once acquires a decided hypersensitivity to radiation.

The effects of radiation on the appearance of Hassall's corpuscles is described, the guinea pig being particularly favorable to demonstrate the relations of these corpuscles to the fibro-vascular trabeculae, their paravascular origin is evident. After radiation they develop all along the vascular framework, even in the cortical substance, undergoing considerable hyperplasia, thus being a typical example of the interrelation between thymocytic involution and the evolution of Hassall's corpuscles.

HENRY BAYON, M.D.

THE EYE (DIAGNOSIS)

Report of Small Tumor of the Iris which caused Secondary Glaucoma, Microscopic Examination, Remarks on the Relation of Melanoma to Sarcoma of the Iris. A Knapp Trans Amer Ophthalmol Soc., 1930, XXVIII, 118-125 (Reprinted from "Cancer Review" by permission.)

This tumor, a sarcoma, occurred in a man, 30 years of age, who had for about nine years complained of a brown spot on the right iris between three and five o'clock and had noticed dimming of vision for a few weeks before examination. The anterior chamber was deep, pupil 8 mm in diameter and immobile, and the intra-ocular pressure was 42 mm Hg. Trehphining was done, but a year later the brown mass had become larger, malignancy was diagnosed, and the eye removed.

F CAVERS, D.Sc.

Large Osteoma of the Orbit. J N Roy Ann d'Ocul, October, 1930, CLXVII, 825-832 (Reprinted from "Cancer Review" by permission.)

The tumor was a typical simple osteoma with the usual clinical and X-ray features, but the report is of interest because despite the large size of the mass, which involved the floor of the frontal sinus and was associated with marked exophthalmos, fixation of the eye, and diplopia, its removal was effected without interference with the eyeball and with restoration of normal vision. The patient had prudently slept with the eye bandaged, hence there was no corneal ulceration such as frequently results in such cases from inability to close the lids.

F CAVERS, D.Sc.

THE EYE (THERAPY)

Primary Sarcoma of the Iris Removed by Iridectomy, No Recurrence in Three and a Half Years. W Zentmayer Trans Am Ophthalmol Soc., 1930, XXVIII, 109-115 (Reprinted from "Cancer Review" by permission.)

The patient, a boy 10 years of age, had a tumor, first noticed four months previously—which was a swelling 5 X 3 mm on the pupillary margin of the iris and translucent on a slit-lamp examination. On removal the tumor proved to be a spindle-celled sarcoma with no definite intercellular substance and with blood-vessels lined only by endothelium. Post-operative X-ray treatment was given five times, in all 175 per cent of an erythema dose.

F CAVERS, D.Sc.

X-ray Treatment of Retinal Glioma. E Janson Klin Monatsbl f Augenh, October, 1930, LXXXV, 542-546 (Reprinted from "Cancer Review" by permission.)

In a one-year-old girl the left eye was enucleated on account of retino-blastoma, histologically verified. Six months later a tumor was observed in the macular region of the right eye. Intensive X-ray treatment (6 series, total dosage about 900 per cent HED) was followed by arrest of the tumor growth, but later this continued, followed by perforation of the eyeball and finally death.

F CAVERS, D.Sc.

GALL BLADDER (NORMAL AND PATHOLOGIC)

Primary Carcinomas of the Gall Bladder. A R Salmon Jour Med fran^c, August, 1930, XIX, 280-286 (Reprinted from "Cancer Review" by permission.)

These tumors, which occur most frequently in women between 50 and 70 years of age, are practical-

there is a very large increase in total N. The blood non-protein N usually shows either no increase or a slight increase, but if the liver area is irradiated, there is a very significant rise. Serum Cl decreases, the extent varying with the amount of irradiation. An initial decrease in the inorganic P is followed by a marked increase. Comparative Study of the Action of X-rays on the Adult Thymus and on the Embryonic Thymus A-P Dustin and Ch Gregoire Compt rend Soc de biol, Sept. 18, 1931, CVII, 1565-1567

During experiments undertaken with an altogether different purpose, in which pregnant guinea pigs were irradiated, the authors' attention was attracted by reactions of the embryonic thymus, suggesting

a filling defect in the midportion of a normal functioning gall bladder. The shape and absence of change of position suggested the roentgenologic diagnosis, which was confirmed at operation and by pathologic examination. The differential diagnosis between stones and newgrowths is touched upon.

THE AUTHOR.

Some Clinical and Experimental Studies on Cholecystography with "Colefanina" Gioacchino Nicolosi Riv di radiol e fisica med, December, 1931, IV, 231-238

The author reports his experience with oral cholecystography using "colefanina" (tetraiodophthalophenone). Good shadows of the gall bladder were obtained by this drug, which has been found to be perfectly harmless and easy to administer. The results in ten cases are reported.

E. T. LEDDY, M.D.

GASTRO-INTESTINAL TRACT (DIAGNOSIS)

The Skeleton Barium Meal in Gastric Diagnosis T D Overend. British Med Jour, Nov 21, 1931, No 3698, p 938.

It has long been customary to commence the radiologic examination of the stomach by watching the first mouthful of barium swallowed and looking for a fleck of barium held up in an ulcer niche, if this were present. If this first mouthful is spread over the interior of the stomach by palpation, a good view of the relief pattern of the mucosa is often obtained. But this procedure has its limitations. The ordinary barium meal is not perfectly adapted for the demonstration of the mucosa, and, in spite of the fact that much work has been done on the subject, it may be said that the study of the alimentary mucous membrane has not yet received the attention it deserves. Some of this neglect is due to the incompleteness of our knowledge of the great variations which may occur in the appearances of the normal relief pattern. Nevertheless, the study of the gastric mucosa is by now a valuable supplement to the usual radiologic investigation, and the method of the "thin film" or skeleton meal reveals details that cannot be otherwise discovered.

Technic—The essential preliminary is the preparation of a solution adapted for adhering to the mucosa. A useful solution is the following: 10 ounces of barium sulphate, 50 grains of tragacanth powder, made up to 20 ounces with chloroform.

water. The patient is first examined in the supine position with a slight tilt to the left, a sip of the barium is swallowed, and the cardia screened. By palpation and changes of posture the barium is spread over the mucosa and the patient examined in the prone position with graduated compression. Further sips of the barium are given until the mucosa is perfectly covered with the preparation. It is unwise to allow the procedure to become stereotyped, each case has its peculiarities which should be studied individually. The principal sites of ulcer should be screened at every possible angle and examined at different stages of filling. Films are taken when necessary. Graduated compression is required to get good relief patterns, and excessive fluid or mucus in the stomach is prevented by giving 1/100 grain atropin sulphate one hour before the examination.

Normal Appearances—A constant feature is the presence of four well-marked longitudinal ridges, visible on oblique illumination, running down the lesser curvature, these enclose the stomach path of Aschoff, which is the chief ulcer-bearing area. Towards the greater curvature the longitudinal folds become more and more tortuous, and transverse folds appear. Under normal conditions the relief pattern is delicate and easy to deform or obliterate by palpation, pathologic changes cause it to stiffen, and it then becomes permanent and cannot be altered by pressure.

Chronic Gastritis—In hypertrophic gastritis the folds of the relief pattern are thickened and stiff, in atrophic gastritis they are very delicate and may be partly absent. Great irregularity and stiffness of the folds favor the diagnosis of gastritis, and a still more trustworthy sign is the presence in the relief pattern of rounded or oval translucent islands due to patches of atrophy.

Although the diagnosis of gastritis by the skeleton meal is by no means easy or free from the possibility of error, there is little doubt but that when its normal appearances are better known it will be found more reliable than any method depending on indirect signs.

Peptic Ulcer—In the skeleton meal, as in the full meal, the direct evidence is given by the actual niche. The skeleton meal is especially well-adapted for the diagnosis of jejunal and gastro-jejunal ulcer, and also for the differentiation between ulcer and diverticulum.

Carcinoma—The skeleton meal here finds its application in determining to what extent the growth has penetrated into the stomach walls beyond the actual filling defect, and it may give valuable information as to the mechanical, as apart from the metastatic, possibilities of resection. It is also of value in the diagnosis between chronic callous ulcer and the malignant ulcer.

WALLACE D. MACKENZIE, M.D.

ly always associated with calculi (11 out of the 12 cases here reported) The author distinguishes four clinical forms, which may, however, occur in combination (1) Tumor palpable, emaciation, asthenia, dyspepsia, fever, pain, death usually from suppurative cholangitis or rupture of gall bladder and peritonitis, (2) icteric form, having, as the first and most prominent symptom, jaundice due to infection or obstruction, difficult to differentiate from carcinoma of the head of the pancreas, laparotomy frequently necessary for correct diagnosis, (3) dyspeptic form, in which gastric symptoms are prominent, while those pointing to gall-bladder disease are slight or even absent, hence early diagnosis is usually impossible (4) pseudolithiasis, here the lesion simulates gall-stone disease with biliary colic, and the rapid course is the chief feature in diagnosis of cancer In some cases X-ray examination is useful for diagnosis The prognosis is so bad that treatment is limited to relief of symptoms, indeed the chief treatment is prophylactic, i.e., removal of the gall bladder in all cases of gallstones

F CAVERS, D Sc

A New Roentgenologic Symptom of Gallstones
Béla Breuer Röntgenpraxis, Oct 1, 1931, III, 879-881

If the gall bladder does not fill with the cholecystographic contrast medium and if one sees star-shaped shadows, gallstones can be diagnosed with certainty The star-shaped shadows correspond with cavities in the stones, a fact which is known to pathologists A case is described in which the flat film showed this type of shadow, which could be seen also when the stones were roentgenographed after operation

H W HEFKE, M D

The Filling of the Gall Bladder by Contrast Material from the Stomach A M Rybak Röntgenpraxis, Sept 15, 1931, III, 844-848

The filling of the gall bladder by barium (and consequently also by food) which comes from the stomach or duodenum, does not lead to any disturbances or ascending infection of the bile ducts The roentgenologic examination of patients after a cholecystostomy or cholecystoduodenostomy is of importance for the determination of advantages and disadvantages of the several different surgical procedures At the time, one may determine the changes in the stomach and duodenum which have taken place after the anastomosis If there is a suspicion of a spontaneous fistula between the stomach or duodenum and the gall bladder (clinically severe colics which suddenly stop), the possibility of filling the gall bladder with barium must be thought of

the examination being repeated occasionally in one or two hours Although such an anastomosis has been described frequently by surgeons, the roentgenologic reports of this occurrence are not frequent,

H W HEFKE, M D

The Value of Fast Exposure Following Fluoroscopy in Cholecystography Ernst Eliasz Röntgenpraxis, Oct 1, 1931, III, 874-878

The technic of cholecystography is of very great importance for a reliable diagnosis Fluoroscopic examination of a contrast-filled gall bladder followed by an "instantaneous, aimed exposure," has been neglected It is this technic which has led to progress in the gastro-intestinal roentgenologic diagnosis An abnormal projection of the gall bladder, or its obliteration by gas in the intestines, is often very bothersome, especially if the patient lies on his abdomen for the exposure If the patient's gall bladder is observed in a standing position by use of the fluoroscope, one is almost always able to get the best possible projection Several cases have been seen, in which a gall-bladder examination of the usual type did not show stones, but the quick, aimed exposure after fluoroscopy demonstrated small stones The small cone used for this technic serves at the same time for compression.

H W HEFKE, M D

Cholecystographic Studies Olshausen Röntgenpraxis, Oct 1, 1931, III, 865-870

The author intends to show that, after determining fluoroscopically the position of the gall bladder, a very short exposure with relatively high voltage, no Bucky diaphragm, a small cone (with pressure), and standing position of the patient may give more information about the gall bladder than the usual technic in a prone position He suggests to look for the gall bladder filled by the contrast material, and if it can be seen, he advises the above technic If it cannot be seen, he employs the old technic In case of an overlying gas-filled bowel, the standing position often leads to a successful demonstration of the gall bladder

H W HEFKE, M D

The Diagnosis of Papillomas of the Gall Bladder by Means of Cholecystography Hans W Hefke Röntgenpraxis, Oct 1, 1931, III, 871-873

Only four cases of papilloma of the gall bladder, diagnosed roentgenologically and found at operation have been reported in the literature (all by Kirklin) Another case is reported, which showed

but did not change its form, except by pouring out its contents with postural changes, according to the more anterior or posterior involvement of the duodenal bulb. These large niches show no peristaltic action and cannot be evacuated by external pressure. Their contours may be entirely smooth. The mucosal structure cannot be differentiated and a relief of mucosal folds concentric to the crater is not to be observed, due to the distention of the residual not involving the mucosal surface. The proximal duodenal knee is shortened and at times so contracted that it may simulate a stenosis.

Instructive illustrations are given, especially those showing a perforated ulcer, burrowing into adjacent tissue and covered over with omentum and gall bladder.

HANS A JARRE, M.D.

Constipation G J Joubert *Jour Med Assn S Africa*, Oct 10, 1931, V, 623-628

The author discusses the problem of constipation from the standpoint of the general practitioner, giving first some of the factors in constipation with especial application to physical and mental types of persons. He states that "Constipation is one of the ailments which follows us through life, beginning in infancy."

The causes of constipation in babies are numerous: (1) Improper feeding of the mother and constipation of the mother, (2) Lack of fat in the milk, (3) Excessive evaporation of the skin, (4) Lack of regular habits, (5) Lack of muscle tone, and (6) Lack of carbohydrates.

Rectification is suggested by the additional feeding of cream or fresh butter. Castor oil or drastic purgatives are not recommended, but enemas are helpful. Fruit juice daily is beneficial, also.

Intestinal stasis in children is common and is often due to wrong diet and habits. A survey of the symptoms is made, and the diet is analyzed in detail. Regular habits are urged.

The surgical aspects of some forms of constipation are emphasized, such as relieving strictures, adhesions, piles, fistulae, etc.

The complete physical examination with the various tests and special studies are necessary in making the proper diagnosis.

In conclusion the author outlines the aims in the treatment of constipation as follows: (1) Regular bowel movement, with a formed stool, (2) Regular habits of life and food with regular and complete evacuation of the bowels, and (3) Use of a drug or drugs to promote the passage of a formed stool, and which can be used without variation.

MURRAY M COPFLAND M.D.

Lymphosarcoma of Cecum F Belcher Riforma Med, Sept 22, 1930, XLVI, 1514-1519 (Reprinted from "Cancer Review" by permission)

In a man, 22 years of age, who complained only of slight abdominal pain (unrelated to meals), a large fairly mobile mass was felt in the right appendix region. Although no localization was obtained by X-ray study after introduction of barium, operation revealed a large tumor of the cecum. This was resected and found to be a lymphosarcoma, two weeks later death occurred, with symptoms pointing to lung metastases. There was no necropsy.

F CAVERS, D.Sc.

The Form, Size, and Position of the Cecum Nicola Lovisatti *Fortschr a d Geb d Rontgenstr*, August, 1931, XLIV, 181-188

Observations were made on 2,000 cecal cases. A new classification is given as follows:

- 1 Funnel-shaped (or fetal)
- 2 Bag-shaped with bulging appendico-cecal junction in the center of the cecal pouch
- 3 Bag-shaped with cylindrical appendico-cecal junction in the center of the cecal pouch
- 4 Bag-shaped with bulging appendico-cecal junction located postero-medially and proximally within the cecal pouch
- 5 Bag-shaped with cylindrical appendico-cecal junction located postero-medially and proximally within the cecal pouch

Complete obliteration exists in from 3 to 6 per cent of all adults. Partial obliteration exists in 25 per cent of all adults (according to Ribbert).

The fourth type is found most frequently, from 55 to 60 per cent of all cases. Size and form vary physiologically in wide ranges. Rudimentary ceca, with a capacity of less than 40 c.c., occur occasionally just as macro-ceca containing up to 400 and more centimeters. A mesenterium commune occurs in from 30 to 35 per cent of the cases (according to Frommon and Treres).

The author observed 47 cases in which the cecum was found tilted dorsally and upward, with consequent abnormal insertion of the ileum. An unusually large percentage of these cases showed intestinal distress and pathology.

(*Abstractor's Note*—Comparison of these observations with the publications of Kantor in this country is suggested.)

HANS A JARRE, M.D.

Visceral Tetany Alkan Arch d mal de l'app digestif, July, 1931, XXI, 813-820

In 1922, an epileptic female, 39 years of age, pre-

Prolapse of a Gastric Polyp into the Duodenum, with Marked Secondary Anemia J W Hinton and I Buckstein Am Jour Surg, November, 1930, X, 355-357 (Reprinted from "Cancer Review" by permission)

An admirably brief and well-illustrated report (including two good photomicrographs) of a case in which a man entered the hospital for relief of anal fistula. He was very anemic and complained of no gastric symptoms. The authors very sagaciously made an X-ray examination after barium filling, and though this showed no gastric lesion it suggested a duodenal tumor. At operation this was confirmed, a stalked gastric polyp of small orange size being found prolapsed into the duodenum.

F CAVERS, D Sc.

The Roentgenologic Diagnosis of Gastro-enterostomy and Its Complications Chr Glockler-Wachramejewa Vestnic Rentgenologii i Radiologii, 1931, IX, Nos 2 and 3, p 143

The purpose of this work was to determine roentgenologically the form, position, and function of the stomach after gastro-enterostomy and the presence of any post-operative complications. Fifty-eight patients were examined, most of whom complained of some gastric disturbance. Examinations revealed that the form, position, and motility of the stomach vary a great deal. Seldom was the contour of the stomach found to be regular in outline. Adhesions and spasms were frequent complications. In a number of the cases gastric or jejunal ulcers were demonstrated.

The author believes that the position of the gastro-enterostomy is a determining factor in the development of complications. In cases in which the gastro-enterostomy was low, complications were less frequent. The roentgenologic investigation of the stomach is important in order to find out the position and form of the stomach before operation, thus enabling one to determine the most convenient place for the gastro-enterostomy. In case of no improvement the roentgenologic method is the best means of determining the character of the changes which have developed.

SAMUEL BROWN, M D

The Clinical Significance of the Roentgenologic Findings of the Stomach and Duodenum Sidney A Portis Illinois Med Jour, LXI, January, 1932, 19-23

When there is a definite discrepancy between the clinical and roentgenologic findings, both of them must be repeated and checked very carefully and the group of findings which have the most weight must be taken as the diagnosis. It is to be remem-

bered that the roentgen ray reveals facts subject to clinical interpretation and that the final diagnosis must depend upon a correlation of the roentgen and clinical findings.

High lying lesser curvature lesions are often difficult to diagnose accurately by the X-ray. These occur most often in elderly patients and are usually malignant. Since surgery offers but little relief in such cases, it is best to treat them with deep X-ray therapy, along with proper medical management.

Lesions of the greater curvature are practically always malignant and should be treated as such from the time of their recognition.

Lesions of the antrum are more open to question since this portion of the stomach is so often the site of reflex spasm. Cholecystitis, duodenal ulcer, appendicitis, and other extragastric lesions produce spasm simulating organic gastric lesions.

The clinical significance of duodenal stasis (easily recognized with the fluoroscope) is not sufficiently appreciated. Many lesions, anomalies, and anatomical conditions may produce it.

CHARLES H DEWITT, M D

Lymphatic Pseudoleukemia of Stomach, with X-ray Film of Hypertrophic Gastric Polyposis V Svab Med Klin, Dec. 24, 1930, 1922-1924 (Reprinted from "Cancer Review" by permission.)

A man, 45 years of age, had symptoms suggestive of cholecystitis, while the X-ray film resembled that of hypertrophic polyposis of nearly the whole of the stomach. At operation the stomach wall was found to be greatly thickened, while long continuous folds of hypertrophied mucosa up to 2 cm. high, ran from cardia to pylorus. The hypertrophied tissue was also enlarged neighboring glands, presented the picture of aleukemic lymphadenosis, and the blood count showed absence of leukemia.

F CAVERS, D Sc.

The Roentgenologic Appearance of the Large Duodenal Ulcer I G Brdicka. Fortschr i d Geb Röntgenstr, August, 1931, XLIV, 177-181

Duodenal ulcers, exceeding pea- or bean-size, are well known to the pathologist but rather unknown to the roentgenologist, as the literature does not contain any radiologic reference to them. The size of such ulcers is usually given as varying between pea per seed and bean dimensions.

The author reports three cases, confirmed by inspection, of very large duodenal ulcers, exceeding the size of a twenty-five cent piece. They showed on roentgenologic study a symptomatology quite different from those usually attributed to duodenal ulcer and described as follows. The crater, somewhat resembling a normal duodenal bulb, filled suddenly

"bowel." Normally, the residue of a meal should be evacuated within 48 hours, a delay of 72 hours may be considered pathological. The physiology of intestinal movements and the act of defecation are discussed. About 350 gm of semifluid chyme are said to pass the ileocecal valve daily, and about 135 gm of feces are passed daily.

The etiology of constipation is discussed and the causes, according to Kast, are listed as follows:

(1) Mechanical obstacles, due to (a) external pressure from abdominal or pelvic tumors, (b) invaginations, volvulus, kinks from adhesions, (c) stenosis of intestines from ulcers, etc., (2) Dyschesia (fissure, hemorrhoids, etc., inhibiting reflex), (3) Inhibiting influences such as spinal disease, abdominal inflammations, endocrine dysfunctions, psychic depressions, (4) Functional derangements, such as toxic disturbances, tone of intestinal musculature, abnormal lack of stimulation, (5) Essential constipation.

The author considers dyschesia as the most common type. Essential constipation is considered to be due partly to defect in mechanism of peristalsis and to endocrine defects.

Under "Clinical Investigations," the author states that sufficient information is often obtained from an ordinary history and clinical examination. Examination of the anus and rectal examination prevent many errors. Other adjuncts to the physical examination are proctoscopic examination, chemical and microscopic examination. An X-ray of the gastro-intestinal tract often gives a clue to the origin of the constipation.

The symptoms and effects of constipation are discussed under the head of headaches, vertigo, insomnia, and fatigue. Digestive disturbances are not infrequent, including flatulence, abdominal discomfort, and offensive breath. Gastritis and duodenal catarrh may supervene. Palpitation, dyspnea and low blood pressure are sometimes noted.

The author discusses the treatment of constipation at length, the essentials of which are (1) Correct diagnosis, (2) strengthening and educating the bowel, (3) removing the cause where indicated and possible (appendix, etc.), (4) regard for diet, and (5) combinations of dietetic, local, and drug treatment.

The diet of the tonic case should contain large quantities of cellulose, increasing the bulk of stools. The spastic constipation case should have food which leaves as little residue as possible.

Enemas are suggested as relief and are discussed in detail. Among the drugs which are mentioned agar agar and mineral oil are considered as important. The vegetable drugs are recorded with dosage and effects on bowel. Salines by mouth are emphasized in certain types of cases. "Mercurial purgatives should be reserved for special occasions," the author states. They do not have action on the

flow of bile. Opium is often used in combination, with cases of colitis.

Some foods have laxative effects (brown sugar, honey, sour milk).

Hormones are discussed. Thyroid extract is considered helpful in cases of sub-thyroid individuals.

The surgical aspects of constipation are not dealt with.

MURRAY M. COPELAND, M.D.

The Diagnosis and the Cure in Gastroduodenal Ulcers, Clinically, Radiologically and by the Gastroscope François Moutier. Arch. d. mal. de l'app. digestif, July, 1931, XXI, 821-832.

There are few questions so delicate to approach as the interpretation of the cure of gastroduodenal ulcers, in spite of the numerous publications of new methods of treatment and rapid cures following each method.

Clinically, the disappearance of pain, hematemesis, melena, and vomiting signifies nothing. It means simply the disappearance of the paroxysm. Anatomically, these ulcers, it is true, may heal rapidly, even in a few weeks, with cicatrization. Many relapse after weeks, months, or years. The intermediate silence does not signify cicatrization. They have, therefore, an evolution, intermittent and spontaneous. Absolute negative clinical or radiologic findings may be observed between attacks, although in general, untreated cases seldom present longer absence of symptoms than one year, while treated cases have been known to have time intervals of over two years. Some cases may have ulcers arising in other areas, following the original involvement.

Radiologically, the disappearance of the niche does not mean a cure. The image seen often represents an ulcer plus something else. Many flat ulcers present such a niche and the actual measurement of the ulcer may vary considerably from that of the X-ray image. Another factor to be explained is the disappearance of this niche sometimes in two or three days or longer. Agreeing with Schindler, Gutzeit, Haudek, Forssell, Berg, and Albrecht that inflammatory and dynamic conditions are present, there are still other factors in evidence. Besides the edema of the borders of the ulcer and inflammatory interstitial reaction, there is a swelling of the adjacent folds, forming around it a pouch and even excluding the ulcer from the gastric cavity in the form of diverticula. Dynamically varying spasms or contractions are present, or are seen by the gistroscope. Such may be like a diaphragm, a purse, or a buccal contraction, forming a separate cavity at the bottom of which lies the ulcer. A film so viewed gives the image of a semicircle which in reality is a trough-like depression. Relief of the surrounding inflammation and spasm is followed by

sented, besides several daily attacks of epilepsy, cramps in the upper abdomen, accompanied by vomiting, which occurred as often as six times daily. In addition, there were symptoms of tetany, particularly Troussseau's phenomenon. Radiology revealed spasm of the antrum only. Within twenty-four hours all spasm had disappeared after injections of paraglandol, an extract of the parathyroid gland.

Carlson and Jacobson produced tetany in nineteen out of twenty-three dogs, after parathyroidectomy, as well as hyperemia and small hemorrhages of the gastro-intestinal mucosa, particularly in the pylorus and the duodenum. Ulcers of variable size were also found in these areas.

Clinical confirmation is found in the report of Falta and Cahn, who, in 1912, reported that ten out of twenty-one cases of idiopathic tetany presented gastro-intestinal spasms and hypersecretion, while three had definite ulcers.

One case is described of a white woman, presenting such symptoms after accidental parathyroidectomy, accompanied by X-ray plates showing spasm of the antrum and pylorus and an ulcer of the antrum.

In 1929, the author published a report of 220 cases showing hypermobility or spasm of the digestive tract, with hypersecretion and with or without ulcers. Of this number, forty-six, or 23 per cent, showed Chvostec's or Troussseau's signs.

The author concludes that these ulcer cases, presenting symptoms and evidence of hypoparathyroid function, are caused by this deficiency. Erosion of the mucosa occurs frequently and is a transient affair, but when this occurs in a mucosa where the mobility is greatly increased and at times exaggerated to such an extent that spasms occur, there takes place a repeated and prolonged anemia around the erosion. Autodigestion by the gastric juice may follow and in this manner a chronic ulcer is formed and persists.

In 148 cases of tetany, he found 66, or 45 per cent, with ulcers. Twenty showed only hypermobility of the antrum. All these cases presented a spasticity of the descending colon, which he believes occurs in all such ulcer cases, due to tetany.

Following the subcutaneous administration of paraglandol and intravenous injections of calcium chloride or bromide, the author had success in three-fourths of these cases, while no results were obtained in ulcers due to other causes. In 65 cases, 54 per cent are well after one year and 31 per cent are well after more than two years. At times parathormone (Collip) was used in very refractive cases. A regime of bland, non-irritating food, without meat, is followed in severe cases. The therapy is favored by the periodicity of the function of the parathyroid gland with its normal summit in spring and autumn. Even in cases apparently well, several injections of calcium are given at the beginning of the perilous seasons.

B. J. DELAUREAL, M.D.

GASTRO-INTESTINAL TRACT (THERAPY)

New Research on the Treatment of Gastro-duodenal Ulcers by Parathyroid Extract. François Moutier and Louis Camus. Arch. d. mal. de l'app. digestif, July, 1931, XXI, 834-848.

Since the original publication, in 1929, Hernando Rocha, of Madrid, and Gallart y Mones, of Barcelona, have reported discouraging results, while Max und Ernst Levy have obtained purely negative results from this type of therapy. Statistically, this has no advantages over other forms of treatment. However, the authors still feel that it has its indications. Forty-five cases so treated are analyzed. Eight cases, or 17 per cent, gave absolutely negative results. Of these, three were intolerant of the drug. Twenty cases were improved both as to clinical and radiologic manifestations. Seventeen cases had relapses.

The extract can be given hypodermically or by mouth, the latter method being preferred. Ten units of parathormone Lilly represents 1 c.c. of parathyroidine Byla. Small doses are preferable and in cases in which there is evidence of intolerance, such as vomiting or exacerbation of pains, the drug should be given at an interval of from 2 to 3 days. Hypercalcemia is a contra-indication. This form of therapy can be combined with others, as bismuth, atropine, pepsin, and insulin. No benefit was observed when calcium was added to the treatment. Vagotonia types tolerate the drug better. Often the relief of pain is immediate, at other times following two or three injections. Nocturnal pain disappears first. Occasionally a rapid fall in acidity occurs. The most favorable cases are those without stenosis, periduodenitis, or perigastritis. The blood-calcium content is but slightly affected. Those cases with an acid-base equilibrium tending towards the acid side seem to react most favorably. It is also most effective in the younger individuals.

Observations on four cases show the variations of response to different treatments. Each case responded to one of the following treatments after failure of all the other types mentioned: parathyroid, pepsin, atropine, and insulin.

After five years' study the conclusion is drawn that parathyroid extract has a definite, but irregular and mysterious, action which needs further study.

B. J. DELAUREAL, M.D.

Constipation. S. F. Silberbauer. Jour. Med. Assn. S. Africa, Oct. 10, 1931, V, 619-623.

The author defines constipation as "a disturbance of intestinal function, usually of the colon, which results in delayed or incomplete evacuation of the

Over-exposures lead to false diagnoses. On the other hand, a perfect film without evidence of the shadow of a stone is not proof of the non-existence of a stone, as 30 per cent of stones do not cast shadows. Phleboliths often mislead one as to the diagnosis of stones in the ureter, a point which can be easily decided by taking another film in another plane. The use of contrast fluids, by either the descending or ascending method, offers also many pitfalls in the diagnosis. The filling defect in uroselectan films is not as valuable for the diagnosis of tumor as that of contrast filling on a pyelogram. Uroselectan is useless for diagnosis of stones, and still more problematical is it in the functional diagnosis. Only an expert can interpret these films. The same holds true in the diagnosis of pathologic conditions of the ureters in pyelograms. Diagnoses of enlargement of the pelvis of the kidney, and stenosis or kinks of the ureter are made far too frequently.

E. A. MAY, M.D.

The Diagnosis of Ureteral Calculi and the Problem of Their Conservative Management. Albert M. Crance. *Am Jour Surg*, January, 1932, XV, 120-129

A series of seventy-seven cases of ureteral calculi is reported, in which three, or 3.89 per cent, required ureterolithotomy, two are still unpassed, and seventy-two, or 92.5 per cent were passed successfully without open operation. In this series, it is interesting to note that fifty-seven, or 74 per cent, showed rather definite roentgenographic shadows of the calculi prior to the filling of the ureter with an opaque solution. The X-ray technic in ureteral stones must be most carefully considered. One must study his roentgenographic findings with great care. Many calculi are missed by too quickly passing a negative opinion on a film in which the stone shadow may be discovered later.

Diagnostic importance is made of the clinical history, the presence of red blood cells in the urine, and the cystoscopic and X-ray technic combined. Cystoscopy is planned, preferably while there is still renal tenderness present. The ureteral catheter or bougie is more apt to meet obstruction at this time, at the point where the stone is lodged. The finding of pelvic retention by syringe test is also of importance at such a time.

If a catheter is passed after the relief of colic, it may occasionally go beyond a stone without the slightest sense of obstruction. However, the technic of passing a catheter should be carried out slowly and cautiously. Rapidity in reaching the renal pelvis loses all the fineness of touch and sensation. If one catheter has passed up successfully, then, and not until then, is an exposure made on a 14 X 17 inch film, using, of course, a Potter-Bucky diaphragm.

The operator may then attempt to pass another No 5 catheter. In a few instances, a second catheter has met obstruction at the stone, but in most cases two have been admitted successfully. The X-ray film should then be studied by the operator. If a shadow is demonstrable, one of the two catheters is plugged and a urogram made; however, this is not always necessary. The degree of hydronephrosis can often be ascertained by withdrawing the residual pelvic urine by means of a syringe. If no shadow is found and there is no reason to suspect a stone, the catheter is removed and replaced with a larger Garceau or Woodruff catheter for the purpose of urography. Filling defects, bulging in the ureteral wall, plus the previous findings of red cells, may be regarded as indicative of ureteral calculi.

A diagnosis having been made, two No 5's are again passed up beyond the stone. No doubt there are some who will say, "Supposing the stone cannot be passed, will the ureter allow a catheter?" Then a heavy No 8 or 9 olive-tipped bougie usually will pass. If one then attempts to introduce a catheter immediately after the removal of a bougie, it will almost always pass. It may be necessary to draw it back and forth a few times, which, incidentally, has been of great value.

The patient is then returned to his room in a recumbent position, and the catheters left in place for twenty-four, forty-eight, or even seventy-two hours. As the catheters are about to be withdrawn, one is plugged (if two are in) and a 30 c.c. Luer syringe is filled with sterile water and connected to the catheter. The kidney is filled slightly beyond the point when the patient feels the renal pressure. The catheter is very slowly withdrawn with one hand, while the syringe is held for injection in the other hand. Two forces are at work with this procedure—the traction caused by the downward motion of the catheter, plus the force from above, which in many instances accomplishes the desired purpose. Frequently, by this procedure, patients have passed calculi within forty-eight hours after the removal of the ureteral catheters, and in most instances without any additional, or so-called "final colic." This method of removing the ureteral catheters during irrigation has resulted rather successfully in a rather high percentage of cases.

The use of ureteral spirals, forceps, rubber-bags, etc., has in no way added to the successful management of this series.

No mortalities occurred in this series.

Several interesting plates of ureteral calculi accompany the article.

DAVIS H. PARDOLL, M.D.

Urethrography with Abrodil as Contrast Fluid
B. H. U. Mohrmann and Heinz Strauss. *München med Wehrnschr*, Oct 2, 1931, LXXVIII 1700-1702

a disappearance of the niche, any new muscular excitation causing its reappearance. This, of course, holds true for only gastric cases. Occasionally the image of a cavity can be seen without, or in an area away from, an ulcer.

In old and callous ulcers, the X-ray cavity may represent its true size, and its disappearance may signify healing. Also, it is possible that the fibrous exudative covering may be brushed off and followed by a reappearance of the niche.

These facts have been established from endoscopic studies. Here ulcers were found which caused no X-ray shadows, others which were very flat but which caused a shadow, still others which were detached from the general gastric cavity by spasm. Gastroscopy and gastrophotography allow one to watch the progress of healing after the X-ray findings are negative, following the suppression of spasm.

A silence of at least two years and possibly three should elapse before one can consider an ulcer cured.

B J DELAUREAL, M.D.

GENITO-URINARY TRACT (DIAGNOSIS)

Recent Advances in Diagnostic Methods in Renal Affections R Ogier Ward British Med Jour, Aug 1, 1931, No 3682, pp 175-177

The first diagnosis of stone by X-rays was made in 1896. Then, in 1906, Voelcker and Von Lichtenberg established instrumental pyelography as a diagnostic method. Von Lichtenberg has now developed excretion urography to its present high efficiency by the use of the pyridine derivative, Uroselectan, first produced by Binz and Raeth. Many other chemical compounds have been tried, but the latest and most successful is D-40, better known as Uroselectan B. It is another pyridine derivative containing 51 per cent iodine as compared with the 42 per cent in its predecessor. It has been produced by the same chemists and tested in Von Lichtenberg's clinic. It is interesting to note that a large amount of iodine is not essential, as only 15 grams of Uroselectan B are used for each injection, compared with 40 grams of the original Uroselectan. The special success of Uroselectan B is due chiefly to the fact that the kidneys eliminate it very promptly (a quarter of an hour) in the urine in high concentration and with a diuresis which is just sufficient to cause it to flow through the urinary tract in an intensity suitable for X-ray work.

The technic of injection is as follows. Uroselectan B is sold as sterile solution in 20 c.c. ampules which contain 15 grams of iodine compound. The dose used for adults. The solution is warmed

to body temperature and injected intravenously with a 20 c.c. syringe. There is no need to inject the solution slowly.

Contra-indications and precautions. Uroselectan B produces no discomfort and is entirely non-toxic. Uremia, either present or impending, is the chief contra-indication and, therefore, a routine blood urea and kidney function test is necessary to exclude this. If any serious general illness co-exists, special caution should be exercised. Due to the inefficiency of the kidneys the liver undertakes in part, at least, the excretion of the drug, therefore, liver disease is a contra-indication. In acute inflammation of the urinary tract excretion urography must be avoided. Iodine idiosyncrasy rarely manifests itself.

One of the most interesting results brought about by this new method of investigation is the fresh light shed upon the neuromuscular mechanisms of the urinary tract. Therefore, it will help us much in the study of the pathology and treatment of hydronephrosis. This disease is the result of a defect in this mechanism, the law which governs the working of a system of unstriped muscle has broken down, contraction occurs in one segment but no relaxation in the segment below, probably owing to the disturbance of sympathetic control. A pyelogram demonstrates clearly a hydronephrosis. Excretion urography sometimes shows the same hydronephrosis but of considerably larger size. This is because in the latter case the kidney has filled the pelvis at a rate to which it is accustomed, whereas in instrumental pyelography the opaque fluid has been run in through the ureteric catheter much more rapidly, and the pelvis has resisted the process. This gives us a clear proof that, though damaged, the pelvic neuromuscular mechanism is not destroyed, and this is an encouragement to the surgeon who wishes to perform upon it a plastic operation.

There are certain conditions in which excretion urography is of special value for other reasons, namely, when it is undesirable or impossible to pass the cystoscope, as, for example, in the presence of a urethral stricture or an enlarged prostate, or severe cystitis. And, again, in circumstances preventing the passage of a ureteric catheter, such as ureteric kink, or a ureteric calculus.

WALLACE D MACKENZIE, M.D.

Mistakes and Pitfalls in the Examination and Treatment of Diseases of the Uropoietic System Eduard Pflaumer München. med. Wchnschr., Sept. 25, 1931, LXXVIII, 1654-1657

This article is written for the general practitioner as well as for the specialist. It illuminates the subject from every angle, not in the least from that of the X-ray specialist. The most important technical mistakes are those of incomplete photography of all uropoietic organs and of unsatisfactory plates.

Over-exposures lead to false diagnoses. On the other hand, a perfect film without evidence of the shadow of a stone is not proof of the non-existence of a stone, as 30 per cent of stones do not cast shadows. Phleboliths often mislead one as to the diagnosis of stones in the ureter, a point which can be easily decided by taking another film in another plane. The use of contrast fluids, by either the descending or ascending method, offers also many pitfalls in the diagnosis. The filling defect in uroselectan films is not as valuable for the diagnosis of tumor as that of contrast filling on a pyelogram. Uroselectan is useless for diagnosis of stones, and still more problematical is it in the functional diagnosis. Only an expert can interpret these films. The same holds true in the diagnosis of pathologic conditions of the ureters in pyelograms. Diagnoses of enlargement of the pelvis of the kidney, and stenosis or kinks of the ureter are made far too frequently.

E A MAY, M.D.

The Diagnosis of Ureteral Calculi and the Problem of Their Conservative Management Albert M. Crance Am Jour Surg., January, 1932, XV, 120-129

A series of seventy-seven cases of ureteral calculi is reported, in which three, or 3.89 per cent, required ureterolithotomy, two are still unpassed, and seventy-two, or 92.5 per cent were passed successfully without open operation. In this series, it is interesting to note that fifty-seven, or 74 per cent, showed rather definite roentgenographic shadows of the calculi prior to the filling of the ureter with an opaque solution. The X-ray technic in ureteral stones must be most carefully considered. One must study his roentgenographic findings with great care. Many calculi are missed by too quickly passing a negative opinion on a film in which the stone shadow may be discovered later.

Diagnostic importance is made of the clinical history, the presence of red blood cells in the urine, and the cystoscopic and X-ray technic combined. Cystoscopy is planned, preferably while there is still renal tenderness present. The ureteral catheter or bougie is more apt to meet obstruction at this time, at the point where the stone is lodged. The finding of pelvic retention by syringe test is also of importance at such a time.

If a catheter is passed after the relief of colic, it may occasionally go beyond a stone without the slightest sense of obstruction. However, the technic of passing a catheter should be carried out slowly and cautiously. Rapidity in reaching the renal pelvis loses all the fineness of touch and sensation. If one catheter has passed up successfully, then, and not until then, is an exposure made on a 14 X 17 inch film, using, of course, a Potter-Bucky diaphragm.

The operator may then attempt to pass another No 5 catheter. In a few instances, a second catheter has met obstruction at the stone, but in most cases two have been admitted successfully. The X-ray film should then be studied by the operator. If a shadow is demonstrable, one of the two catheters is plugged and a urogram made; however, this is not always necessary. The degree of hydronephrosis can often be ascertained by withdrawing the residual pelvic urine by means of a syringe. If no shadow is found and there is no reason to suspect a stone, the catheter is removed and replaced with a larger Garceau or Woodruff catheter for the purpose of urography. Filling defects, bulging in the ureteral wall, plus the previous findings of red cells, may be regarded as indicative of ureteral calculi.

A diagnosis having been made, two No 5's are again passed up beyond the stone. No doubt there are some who will say, "Supposing the stone cannot be passed, will the ureter allow a catheter?" Then a heavy No 8 or 9 olive-tipped bougie usually will pass. If one then attempts to introduce a catheter immediately after the removal of a bougie, it will almost always pass. It may be necessary to draw it back and forth a few times, which, incidentally, has been of great value.

The patient is then returned to his room in a recumbent position, and the catheters left in place for twenty-four, forty-eight, or even seventy-two hours. As the catheters are about to be withdrawn, one is plugged (if two are in) and a 30 cc Luer syringe is filled with sterile water and connected to the catheter. The kidney is filled slightly beyond the point when the patient feels the renal pressure. The catheter is very slowly withdrawn with one hand, while the syringe is held for injection in the other hand. Two forces are at work with this procedure—the traction caused by the downward motion of the catheter, plus the force from above, which in many instances accomplishes the desired purpose. Frequently, by this procedure, patients have passed calculi within forty-eight hours after the removal of the ureteral catheters, and in most instances without any additional, or so-called "final colic." This method of removing the ureteral catheters during irrigation has resulted rather successfully in a rather high percentage of cases.

The use of ureteral spirals, forceps, rubber-bags, etc., has in no way added to the successful management of this series.

No mortalities occurred in this series.

Several interesting plates of ureteral calculi accompany the article.

DAVIS H. PARDOLL, M.D.

Urethrography with Abrodil as Contrast Fluid
B. H. U. Mohrmann and Heinz Strauss Münchener Wochenschr., Oct 2, 1931, LXXVIII 1700-1702.

The injection of contrast fluids in the male urethra for X-ray diagnosis has been done since 1910. It can be used in cases of acute gonorrhea, and shows, by means of the X-ray, early as well as advanced strictures. It demonstrates the condition of the urethra beyond the stricture, also diverticular abscess cavities and injuries. It is ideal as a follow-up examination, the technic being simple. From 20 to 50 c.c. of abrodil are injected into the urethra. The patient lies on his back in a semi-oblique position, with the penis parallel to the leg.

E A MAY, MD

Excretion Pyelography (Urography) by Means of Subcutaneous Abrodil Infusion O Butzengerger Röntgenpraxis, Oct. 1, 1931, III, 881-884

Excretion pyelography has proved itself a very valuable diagnostic means, being often the only possible means for a roentgenologic diagnosis of kidney diseases. Intravenous injection of the contrast material has been the only means of getting a good pyelogram. It is, however, not always technically easy and even occasionally impossible (children, fat persons). The author has endeavored to present a subcutaneous method of introducing the abrodil (skiodan in the United States). In association with Hecht, the discoverer of abrodil, the method was worked out. A 4 per cent sterile abrodil solution, which is practically isotonic, is used and two ampules of impletol (a combination of caffeine and novocaine) are added. If 20 gm of abrodil are to be used, 500 c.c. of this solution are injected subcutaneously between the breast and axilla.

After using this method in thirty cases the author came to the following conclusions. The best roentgenograms are obtained from 30 to 50 minutes after completing the injection, but good roentgenograms are still given from 1 to 2 hours afterwards. Skin damage or necroses were not observed. No general reaction took place. In a few cases some slight pain was complained of during the injection. In all thirty cases the demonstration of the urinary tract was satisfactory. This method seems indicated especially in children.

HANS W HEFKE, MD

GENITO-URINARY TRACT (THERAPY)

Transplantation of Ureters to Rectosigmoid and Cystectomy for Exstrophy of Bladder Report of Seventy-six Cases Waltman Walters Am Jour Surg, January, 1932, XV, 15-22

The results obtained in transplantation of ureters to the rectosigmoid and removal of the exstrophied bladder in a group of seventy-six patients operated

on at the Mayo Clinic are reported. The method of transplantations was first used by C H Mayo in February, 1912, he applied Coffey's principle of submucous duct transplantation to the ureter. The operative procedures have been divided into three stages (1) Transplantation of the right ureter into the rectosigmoid, (2) two weeks later transplantation of the left ureter, and (3) ten days later removal of the exstrophied bladder. In none of these cases were ureteral catheters used in the transplantation. Three patients died in the hospital subsequent to operation. Twenty-seven patients have lived five years since the operation, and thirteen have lived ten years. Results were unsatisfactory in only three cases. In 50 per cent of the cases there was no evidence of renal infection. In 21 per cent there were short periods of mild renal infection, the interval between such periods in most cases being many months, sometimes years. The infection, too, was mild and apparently had little effect on the patient. The use of compounds such as uroselectan, or skiodan, intravenously, has made possible the study of renal function as well as of the outline of the renal pelvis and ureter in many of these cases. The use of this method and other methods of study of renal function leads to the belief that renal function is normal and that there is no dilatation of the pelvis, calices, or ureters in cases in which the uretero-sigmoidal transplantation is accurately carried out.

Several uretero pyelograms taken before and after operation for exstrophy of the bladder accompany the article.

DAVIS H PARDOLL, MD

Ureter Catheter Drainage in Ureterotomy W M Kearns and S M Turkeltaub Am Jour Surg, January, 1932, XV, 56-60

The author presents a case record which demonstrates the consequences of omitting catheter drainage. The indwelling catheter has a distinct place in ureteral surgery because it insures kidney drainage, eliminates fistula and urinary extravasation by diverting the stream, promotes prompt healing, and prevents stricture formation. It may also act as a prophylactic against suppression of urine.

In the case cited by the writers, attempts to pass a ureteral catheter at operation, following ureterolithotomy, were unsuccessful. The rubber drain was removed from the ureteral bed twenty-four hours following operation. This early removal was carried out with the hope that the urine would make its way through the lower ureter promptly instead of through the fistula, thus obviating ureteral obliteration. The urine continued to extravasate and the fistulous tract closed, with the development of symptoms of sepsis, urinary absorption, and anuria. Blood transfusion overcame the anuria in a phenomenal

way The symptoms of sepsis and urinary absorption were miraculously relieved by the passage of a ureteral catheter

Several roentgenograms illustrative of calculus in the ureter and extravasation of the pyelographic media accompany the article

DAVIS H PARDOLL, MD

Endothelioma of Penis Urethrography W Dobrzaniecki Jour d'Urol, April, 1930, XXIX, 368-377 (Reprinted from "Cancer Review" by permission)

In a man 59 years of age, complaining of burning pain on micturition, examination showed escape of somewhat purulent liquid on compressing the penile urethra, infiltration of glans, slight soft enlargement of inguinal glands, and a hard, enlarged prostate. Tumor was suspected and its site accurately determined by urethrography, using a contrast material 100 c.c. of barium suspension mixed with 10 c.c. of 2 per cent collargol solution. The penis was amputated in its upper third and the inguinal glands dissected out. The microscopic diagnosis was hemangio-endothelioma. There was no sign of recurrence when seen four months later

F CAVERS, D Sc

GYNECOLOGY AND OBSTETRICS

Anatomic Changes Subsequent to the Radiotherapeutic Treatment of Benign Uterine Conditions James A Corsaden Am Jour Obst and Gynecol, July, 1931, XXII, 74-86

The author analyzes 434 cases with reference to the effect of irradiation on the size of the myomatous uterus, the importance of X-ray and radium as excitants of latent infections, the frequency and importance of subsequent changes within the tumor, such as degeneration and sarcoma, the occurrence of carcinoma of the body and neck of the uterus and disease of the tubes and ovaries, especially those conditions which were overlooked at the time the treatment was given and later became apparent.

In the literature, considerable emphasis is placed upon the danger of exciting quiescent foci of infection by radium and X-ray. Many such cases are reported, but the precise lesion is less often described. The author, a gynecologist, and presumably impartial toward irradiation, concluded that the cause of inflammation following the introduction of radium was due to an operative contamination rather than to some less obvious effect of the electromagnetic waves upon either the tissues or bacteria in a residual inflammatory focus. In fact, several cases in which there was definite inflammation showed improvement following roentgeno-

therapy. Polak and Bal, who have had similar experiences, employ the X-ray as a therapeutic measure in the management of acute pelvic inflammatory disease.

In all patients treated for uterine myomas, the growth was stopped, reduction has occurred to a satisfactory degree in 83 per cent, and there has been complete reduction of the mass to the size of a normal uterus in 55.2 per cent.

The author, basing his statement on the government mortality statistics, states that 2.4 per cent of women in general develop carcinoma of the uterus. Only 1.28 per cent of his cases treated for fibromyomas subsequently developed carcinoma of the uterus, observations having been over a period of seven years.

The evidence permits the author to conclude that the incidence of diseases in the organs of reproduction of women after treatment by X-ray and radium is a little less than in women in general. The occurrence of uterine bleeding and discovery of a small myoma does not make one a candidate for promiscuous prophylactic excision. With the growth stopped and the uterus made smaller by X-ray or radium, she has the same chance for health as the women without these conditions.

The importance of a diagnostic curettage is emphasized. The author encountered unexpected pathology (carcinoma of the body of the uterus, epithelioma of the cervix, pedunculated intra-uterine myomas, polyp) in 3 per cent of his cases, which caused a change in the method of treatment.

JACOB H VASTINE, MD

Myoma of the Uterus E Vogt München med. Wochenschr, Sept 4, 1931, Vol 78, No 36, pp 1525-1529. Also issue of Sept 11, 1931, 1562-1565

The author deals with symptomatology and diagnosis minutely. He compiles the different types of treatment and gives the indications for each, which do not, in any way, deviate from the methods used in this country.

E A MAY, MD

Significant Problems for the Obstetrician in the Field of Mammary Cancer B J Lee Am Jour Obst and Gynec, December, 1930, XX, 775-781 (Reprinted from "Cancer Review" by permission)

Out of 306 cases of breast cancer in women under 40 years of age eleven were pregnant. The longest period of survival after operation was five years and ten months. In such cases the pregnancy should be terminated, the radical breast operation done directly afterwards, and the patient advised to undergo

ovarian sterilization by high-voltage X-rays, or if not consenting to this measure, to avoid further pregnancy. In fourteen of these 306 patients, the breast cancer co-existed with the puerperium, and the results of operation were not much better in this group. Out of 1,827 patients seen at the Memorial Hospital with breast cancer, eleven had a malignant tumor of the genital organs (cervical cancer, corporeal cancer, 4; vulva and ovary one each).

F. CAVERS, D.Sc.

Actinotherapy in Gynecology Jose Luis Molinari
Rev. Med. Cubana, November, 1931, XLII, 1338-1358

In this article the author not only discusses actinotherapy as it applies to gynecology but gives complete and comprehensive information on the entire subject of actinotherapy. At the beginning of the article he limits his discussion to ultra-violet ray therapy, leaving the discussion of infra-red rays for a future date.

After defining the terms which will be used, the author goes on to describe the place occupied by the ultra-violet rays in the spectrum. This is followed by the list of physical and chemical properties of these rays. After describing the Herz-Hallwachs' phenomenon, the intensity of the rays is taken up. He points out the various intensities which will produce different physiologic changes. Using different Angströms, diverse physiologic reactions are produced. In this connection the author makes mention of the results obtained by Nogier and d'Hasselbach and Macht and Bells.

The discussion continues with the physiologic and biophysiologic reaction produced by the ultra-violet rays. In this connection we may list some of the most important bactericidal action and metabolic action on calcium, phosphorus, sulphur, sodium chloride, and the general action on protoplasm. In the consideration of the action of ultra-violet rays on the human organism the author takes up the effect on the integument. Erythema, being the most important, is taken up first. The author presents Finsen's conclusions, which are as follows: (1) The thermic rays produce only a temporary erythema lasting about two hours; (2) ultra-violet rays produce an erythema which is late in appearing but lasts long; (3) the rays next to the ultra-violet rays also produce an erythema but it is less lasting.

In the author's opinion most physiotherapists prefer to use from 2,970 to 2,800 Angströms to produce an erythema. Using this amount, the erythema appears in from four to six hours, this naturally varying with the cutaneous sensibility of the various body regions. According to Hill, Elinart, Kisch, and Sobodka, erythema is produced more quickly and to a more intense degree when the integument has

been heated previously. The erythema varies with the individual, age, and certain diseases, such as asthma, adenopathies, hepatitis, and hyperthyroidism.

The duration of the erythema varies from forty-eight hours to a week. The redness changes to violet and later to maroon. This is a sign of the beginning of pigmentation, the mechanism of which is not exactly known at present. Turning to physiologic chemistry for information one has to consider the skin as a gland as well as a protective covering. Chemical analysis has shown that there are various diastases present in the skin. The following have been isolated: amylase, lipase, catalase, phosphatase, sulphatase, carboxylase, oxidase, a peptolytic ferment, and tyrosin ferment. Thus, it is reasonable to assume that through oxidation and reduction processes on the diastases, ultra-violet rays cause pigmentation. Keratotic changes of the skin take place when the pigmentation disappears, however, these changes occur simultaneously with pigmentation but independent from it. According to the studies of Lederle, Pautrier, Magnus, Müller, etc., the following take place: (1) The most superficial layers of the skin show intracellular and intercellular edema. (2) The blood vessels in the dermis are engorged and show a lymphocytic infiltration.

The author here gives a complete report of the ultra-violet rays on the following organs and tissues: the eye, blood, nervous system, spleen, suprarenals, thyroid, ovaries, and bones. He continues by giving a discussion of the various theories on the general action of ultra-violet rays. Of these the following workers and their theories are mentioned: Christen (1917-1919), S. Rothmann (1924, 1925), and Rohler. The two theories best recognized are those of Keller and Guillaume. Keller believes that the reactions produced by ultra-violet rays are due to a toxic effect caused by the reabsorption of by-products, which are the results of the irradiation. Guillaume takes up Keller's theory and adds more detail to it. Vignal, on the other hand, does not accept either theory because neither one is based on chemistry, physics, or biology. He thinks that the changes are produced by oxidation-reduction processes.

In discussing the artificial supply of ultra-violet rays, the author mentions the voltaic arc, the mercury lamp, and the specially named lamps, such as Walter's and Landeker's.

For the determination of ultra-violet doses many methods have been proposed, the most important of which are enumerated:

(1) *Photo-thermic*—This is based on the transformation of light into heat. The apparatus used is the "pireliometro" of Pouillet and the "pilatermo-electrica" of Melloni.

(2) *Photo-chemical*—This is based on the chemical actions of the ultra-violet rays. Keller's apparatus is used for this measurement.

(3) *Photo-electric*—If light falls on a film immersed in a conducting liquid, a current is produced.

which goes over to another film kept in darkness The apparatus of Mallet and Chquet is used

Since the skin sensibility varies with the individual, it is best to determine this sensibility, using either Keller's or Saidman's apparatus With the latter apparatus one can determine the various stages of erythema from its formation to its hemorrhagic stage.

In the discussion of gynecologic conditions the treatment is taken up in anatomic order from the outer to the inner structures

Affections of the Vulva—Schlein thinks that actinotherapy is of no value in the treatment of pruritus Using the technic of Aimard and Dausset, that is, local and general applications of ultra-violet rays, giving an erythema dose from time to time, good results are obtained A local erythema dose is given two or three times a week If necessary, small doses of X-ray are given The above named authors have obtained good results using the technic outlined In fact, they report improvement even in difficult cases, having given them twelve applications The use of the high frequency current has also given favorable results Other vulvar conditions treated successfully are eczema, fissures, vulvitis, and kraurosis (using the X-ray) Fissures due to bartholinitis heal very quickly under ultra-violet-ray treatment

Vaginal Affections—Wagner began the treatment of vaginitis in 1913 Later, Lang reported good results The latter gives his results in the treatment of both children and adults The therapy consists of both local and general irradiation He begins with exposures of five minutes each

Cervical Lesions—Non-cancerous lesions of the cervix respond remarkably well to ultra-violet irradiation Wagner, Van de Velde, and Mateucci have obtained satisfactory results with six exposures In cases of cervical discharge ultra-violet irradiation has proved of inestimable value Complete cures have been obtained in 51.3 per cent of the cases Using the Landeker lamp, applications may be given for as long as thirty minutes at a time Complete cures have been obtained with from three to eight applications Even the chronic cervical lesions have responded to this treatment The lesions due to inflammatory causes respond quicker than those due to other causes

Lesions of the Corpus Uteri—Wagner thinks that ultra-violet-ray treatment will control uterine hemorrhage due to fibroids In sclerosis of the corpus uteri, Francillon-Lobre and Palisse have obtained good results Landeker has obtained 60 per cent cures in chronic endometritis Casati, Viana, and Mateucci also report satisfactory results Local applications are given by means of the speculum of Ferguson or by a quartz lamp applicator in doses of from six to ten minutes' duration

Lesions of the adnexa and parametritis have also been treated with good results Pyosalpinx has been

treated by a combination of abdominal and general ultra-violet irradiation The parametritis cases have required long applications but even cases due to gonococcal infection have subsided Inflammatory masses, especially those due to gonococcal origin, have responded remarkably well to ultra-violet treatment Those reporting cases of this nature give 70 per cent cures Salpingitis also responds with the same favorable results

In the treatment of ovarian disorders ultra-violet rays have demonstrated the following That (1) menstruation is stimulated in the young, (2) the menstrual flow is regulated, and (3) the menopause is retarded.

Hypoplasia—Landeker has reported ten cases of delayed ovarian function due to congenital deformity which improved under ultra-violet irradiation In the treatment of ovarian disorders as amenorrhea, the condition shows quick improvement This is especially true of those cases due to ovarian insufficiency The ultra-violet rays have no direct action on the uterus but accelerate the ovarian tissue Aimard and Dausset give local and general irradiation using both sunlight and ultra-violet light After twenty exposures most cases show improvement. Dysmenorrhea and oligomenorrhea respond to ultra-violet treatment by improvement of the condition Scanty menstruation is improved and dysmenorrhea is practically corrected In cases of premature menopause, especially those due to X-ray exposures, satisfactory results are obtained The symptoms of menopause disappear, and the patient feels relieved The internal ovarian secretion is accelerated under ultra-violet irradiation These internal secretions stimulate the secondary sexual characteristics

Genital Hemorrhage—Ultra-violet irradiation is particularly indicated in the following (1) Juvenile hemorrhages, (2) pre-climacteric and climacteric hemorrhages, and (3) hemorrhages due to secondary anemias

Genital Tuberculosis Including the Adnæa and Peritoneum—In treating genital tuberculosis, one aims to give the patient a supportive treatment as well as to produce a local hyperemia The technic used is as follows (1) Gradual increase of doses of sunlight treatment, (2) local ultra-violet irradiation combined with sunlight exposures, (3) general increase of ultra-violet irradiations, (4) abdominal applications of ultra-violet rays from time to time, and (5) combination of ultra-violet and X-ray therapy

Most of the cases with ascites show improvement Those cases having perivisceritis or pericolitis show an acceleration of the symptoms On the whole the majority of cases of genital tuberculosis shows improvement

Ultra-violet rays in gynecology give the following (1) A local action, as in dermatology, on eczema, abscess, etc., (2) a general action, especially on

tuberculosis and anemia, and (3) a direct action on the ovary

JOSEPH MALDONADO, M.D.

Unusual Tumor of the Nipple. E. Fischel and L H Jorstad Am Jour Surg, January, 1931, XI, 121-124 (Reprinted from "Cancer Review" by permission)

The patient, a woman of 27 years, said she had had a wart on the nipple for seven years, which had not been influenced by electrodesiccation or X-ray treatment. The growth was reddish brown and measured 3 X 2 millimeters. The nipple and the surrounding normal areolar tissue were excised and examined microscopically, good photomicrographs being given. The chief features of the lesion are hyperplasia and keratosis of the epithelium, with inflammatory changes in the surrounding tissue. It seems to be an atypical early Paget lesion.

F. CAVERS, D.Sc.

Radio-active Modifications in Ovarian Insufficiency Iribarne Bruxelles-Med, Sept. 13, 1931, XII, 1336, 1337

After presenting new ideas concerning ovarian insufficiency and its different clinical types, together with results of his own experience, the author is convinced of the stimulating action of radio-active substances on cellular activity, especially when small doses are employed. Parallel experiments have been made on the germination of seeds and the growth of vegetables and animals.

In the organism, radium has a very complete action on account of its affinity for certain tissues.

Numerous clinical observations have convinced the author of the beneficial influence of radio-active therapy on ovarian insufficiency. Association of oopherectomy is recommended. This double treatment is particularly indicated in ovarian insufficiency of puberty. The nervous symptoms and menstrual pains are favorably influenced.

HENRY BAYON, M.D.

The X-ray Treatment of Uterine Hemorrhage and Uterine Fibroids L J Carter Canadian Med Assn Jour, November, 1931, XXV, 582-584

This paper is the tenth in the series of papers being contributed by members of the Canadian Radiological Society in the educational campaign. It is being conducted for the purpose of familiarizing the general profession with the accomplishments of physio-therapeutic methods in diagnosis and treatment.

In this article the hope is expressed that through the publication of this and other articles in the

Canadian Medical Association Journal, every family physician in Canada may become familiarized with the benefits which the radiotherapist can confer by X-ray treatment of aggravated and persistent hemorrhage of the menopause. One hundred consecutive cases of uterine hemorrhage and uterine fibroid were reported before the Radiological Society of North America as having received X-ray treatment. All were cured, with the exception of three which proved to be malignant, while in these three the X-ray treatment was a good preliminary measure to the subsequent use of radium and surgery. Similar uniformly good results are reported by all X-ray workers who have published their results.

Emphasis is laid on the fact that the treatment should be carried out only by a radiotherapist who is devoting all of his time to radiology. "For the physician who is only occasionally operating an X-ray machine to attempt the X-ray treatment of uterine hemorrhage is hazardous in the extreme. Over-dosage will precipitate a type of menopause that will be extremely stormy both for the patient and the family physician, while under-dosage will probably only aggravate the hemorrhagic condition." The referring physician should, however, be in a position to give the patient some information concerning the amount of time required to complete the treatment. This would usually consist of three series of treatments one month apart, each series occupying from three to six days, according to the condition of the patient and the particular type of treatment employed. Further, the referring physician should warn the patient that there may be an exacerbation of the hemorrhage following the first series of treatments. Failure to give this warning may make subsequent explanations difficult.

The writer regards as contra-indications to the X-ray treatment of uterine hemorrhage the following: Excessive size of a fibroid tumor, subserous pedunculated fibroid, a large incarcerated fibroid giving rise to urgent pressure symptoms, a submucous fibroid that bleeds subsequent to a course of treatments. Malignancy is a contra-indication for the use of the X-ray alone, to the exclusion of radium and surgery. Pelvic inflammatory conditions are not contra-indications but rather the reverse, providing a pus tube or some other pus pocket is not present, requiring evacuation by surgical methods. The striking results secured in the X-ray treatment of boils and carbuncles find an analogy in the magic disappearance of pelvic inflammations after a course of X-ray therapy.

The X-ray treatment of uterine hemorrhage in women during the child-bearing period should generally be avoided. There is experimental evidence which indicates that the germ cell may be so modified by irradiation as to establish hereditary abnormalities, not in the immediate offspring but in descendants one or more generations removed.

The *modus operandi* of the X-ray in the arrest-

ing of uterine hemorrhage and the reduction of uterine fibroids is generally regarded as being a combination of a number of actions

Radiation is essentially a destructive process, involving the disappearance of the immature rapidly growing fibroid cell and its replacement by fibrous tissue. There is also an endarteritis which shuts off the blood supply of the growing tumor or bleeding uterus, also a direct action on the ovary. The Graafian follicle is either destroyed or undergoes cystic degeneration. The corpus lutea and the internal secretion of the ovary are depressed but not destroyed when the proper dosage is administered. The artificial menopause induced by X-ray does not differ in kind or severity of symptoms from the normal climacteric.

HEART AND VASCULAR SYSTEM (DIAGNOSIS)

A Case of Aneurysma Dissecans of the Thoracic Aorta Robert Kienböck and Konrad Weiss Fortschr a d Geb d Röntgenstr, August, 1931, XLIV, 211-214

Retrospectively, an intrathoracic lesion, originally merely reported as an aortic aneurysm with some unusual features, was assumed to be an aneurysma dissecans. It is believed that this diagnosis may occasionally be made *in vivo* in the presence of a dense shadow (nucleus) within a relatively transparent and unusually formed aneurysmatic picture.

HANS A JARRE, M D

New Facts Concerning the Question of Orthocardiography J I Arcoussky Vestnic Rentgenologii i Radiologii, 1931, IX, Nos 2 and 3, p 133

The author presents a full discussion of orthocardiography of the heart and aorta. He considers orthocardiography to be a very valuable roentgenologic method of investigation, but as it is now practised, the method is not adapted to clinical study. His modifications make the method of greater usefulness in clinical medicine. Upon the basis of his investigations and measurements of the heart, he succeeded orthodiagnostically in proving that the volume of the heart increases at the moment of inspiration.

SAMUEL BROWN, M D

Persistence of the Right-sided Aortic Arch, Demonstrated Radiologically Klaus Mardersteig Fortschr a d Geb d Röntgenstr, August, 1931, XLIV, 163-169

This is a case report. By careful roentgenologic examination suspected specific aortitis could be

ruled out. A persistent right-sided aortic arch was found associated with a congenital ventricular septal deficiency. The esophagus and trachea were considerably displaced by a persistent left-sided aortic root (knob), resembling an aortic diverticulum.

For literature on this subject see Biedermann *Fortschr auf dem Gebiete der Röntgenstrahlen*, 1931, XLIII, 168

HANS A JARRE, M D

HERNIA

Retroperitoneal Parajejunal Hernias or Hernias of Treitz and of Waldeyer Georges Brohée Arch d mal de l'app digestif, July, 1931, XXI, 794-812

The depressions described by Treitz and Waldeyer are parajejunal on the right and left sides, not para-duodenal. They are three in number right, left superior and inferior. The various theories of development are described and found to be insufficient.

Rarely retroperitoneal hernias may develop at these points. About 175 have been reported, about 30 of which were on the right side. Four clinical types are recognized: the insidious, the type due to diarrhea, to constipation, and the acute or subacute occlusive type. Vague digestive disturbances, resisting all medication, mesogastric pain radiating to the left, tumefaction to the left of the vertebral column in the umbilical region are all strong presumptive signs. The radiologic findings are not fixed. The diagnosis is seldom made pre-operatively and the prognosis is that of all abdominal hernias.

Treatment depends on circumstances in the occlusive or strangulated type, if the strangulated area does not preserve its vitality, debridement is recommended, in other types, a reduction of the hernia followed by an obliteration of the orifice, directly or indirectly, is the treatment of choice.

B J DE LAUREAL, M D

HODGKIN'S DISEASE (DIAGNOSIS)

Roentgenologic Study of Intrathoracic Lymphoblastoma. B R. Kirklin and Hans W Hefke. Am Jour Roentgenol and Rad Ther, November, 1931, XXVI, 681-690

The authors studied and analyzed the intrathoracic roentgenologic findings in sixty-seven cases of lymphoblastomas, these being sub-classified by clinical and microscopic findings as Hodgkin's disease (forty cases), lymphosarcoma (seventeen cases), and leukemia (ten cases). X-ray changes in the chest were

seen oftener (50 per cent) in cases of Hodgkin's disease than in cases of lymphosarcoma or leukemia (20 per cent)

The proven cases of Hodgkin's disease were divided into two groups, the larger group comprising 62 per cent of the cases showing mediastinal and hilar node changes only, the smaller group of 30 per cent showing involvement of the pulmonary tissue, either infiltrative or metastatic, with or without node involvement. The most commonly seen changes in the cases of Hodgkin's disease consisted of multiple well-defined discrete rounded or oval shadows in one or both hilar regions, with a more or less lobulated superior mediastinal shadow. The cases with lung involvement showed a much more variable picture, some resembling the patches of bronchopneumonia, one resembling extensive bronchiectases, and several simulating primary or metastatic pulmonary neoplasm.

The seventeen cases of lymphosarcomas all showed either mediastinal or hilar node involvement, or both. The majority of the cases showed bilateral, lobulated mediastinal widening. Four of the seventeen cases revealed pulmonary involvement also. The appearances of the ten cases of leukemia showing intrathoracic involvement were not appreciably different from the cases of lymphosarcoma. Four cases of leukemia showed pulmonary as well as node involvement.

The authors conclude that there is no absolutely characteristic difference in the roentgenologic appearance of these closely allied malignant lymphomas. Differentiation from aneurysm, benign tumors, substernal goiter, carcinomatous and sarcomatous metastases, primary carcinoma of the lung or bronchus, pulmonary tuberculosis, Pott's abscess, marked dilatation of the esophagus, and mediastinitis must be made.

J. E. HABBE, M.D.

THE KIDNEY

Pyelographic Evidence of Horseshoe Kidney. Report of a Case in a Girl Thirteen Years of Age. Samuel J. Sinkoe. Am. Jour. Surg., January, 1932, XV, 51-55

A correct pre-operative diagnosis of horseshoe kidney is not a simple matter, and it is only on the operating table or in the autopsy room that we are able to confirm our diagnosis. There are, however, certain clinical facts in addition to our pyelographic findings which may justify one in arriving at a tentative diagnosis, and should any surgical emergency arise in a patient suspected of having this congenital anomaly, the surgeon should be on guard and proper measures should be carried out accordingly. The

anomalous rotation of the renal pelvis, the unusual location of the calyces, the finding of the renal shadow lying close to the vertebral column, the abnormal insertion and shortening of the ureter, the visibility of the presence of an isthmus, all point to a definite renal abnormality, and that abnormality suggests a horseshoe kidney. Clinically, the presence of Rovsing's sign may be of great value. One must also remember that horseshoe kidney is more liable to infection than a normal kidney, and may be subject to various diseases, such as stone, tuberculosis, pyonephrosis, etc. One must, therefore, be on guard for suggestive symptoms and treat the condition accordingly.

In conclusion, the author emphasizes the fact that in congenital anomaly of the kidney, especially of the horseshoe variety, stasis and infection are usually present and proper therapy depends upon carrying out ureteral dilatation and pelvic lavage in order to alleviate the patient's symptoms.

The writer has included a brief review of the literature on this subject, together with detailed accounts of a case reported by D. N. Eisendrath and one of his own. Interesting pyelo-ureterograms accompany the article.

The importance of a thorough urologic investigation of individuals with a persistent pyuria is emphasized.

DAVIS H. PARDOLL, M.D.

Nephroptosis Its Diagnosis and Treatment. Jay J. Crane. Calif. and West. Med., September, 1931, XXXV, 201-204

The author discusses surgical fixation of the kidney as practised before the modern methods of diagnosis were used, noting particularly that many times there was failure to relieve the symptoms. To-day he does not advise anchoring every floating kidney, and, therefore, limits himself in this line to those kidneys in which urinary stasis is found, with the aid of the cystoscope and X-ray.

Under the heading of symptoms he notes that he has come to rely on the X-ray findings for the position, rather than on palpation of the kidney. He divides the kidney mobility into three degrees, namely First degree, when the pelvis rests opposite the third lumbar vertebra, second degree, when the pelvis rests opposite the fourth lumbar vertebra, and third degree, when the pelvis rests opposite the fifth lumbar vertebra.

Diagnosis is made by the subjective symptoms and the findings, sometimes by palpation, plus the objective evidence of pathology as demonstrated with the X-ray and cystoscope and the reproduction of the pain by injection of pyelographic fluid. The surgical treatment is also discussed.

FRANCIS B. SHELTON, M.D.

Solitary Cyst of the Kidney Report of Two Cases Joseph A Lazarus Urol and Cutan Rev, November, 1931, XXXV, 698-703

In the seventeenth century, Fabry, of Hilden, a famous German surgeon, and the noted English internist, Thomas Willis, made some interesting observations on renal cysts. The first precise remarks concerning cystic renal disease are to be found in Rayer's treatise on disease of the kidneys, published in 1837. In 1867, Laveran, in his monograph, distinguished between solitary renal cysts and polycystic disease of the kidneys.

A solitary cyst of the kidney is a typically benign cyst, usually of considerable size, and situated, as a rule, in one pole of the kidney. It may be designated as "serous" if its contents are clear and watery, or "hemorrhagic" if they are bloody. The serous cyst, which is the more commonly observed, is lined with an epithelial layer of flat or low cuboid cells. As a rule, there is no communication between the cyst and the kidney pelvis. Numerous theories regarding the pathogenesis of solitary cysts have been offered, but the preponderance of evidence thus far adduced seems to favor the theory that solitary renal cysts are congenital and bear a close relationship to polycystic renal degeneration. There is, likewise, a great variance of opinion regarding the site of origin of such cysts.

This condition gives rise to no pathognomonic symptoms. The cyst is accidentally discovered at autopsy, or during an exploratory operation in some cases. Pain of a dull and dragging character is present in many cases. Pressure upon neighboring organs may give rise to symptoms in those organs. Hematuria has been reported in only two cases.

The author believes that a tentative diagnosis can be made by a careful reading of the plain roentgenogram. In this condition the X-ray will reveal a globular enlargement of one of the renal poles of lighter density than the remainder of the renal shadow, or a notching of the convex border of the kidney at its point of attachment to the cyst. A distinct line of demarcation between the cyst and the kidney may be seen in some cases. In cysts of the lower pole a medial deviation of the opaque ureteral catheter may also occur. According to Braasch, pyelography shows a shortening of adjacent calices, a flattening of the portion of the pelvis in contact with the cyst, and a change in the axis of the kidney, due to the weight of the cyst. While, as a rule, the pyelographic findings in solitary cyst are distinct from those of tumor of the kidney, in certain cases the differential diagnosis of the two conditions is impossible. Palpation usually reveals an enlarged renal mass.

The treatment of solitary cysts of the kidney is surgical. In cases with good functioning renal parenchyma, the cyst is completely removed with the

entire lining. Following extirpation of the cyst the kidney should be suspended. In those cases in which the cyst is in intimate contact with the renal pedicle, nephrectomy must be done.

The author reports two cases illustrating the points mentioned by him to be observed in diagnosis and treatment. The first case was that of a woman, 63 years of age, who presented a solitary serous cyst, involving the lower pole of the right kidney. The pre-operative diagnosis was made from the plain roentgenogram, and nephrectomy was performed. The second case was that of a woman, 53 years of age, with involvement of the lower pole of the left kidney. A tentative pre-operative diagnosis of solitary cyst was made from the plain roentgenogram. Owing to the finding of blood in the specimen obtained from that kidney, tumor could not be ruled out prior to operation. Partial nephrectomy was performed in this case.

J N ANÉ, MD

LIGHT THERAPY

On the Photochemical Decomposition of Hemoglobin and the Relations of the Reaction to Chlorophyl G Kögel Strahlentherapie, Oct 3, 1931, XLII, 379-383

On the Acceleration of the Reduction of Methylene Blue by Proteins under the Influence of Light. G Kögel Strahlentherapie, Oct 3, 1931, XLII, 384, 385

In the first article the author relates his experience with the effects of light on chlorophyl solutions under the influence of sensitizing substances. Hemoglobin and its derivatives were also studied. It appeared that the sulphydryl group was most effective in the splitting up of hemoglobin.

In the second paper the effect of several amino acids on the reduction of methylene blue were investigated. Leucine, alanine, and glycocoll seem to be most active.

ERNST A POHLE, MD, Ph.D

The X-ray as a Complement to Actinotherapy Sir Howard Humphris Canadian Med Assn Jour, September, 1931, XXV, 311-314

As radiography should not be considered an entity in diagnosis but kept in correlation with other methods of diagnosis, there seems to be reasonable grounds for assuming that the X-ray can be used as a valuable adjunct to the rays of the spectrum not far removed from it. Especially is this true of ac-

tinotherapy, since the space between X-rays and ultra-violet has been bridged spectroscopically by Millikan and Holweck.

As instances of diseases in which the X-rays and actinotherapy may supplement the action, the one of the other, the author quotes from the work of Bayliss and Sampson. The former states "The effect of the X-rays on cells is similar to that of ultra-violet light. Their lethal effect, however, continues for a long period." Sampson says "In lupus vulgaris, often after the first few actinic-ray treatments, a dermatitis dose of X-rays is of the greatest utility." Again in psoriasis some of the more recent areas cleared up promptly under actinotherapy, but some of the older and more indurated regions were intractable until the ionizing X-ray dose was given.

Even as they may be used together clinically, X-rays sometimes, not indiscriminately however, may be given when there is dermatitis from ultra-violet radiation. When the ultra-violet radiation is given to increase skin tolerance the reaction should be allowed to die down before administering the X-rays. In lupus vulgaris, in cases in which it is desirable to produce extreme dermatitis, the best results are obtained by superimposing the X-rays upon the ultra-violet dermatitis.

In considering team work between X-ray and ultra-violet radiation, let us recall the way in which the former produces its therapeutic effects.

1 The endothelial lining of the blood vessels becomes edematous, this edema eventually occluding the artery and cutting off the nutrition of the growth, and resulting, if the treatment is pushed to that extent, in an obliterating endarteritis in the capillaries.

2 X-rays appear to have special action on new cells and on elementary embryonic tissue. Here the nucleus becomes cloudy, the nuclear membrane disappears, and then is carried away by the process of phagocytosis, and replaced by connective tissue in those cases in which the treatment is prolonged.

These and other changes that are brought about greatly depend upon the blood condition of the patient. We have seen that ultra-violet rays are actually absorbed by the capillaries, and cause chemical changes in the composition of the blood. This consideration may explain the mechanism by which are brought about the good effects of the combined use of the two measures.

The problem of the successful use of the combined measures of X-ray and actinotherapy involves, *inter alia*, two main questions. These are the measure of the sensitivity of the pigmented skin to the X-rays, and the possibility that such simultaneous and combined application may be productive of cumulative effect. Researches show that the pigmented skin is not abnormally sensitive to such treatment. Should, however, the skin be exposed to the ultra-violet rays of the quartz lamp, the result is somewhat different. If the ultra-violet rays are found

to produce a violent reaction, the effect of the X-rays would be to increase it. Such treatment should, therefore, be reserved for those cases in which previous light treatment has brought about a certain degree of tolerance of the tissues. So far as cumulative action is concerned there is no evidence of any harmful effect from the combination of treatments.

In considering the therapeutic effect of these two agents, it is interesting to contrast their several actions on the skin. Either will produce a dermatitis, but the X-ray one takes weeks, months, or even years to develop, while that from ultra-violet occurs in a few hours. X-ray dermatitis causes baldness, while the ultra-violet stimulates the growth of hair. Atrophic changes may develop from X-ray dermatitis, while the ultra-violet causes little more than desquamation. The irritability of a given area is increased following an X-ray dermatitis, while it is decreased following an ultra-violet dermatitis.

The conjoined employment of X-ray and actinotherapy followed the observation that X-ray dermatitis, if not too severe, yielded readily to the application of the ultra-violet. If, however, cicatrical tissues have formed, these must be softened up by X-ray treatment before the ultra-violet will be effective.

In conclusion, the author regards as definitely proven the facts that X-ray and ultra-violet are mutually complementary methods of treatment. Each has added to the field of usefulness of the other, when used to supplement it, under carefully selected conditions. Up to the present, research has not gone far enough to make it possible to postulate any exact technic for the combined use of the two measures.

L J CARTER, M.D.

THE LIVER

Flat Film of the Liver Arthur Wolf Röntgen-praxis, Aug 15, 1931, III, 732-739

A flat film of the liver, if technically good, gives a considerable amount of information. One is usually able to show the lateral and the lower edge of the liver up to the gall-bladder region. Changes in the shape and size of the liver can usually be demonstrated. In one case, a carcinomatous nodule could be seen on the lateral edge of the liver.

H W HEFKE, M.D.

New Methods of Radiologic Visualization of the Liver and Spleen Carlos B Udaondo, Eduardo Lanari, Pedro A Maissa, and Juan C Galan

Prensa Med Argentina, July 10, 1931, XVIII, 161-166

The authors present five cases of visualization and follow the method introduced by Radt. They use Tordiol and Heyden 1,073 A., giving from 10 to 20 c.c. intravenously daily until a total of from 40 to 80 c.c. have been given. Their results were very good, and they conclude that the method of Radt is a great step in the diagnosis of diseases of the liver. Only one case showed intolerance of the substance as indicated by slight rise in temperature, dizziness, and headaches.

N G GONZALEZ, M D

MASTOID

Radiographic Evidence of Mastoid Pathology
Richard A Rendich Med Times and Long Island
Med Jour, September, 1931, LIX, 319, 320

The roentgenogram serves as an anatomic as well as a pathologic study of the mastoid. It furnishes information concerning the type and size of the mastoid, its development, size and extension of cells, thickness of the cell walls and mastoid cortex, and the position and course of the lateral sinus and emissary vein. Pathologically, the decrease of aeration indicates the amount of serum, purulent material, or granulation tissue in these cells, structural changes in the septa being shown by changes in density. An abscess of the mastoid is recognized by absence of cell septa in a more or less irregular spherical area of varying size, delimited by a zone of slightly increased density. Sclerotic mastoid is readily distinguished by absence of cells and a dense eburnated triangular area marked posteriorly by the lateral sinus groove. An acute exacerbation of an otitis media will give no X-ray evidence in a mastoid of this sort. The radiograph must show the entire mastoid in the finest detail. It is then a distinct aid in deciding on surgical procedures.

W W WATKINS, M D

MEDICAL PRACTICE

A Radiologist's Duty to His Specialty Charles M Richards Calif and West Med, June, 1931, XXXIV, 395, 396

The author criticizes the profession for using the lay laboratory and for oftentimes accepting diagnosis from these laymen. At the same time he condemns the radiologist for not being a true consultant, stating that he has oftentimes not seen the patient or demanded the history or clinical findings to

assist him in making his diagnosis, and that he has not stressed the point that the work of the radiologist is after the films are made.

The fact that the practice of radiology is in every sense the practice of medicine should be impressed on our medical confreres, by the conduct of our work both at the hospital and in private practice. In connection with the report of the death of a member of our specialty, the author notes there was used the following significant statement "He was a physician, practising radiology."

FRANCIS B SHELDON, M D

The Training in Radiology for the Dermatologist
A Stühmer Strahlentherapie, Oct 24, 1931, XLII,
599-604

The author, who holds the chair of Dermatology at the University of Munster, outlines in this article his opinion concerning the training of specialists in radiology as the dermatologist sees it. In view of our interest in all matters of training regarding our chosen field of endeavor, his conclusions will be related here.

The creation of chairs for general and clinical roentgenology to be occupied by a physician must be demanded. A radiation institute for teaching and research purposes is essential. In such an institute the students should be taught roentgen physics, radiobiology, general clinical roentgenology, as well as biology of light and light therapy. Special courses should be given for clinical assistants in order that their knowledge of roentgenology may be widened. More attention should also be paid to roentgenology in the clinical teaching. It should also become obligatory for the student to pass an examination in radiology.

He says "The training of physicians using roentgen rays for the treatment of skin diseases should be supervised by the dermatologist." A specialist in radiology should, therefore, not include among his activities the treatment of skin diseases, since that presupposes a complete training in dermatology. If radiation institutes desire to treat skin diseases, such a procedure is acceptable, from the standpoint of the dermatologist, only if he is in complete charge of the case and of the treatment.

ERNST A POHLE, M D, Ph D

PHYSIOTHERAPY

Hyperpyrexia, a New Field for Physical Therapeutics Clarence A Neymann Brit Jour Phys Med, October, 1931, VI, 141-144

The author discusses the production of fever with high frequency currents and describes the technic

used in application when the body temperature is to be raised to about 104° Fahrenheit. He states that it usually requires from one and one-half to two hours before 104.5° is reached, but it is very easy to maintain this temperature for periods of from five to eight hours, providing the patient is adequately insulated. A temperature recording device is also described.

The results in the treatment of eighty-five cases of general paresis at the Cook County Psychopathic Hospital, the Elgin State Hospital, and in private practice are enumerated.

In this series, "41 per cent of these patients showed an absolute clinical remission, and returned to their former occupations, 19 per cent made a partial recovery and were able for the most part to adjust themselves outside an institution, and 40 per cent remained unimproved. These results are the more noteworthy since only 34 patients (about 40 per cent) had what we now consider adequate treatment, i.e., at least 100 hours of fever above 103.5° Fahrenheit. Some have received as many as 50 treatments, with over 200 hours of fever above 103.5°."

The results in tertiary endarteritic syphilis of the brain, Parkinsonian syndromes, and arteriosclerotic conditions do not appear to yield as good results.

The author also states that, "Three years have elapsed since the first cases were discharged from custodial institutions. Thus far not a single case has been recommitted. There seems no mental deterioration in any of the discharged cases of this series, whom we have been able to re-examine from time to time."

WILLIS S PECK, MD

RADIATION

Radiation Therapy of Carcinoma of the Fundus
Iwan v Büben Strahlentherapie, Nov 14, 1931,
XLII, 769-774

During the period from 1919 to 1929, the author observed 101 cases of carcinoma of the fundus. Thirty-eight of these had never had any pregnancy, two were virgins, 14 had one child each, and 49 had had several pregnancies. Forty-five were irradiated and 56 operated on. Histologically there were 86 patients with adenocarcinoma 13 with carcinoma solidum, and two with carcinosarcoma. Twenty-eight of the cases operated on could be observed over five years, 12 of these were cured (42.9 per cent). Radium and roentgen rays were used in combination. From 50 to 75 mg in a silver brass screen, equivalent to 10 mm Pt were inserted in rubber tubes intra-uterine to give a dose of from 2,400 to 3,600 mg-hrs in the uterus and from 2,000 to 2,400 mg-hrs in the vaginal wall. Three series of roentgen treatments were given,

using from 2 to 6 fields each time, the dose per area being 470 r (measured in air) produced at 183 K.V., 5 ma, 0.5 mm Zn + 0.5 mm Al at 30 cm. F.S.D. Examinations of the patients took place first every six weeks, then every three months. Twenty-six patients could be observed for five years, nine remained well less than one year, five remained well for one year, seven for two years, one for three years, one for five years, one for six years, one for seven years, and one for eight years. Four women are considered cured, corresponding to 15.3 per cent.

The author states that the question of radiation therapy of carcinoma of the fundus cannot be considered as a solved problem. However, he feels that the results are so encouraging that further efforts should be made to improve what has been accomplished so far by irradiation.

ERNST A POHLE, MD, PhD

Radium Irradiation with and without Filter
George Schaprirger Strahlentherapie, Oct. 3, 1931,
XLII, 386-393

The author analyzes the most common types of radium applicators and their effect on tissue. Expressing the amount of radiant energy emitted as alpha-, beta-, and gamma-rays in calories per hour, he comes to the conclusion that it does not suffice to indicate dosage in milligram-hours. It is necessary to specify the percentage of alpha-, beta-, and gamma-rays affecting the irradiated tissue. He gives some examples illustrating his method.

ERNST A POHLE, MD, PhD

Chronic Myelogenous Leukemia Value of Irradiation and Its Effect on the Duration of Life. William J Hoffman and Lloyd F Craver Jour Am Med Assn, Sept. 19, 1931, XCVII, 836-840

Since the disease is comparatively rare, its gradual development makes it difficult to determine the exact time of onset.

The average duration of life after the onset of the disease was 3.36 years, and varied from more than sixteen years to as little as six months. Eighty-two cases of myelogenous leukemia are analyzed and compared with a series of 130 cases reported by Minot, Buckman, and Isaacs. The decade of greatest incidence is that between thirty-four and forty-five years. The incidence of the disease increases from infancy to thirty years of age and from that time onward remains practically constant. The youngest patient in their series was fourteen and the oldest sixty-six years. The disease is rare below twenty-five years. In their series 68 per cent were males and 32 per cent were females. Splenomegaly was present in seventy-seven of the eighty-

two patients at the time of diagnosis, indicating that the disease is rarely recognized before this enlargement has developed

Comparison with Minot's group of non-irradiated patients showed that irradiation actually adds little to the duration of life in this disease. Irradiation early in the course of the disease had no effect on the duration of life. Repeated cycles of irradiation produce remarkable improvement in the condition of patients. The effect, while temporary, lasts from a few months to a year, repetition of the treatment being necessary. The average duration of efficient life after the diagnosis of the disease was 30 per cent greater in their irradiated patients than in Minot's non-irradiated patients. The radiation treatment causes an average increase of about ten months in the duration of efficient life—a period of usefulness that the patient otherwise could not hope to enjoy.

C G SUTHERLAND, M B (Tor.)

Roentgen Therapy of Carcinoma of the Penis
Juraj Körbler Strahlentherapie, 1931, XLII, 780-783

The author describes two cases of carcinoma of the penis treated by roentgen rays with the following technic: 15 H filtered through 0.5 Cu + 10 Al given over two areas in two sittings three weeks apart. The inguinal lymph nodes were involved in the first case and were removed by operation. Although the primary tumor responded well to roentgen rays, a recurrence developed in the preputium, and the biopsy showed carcinoma. Amputation was carried out, therefore.

The second case was a student, 23 years old, who had a tumor along the entire circumference at the insertion of the preputium. The inguinal lymph nodes were removed but did not show any involvement. X-ray therapy was started in August, 1927. The tumor responded well, and eight months after the treatment no traces of it could be found. However, the patient developed phimosis and was operated on. Histologic examination of removed tissue did not show any carcinoma. Re-examination was done four years afterwards, and the patient is still well. The author believes that it is worth while to give roentgen therapy a trial in carcinoma of the penis in order to avoid amputation, if possible.

ERNST A POHLE, M D, Ph D

Roentgenotherapy of Hay Fever F E Haag and H Schreus Strahlentherapie, Oct 24, 1931, XLII, 485-491

Roentgenotherapy in cases of hay fever is given over the entire nose, using a 0.5 mm. Cu filter, 6 X 8 cm field, 120 r up to three times every two or three days. No other therapy was applied, in order to

obtain correct statistics. Of sixteen cases, six had good results, one temporary improvement, eight did not respond, and one could not be traced. Studies of the skin reactions following a pollen vaccination showed that they run parallel to the clinical symptoms. The reactions during the period of roentgenotherapy were also observed. In some cases the reactions did not appear at all and in others the number and intensity were decreased, while in some there was an increased response.

ERNST A POHLE, M D, Ph D

Studies on the Effect of the Time Factor in Roentgen Irradiation R. Glocker, H Langendorff, and A Reuss Strahlentherapie, Sept. 12, 1931, XLII, 148-156

In this study of the influence of the time factor in irradiation the authors differentiate two stages. First, exposures of such a duration that the velocity of growth of the cell during irradiation can be neglected. It can be expected in such a case that photochemical laws govern the effect of the time factor. Second, exposures which extend over such time intervals that the status of the cell undergoes definite changes. In that case there occur biologic processes which must vary in different objects and cannot be expressed by a general law. Bean seeds and eggs of axolotl were used. It was found that for exposures of short duration (up to one hour for beans, up to one-half hour for eggs of axolotl) the effect of the time factor for intensity changes 1/200 followed Schwartzschild's law. The exponent in this law is 0.96 for beans and 0.95 for eggs of axolotl. A graph is appended which permits the determination of the necessary corrections for the exposure time. If the interval between two fractional doses is varied, then the percentage of injury changes according to the length of the interval. The effect is directly related to the number of mitotic cells present at the time of the second exposure.

ERNST A POHLE, M D, Ph D

Roentgenotherapy in Non-malignant Disease of the Central Nervous System Gerd Kohlmann Strahlentherapie, Oct 24, 1931, XLII, 453-465

The author outlines, briefly, the indications and method of treatment in non-malignant diseases of the central nervous system. He begins with inflammatory processes as, for instance, tabes. Twenty-three cases with crisis were treated, fifteen responded well, six moderately well, and two did not respond at all. The technic was as follows: 3 or 4 fields 10 X 15 sq cm, 30 cm FSD, 180 K.V., 0.5 Cu + 1 mm Al, from 40 to 50 per cent H.E.D. per field. The entire spinal cord is irradiated, one field every second day. A second series may be

used in application when the body temperature is to be raised to about 104° Fahrenheit. He states that it usually requires from one and one-half to two hours before 104° is reached, but it is very easy to maintain this temperature for periods of from five to eight hours, providing the patient is adequately insulated. A temperature recording device is also described.

The results in the treatment of eighty-five cases of general paresis at the Cook County Psychopathic Hospital, the Elgin State Hospital, and in private practice are enumerated.

In this series, "41 per cent of these patients showed in absolute clinical remission, and returned to their former occupations, 19 per cent made a partial recovery and were able for the most part to adjust themselves outside in institution, and 40 per cent remained unimproved. These results are the more noteworthy since only 34 patients (about 40 per cent) had what we now consider adequate treatment, i.e., at least 100 hours of fever above 103.5° Fahrenheit. Some have received as many as 50 treatments, with over 200 hours of fever above 103.5°."

The results in tertiary endarteritic syphilis of the brain, Parkinsonian syndromes, and arteriosclerotic conditions do not appear to yield as good results.

The author also states that, "Three years have elapsed since the first cases were discharged from custodial institutions. Thus far not a single case has been recommitted. There seems no mental deterioration in any of the discharged cases of this series, whom we have been able to re-examine from time to time."

ERNST A. POHLE, M.D., Ph.D.

Chronic Myelogenous Leukemia Value of Irradiation and Its Effect on the Duration of Life. William J. Hoffman and Lloyd F. Craver Jour Am Med Assn, Sept. 19, 1931, XCVII, 836-840

Since the disease is comparatively rare, its gradual development makes it difficult to determine the exact time of onset.

The average duration of life after the onset of the disease was 3.36 years, and varied from more than sixteen years to as little as six months. Eighty-two cases of myelogenous leukemia are analyzed and compared with a series of 130 cases reported by Minot, Buckman, and Isaacs. The decade of greatest incidence is that between thirty-four and forty-five years. The incidence of the disease increases from infancy to thirty years of age and from that time onward remains practically constant. The youngest patient in their series was fourteen and the oldest sixty-six years. The disease is rare below twenty-five years. In their series 68 per cent were males and 32 per cent were females. Splenomegaly was present in seventy-seven of the eighty-

appeared on the amputation scar of the right index finger, with enlarged right supraclavicular nodes and also a tumor in the right breast

In April, the patient died, after having severe pain in the abdomen and right hip followed by paralysis of the right leg. At necropsy, metastases were found in the lymph nodes of the hilum of the right lung, heart, liver, pancreas, stomach, spleen, kidneys, left suprarenal, and appendix. The authors state that this is the first case of occupational X-ray cancer on record in Japan

F CAVERS, D Sc.

The Danger of Roentgen Carcinoma Developing after Roentgenotherapy H Holthusen and K Engmann Strahlentherapie, Oct 24, 1931, XLII, 514-531

Carcinoma developing in irradiated areas has been reported, however, the percentage of incidence is very small. It seems that professional workers are much more in danger in that respect than a patient treated by irradiation. The authors relate the history of a man who, at the age of 26 years, received superficial roentgenotherapy because of syrosis barbae. Immediately after the treatment he developed an acute reaction in the face, the neck, and upper chest. The epidermis underwent necrosis, and only eight months after the treatment complete epithelialization had occurred. One year after the exposure he was treated because of skin necrosis in several areas in the neck. These healed, however, under radiation therapy (the type of radiation is not stated). Atrophy of the skin developed in the following years, which interfered greatly with the motion of the head, particularly with the function of the mandible during eating and talking. In 1924, a large ulcer appeared in the left cheek, which healed after from six to seven weeks. In 1929, a small growth developed on the right cheek. Though this growth dropped off, it recurred repeatedly. He returned for examination in June, 1929, and a diagnosis of roentgen carcinoma was made. Biopsy showed a typical squamous cell cancer. There was also a small gland in the right submandibular region. Radium therapy could not halt the process, but the growth increased in size, and broke through into the mouth until a hemorrhage from the temporal artery and subsequent pneumonia ended the patient's sufferings.

Thirty-nine cases collected from the literature are briefly quoted. An analysis of these shows that carcinoma develops most frequently in patients who have received several series of exposures. Head, vulva, and anus are more frequently involved. In conclusion, it is stated that the occurrence of a roentgen carcinoma following irradiation for therapeutic purposes is extremely rare. Since 1910, only three cases have been observed.

ERNST A. POHLE, M D, Ph D

The Treatment of X-ray Burns with Rays of Long Wave Length W Bröcker Strahlentherapie, Oct. 24, 1931, XLII, 551-570

Experiments showed that exposure to infra-red light applied before or after roentgen exposure does not influence the roentgen reaction of the human skin. In the animal experiment a prophylactic effect of infra-red rays toward roentgen injuries could not be proved. A roentgen ulcer appeared, regardless of infra-red exposure being applied before or after roentgen irradiation. Clinical experience has shown, however, that infra-red light is of value in treating already existing roentgen burns. Two cases are reported, the X-ray injuries of which healed following exposure to infra-red light, although all other therapeutic measures had failed to bring relief.

RADIUM

Radium and Microglia Desiderio Perotti Riv di radiol e fisica med, December, 1931, IV, 175-178

The author inserted under the skull of rabbits a tube of 10 mg radium element filtered with 1 mm platinum and left it in place in one animal for 48 hours, in another for 108 hours. He found the changes produced by this method of irradiation were quite similar to those produced by the X-ray. There was a heaping up of microglia cells in the white submeningeal layer of the cortex. This, the author thinks, is due to the larger dose of radiation received by the submeningeal layer in comparison to that received by the deeper layers distant from the radium-bearing tube.

This accumulation of microglia cells, whose phagocytic power is evident where the radiation is most intense, seems to be of much importance in the regression and cure of cerebral tumors treated by radiotherapy.

E T LEDDY, M D

Plastic Apparatus Made from Reinforced Paraffin-wax ("Gammoplast") for Use in Superficial Radium Therapy Gian Giuseppe Palmieri and Giovanni Paltrinieri Riv di radiol e fisica med, December, 1931, IV, 150-174

The authors discuss the use of "gammoplast," first described by them in 1929, as used in moulded applicators in the Radium Institute of Bologna. This technic avoids the main drawbacks found in the usual plastics, such as brittleness, great weight, difficulty of moulding to exactly fit the lesion, and expense of preparation of the "moulage." Numerous photographs illustrate the preparation and clinical applications of the authors' devices.

E. T. LEDDY, M D

given after from six to seven weeks and a third series after three months. In gastric crisis one can also apply from 20 to 25 per cent H.E.D. to the plexus solaris.

Poliomyelitis can be treated also, particularly in combination with diathermy. The entire spinal cord is treated through 4 fields of entry, acute cases receive from 25 to 30 per cent H.E.D. and in chronic cases 50 per cent of the H.E.D. is given. If only the lower extremities are affected, it suffices to apply 2 fields to the lower part of the spine. Not so favorable are the results in roentgenotherapy of encephalitis. In acute meningitis other methods are much more important. Roentgenotherapy may be given a trial in cases of solitary tuberculosis, particularly if it has been localized by operation. In multiple sclerosis, from 20 to 25 per cent H.E.D. can be given per field. Twelve out of seventeen cases were considerably improved. In cases of chronic headache, relief has also been obtained following the application of from 30 to 35 per cent H.E.D. in two or three series at from six- to eight-week intervals. Cases with traumatic compression and those of meningitis serosa do sometimes respond well to roentgenotherapy. The same holds true of hypersecretion, as, for instance, in patients with liquor fistula. The author has seen good response in epilepsy, it takes, however, many series of treatments and sometimes as long as two years until a definite improvement can be noticed. The technic consists of 50 per cent H.E.D. through 4 fields of entry (9×12 sq cm). Syringomyelia seems to be very suitable for radiation therapy. The technic of treatment is similar to that in tabes and multiple sclerosis. Raynaud's disease ($\frac{1}{3}$ H.E.D., three series at from four- to eight-day intervals over the cervical and lumbar spine), torticollis (75 per cent H.E.D., distributed over three successive days), neuralgia (60 per cent H.E.D. over both central and peripheral nerves), and paralysis agitans (20 per cent H.E.D. directed to the fourth ventricle, 5 fields, to be repeated once or twice at from four- to six-week intervals) have also been tried in some cases with success. Reference is made to the work of Wieser, who, for the past several years, has irradiated mongoloid children. In conclusion, it is stated that not enough attention is paid to roentgenotherapy in non-malignant diseases of the central nervous system.

RADIATION INJURIES

Injuries Resulting from the Application of Electro-physical Treatment Methods F. M. Groedel and Heinz Lossen Strahlentherapie, 1931, XLI, 372-394

The entire material collected in four medico-legal cases following the use of the quartz mercury vapor

lamp, the solux lamp, diathermy, and radium is published by the authors and should be looked up in the original by those interested in this subject.

ERNST A. POHLE, M.D., Ph.D.

The Problem of Total Body Exposure to Roentgen Rays F. M. Groedel and Heinz Lossen Strahlentherapie, Oct. 24, 1931, XLII, 532-538.

Total body exposure to roentgen rays has been suggested in the treatment of malignant tumors and was tried out recently in cases of leukemia and generalized skin disease. The danger of too high a total dose, because of the enormous absorption, is strikingly shown in a case seen by the authors. A man, 61 years of age, who had psoriasis involving almost the entire body, received exposures in numerous small areas distributed over a number of sittings. In a first series given in December, 1928, a total of 247 per cent H.E.D. was applied. In February, 1929, he received a total of 290 per cent H.E.D. In March, 1929, he received a total of 1,345 per cent H.E.D. In May, 1929, he received 1,830 per cent H.E.D. applied over thirty-seven areas. This brought the total dose given to the patient to about 38 H.E.D. During the entire time no blood examination had been made. Immediately following the last exposure in extreme anemia was observed and there were 2,350,000 red blood cells, 3,200 white blood cells, and 47 per cent hemoglobin. Under As and liver therapy combined with blood transfusions this typical aplastic anemia healed slowly. The importance of blood examinations during an extensive series of X-ray therapy is emphasized and a warning is issued concerning the dangers of excessive general body exposure.

ERNST A. POHLE, M.D., Ph.D.

Occupational X-ray Carcinoma H. Yamakawa and K. Shimadai Gann, 1931, XXV, 1-4 (Reprinted from "Cancer Review" by permission)

A man, 51 years of age, who had been employed in an X-ray laboratory for seventeen years had, ten years prior to being examined by the authors, noticed on the back of his hands a number of small warts which he treated with ointments. In 1926, a painful ulcer appeared on one of the warts, and as it did not heal, the finger (right index) was amputated. In July, 1929 an ulcer on the right middle finger was treated by amputation of the two terminal phalanges. Microscopic examination showed a deeply infiltrating medullary carcinoma of the anaplastic basal-celled type. Soon after this there appeared enlargement of the lymph nodes of the right elbow and axilla, which were removed in September. Shortly afterwards recurrence of the growth

made. A blood-count and Wassermann reaction should be done and a renal efficiency test carried out. In many cases of carcinoma of the cervix, death is due, not to cachexia, but to complicating uremia. Biopsy is also indicated in all cases. According to the author it is not an operation tending to cause dissemination of the disease.

The following classification is used: (1) The growth is early when it is limited entirely to the cervix, (2) The growth is borderline when, in addition to the cervix, it involves an adjacent vaginal wall or parametrium, but is still freely movable on bimanual palpation, (3) The growth is advanced when there is extensive fixation on one or both sides, (4) Recurrences after operation. Using this classification, cures by surgery can be expected only in the first group, there being an operative mortality varying from 11 to 18 per cent. Using radium, the author has had no primary mortality and has had 50 per cent five-year cures in Group 1, 31 per cent five-year cures in Group 2, 9 per cent five-year cures in Group 3, and 10 per cent five-year cures in Group 4. In most of the cases under observation for less than five years there has been considerable amelioration of the disease. The author has been unable to establish any definite relationship between the histology of the growth and the response to radiation.

The author does not give his technic in detail, but he prefers radium emanation to radium salts. He does not advocate intra-uterine radiation as he fears the risk of slough and infection in the uterus. His radium containers are held around the growth by gauze soaked in water. Very large doses are given (from 3 to 4 curie hours in a single dose), so that the treatment is completed in from one to two hours. Parametrial nodes are treated by implantation with gold seeds. Hysterectomy following radiation is not advisable and the use of X-rays to the pelvis after local radium treatment does not appear to alter the prognosis. X-rays should be used only in the advanced cases as a palliative.

P J KERLEY, M.B.

Radium Injuries to Bladder and Rectum in Treatment of Cancer of Uterine Cervix F C Wille. Monatschr f Geburtsh u Gynäkol, August, 1930, LXXXV, 383-390 (Reprinted from "Cancer Review" by permission.)

The author doubts whether or not radium is often responsible for early radium injury to the bladder, because cystitis is common in advanced cancer of the cervix. The late results attributed to radium are of two kinds: grevish patches (also occurring sometimes after operation when the bladder has been freed from the adjacent tissues) and ulcers with a surrounding area of bullous edema (also at times

seen in non-irradiated cases in which there is commencing invasion of the bladder wall by the growth, i.e., a stage in perforation of the bladder).

The author describes ten cases of fistula (five vesicovaginal, three rectovaginal, two a combination of these), apparently attributable to repeated treatments rather than to single large doses. The fistulas developed within a year at most after the last treatment. These cases occurred between 1915 and 1928, during which time 386 cases were treated with radium. The author believes that with the method now used at the Charité, in which a total dosage of from 3,000 to 3,600 mg-hrs is given in two sittings with an interval of eight days, these injuries will be less frequently seen.

F CAVERS, D.Sc.

Chemical Changes Produced in Malignant Tissue by Radium Radiation and the Importance of These Changes in the Treatment of Cancer J Flaszen and H Wachtel Bull Assn franç p l'étude du Cancer, January, 1931, XX, 18-30 (Reprinted from "Cancer Review" by permission.)

The authors, having observed in certain cases of cancer treated by radium a very early reaction without any latent period, have investigated the question of chemical changes produced at the site of irradiation. They have discovered what they term a "histolytic action," provoked mostly by the beta rays of radium, which leads to a modification of the power of the malignant cells to resist destruction by the protective processes of the body. This results in an immediate decrease in the size of the malignant tumor and even, in some cases, to a complete local cure of the condition before the expiry of the latent period which precedes the appearance of effects due to the gamma rays.

ROENTGEN RAY (INDUSTRIAL APPLICATION)

Radiographic Inspection of Metals Herbert R Isenburger Mech Eng, 1931, LIII, 729-735

The relative value and application of X-rays and γ -rays for the inspection of metals are discussed. The X-rays are used for industrial purposes. The equipment is described and the various defects of castings and welds are demonstrated and explained by means of photographs. For very heavy material of more than 3 in thickness, γ -rays should be used, because they are more penetrating. They also give finer details in thinner materials. The operating cost with X-rays amounts to from \$3.00 to \$5.00 per hour, depending on the way in which the material is writ-

A Method of Anchoring Radium Needles in the Pharynx J E G McGibbon British Med Jour, May 16, 1931, No 3671, p 843

The technic described below has been adopted to overcome the difficulties encountered due to involuntary swallowing movements, hawking, and coughing

In all previously described methods the needles have either been sutured in position, or the threads brought out through the mouth. In this method the needles are inserted in the usual manner through healthy tissue around the lesion, and the threads are left some ten inches in length. After insertion of a needle, its thread is secured outside the mouth, without any tension, by pressure forceps. When the requisite number of needles has been introduced a soft rubber urethral catheter, lubricated with liquid paraffin, is passed along the floor of one nasal fossa into the nasopharynx. As soon as the tip of the catheter is seen below the soft palate it is caught by a pair of forceps and brought outside the mouth. Half the total number of radium needle threads are then released from the pressure forceps and tied securely to the end of the catheter. The catheter is now carefully withdrawn from the nose, and immediately the attached threads appear at the nasal orifice, they are freed from the catheter. Each thread is gently drawn taut, and during traction, observation must be kept on the site of insertion of the attached needle in order to prevent accidental withdrawal. These threads are then tied together with a piece of silk or catgut. The lubricated catheter is now passed through the other nasal fossa, and the remaining free threads are dealt with in a similar manner. Finally, the two bundles of threads are tied securely together across the columella and the redundant ends cut off.

This method can be used successfully for lesions affecting the tonsil alone, the soft palate alone, the tonsil and palate, the tonsil and side of the tongue, the tonsil, palate, and side of the tongue, and the posterior pharyngeal wall.

Nasal respiration, speech, and swallowing are not interfered with, and the patient can take ordinary soft food up to the fifth day. From the fifth to the eighth day, when the needles are removed, only liquids may be taken.

Needles 21.7 cm in length (active length 10 mm), 1.65 mm external diameter, containing 1 mg of radium screened by 0.5 mm platinum, have been found most convenient for use in the regions discussed above.

WALLACE D MACKENZIE, M.D.

On External Radium Treatment in Gastro-intestinal Ulcers and in Their Post-operative Symptoms
Fritz Dautwitz. Strahlentherapie, Oct 3, 1931,
XLII, 219-248

During the years from 1912 to 1929, the author

treated twenty-five cases with gastro-intestinal symptoms which led to a diagnosis of either ulcer or carcinoma by external radium application. A fractional dose method was used, giving exposures daily or every other day. A series consisted of from four to eleven treatments of from eight to nine hours each and from one to three series were applied. The radium was filtered through 15 mm lead and was usually given through three anterior and two posterior fields. The dose varied between 2,000 and 13,700 mg-hrs radium element. No other medication was given nor a special diet prescribed, in order to study the efficacy of the irradiation alone. There were seven cases of gastric ulcer, three of pyloric ulcer, three cases of questionable ulcer, six of duodenal ulcer, one of pylorospasm, one of hyperacidity, three of gastric and one of pyloric carcinoma. In only one case was there no response, while in four others, three of which had been operated on after radium treatment, no permanent cure could be obtained. All the remaining seventeen were benefited by the treatment, although surgical procedures had not given them definite relief from their symptoms. There follows then a lengthy discussion of the possible mechanism of the effect of irradiation on gastro-intestinal ulcers. Briefs of the twenty-five case histories are also appended. The author recommends this method for trial on a large number of patients.

ERNST A. POHLE, M.D., Ph.D.

Radium Treatment of Cancer of the Mouth. A. Santoro. Radiol Med, January, 1931, XVIII, 115-128. (Reprinted from "Cancer Review" by permission)

This is a report, with clinical histories, of eighteen cases treated for from four to twenty months. Clinical cure is claimed in twelve cases (though, of course, all are much too recent to be worth reporting). The technic varied according to the site of the tumor (contact application, external radiation with wax-modelled applicators, needling, combinations of these with X-rays, and diathermo-coagulation).

F. CAVERS, D.Sc.

Radium in the Treatment of Carcinoma of the Uterine Cervix W Neill. Med Jour and Record, 1931, CXXXIV, 74-76. (Reprinted from "Cancer Review" by permission)

The value of radium treatment for carcinoma of the cervix is now well known and the results obtained in both early and advanced cases are superior to those of any other treatment. The efforts of the American Society for the Control of Cancer have undoubtedly accomplished something towards the education of the public as regards the early symptoms of this disease. Before radium treatment is commenced a very careful examination should be

CHEMICAL ABSTRACTS

The Use of X-rays in Petrography of Bituminous Coal H Winter Glückauf, 1931, LXVII, 1105-1111

The nature and distribution of ash in pulverized coal are shown by the roentgen-ray method. An improved procedure is described in which an ionization chamber and gold leaf electroscope are used. Means are provided for accurate standardization of the ionizing current, and instantaneous readings of the rate of discharge of the electroscope are obtained by means of a Siemens charge meter. Since the nature of the ash in coal affects the degree of penetration of the rays, accurate determination of the amount of ash present is possible only when its chemical composition varies only slightly from sample to sample as is the case with different samples of coal from the same mine.

CHEMICAL ABSTRACTS

SINUSES (DIAGNOSIS)

Further Studies in the Use of Iodized Oil (Lipiodol) in the Diagnosis of Maxillary Sinus Disease, with a Report of 225 Cases E L Whitney and H P Doub Jour Michigan St Med Soc, February, 1931, XXX, 72-77

In the borderline cases, iodized oil is of greatest value in determining the type and extent of the pathology, in ascertaining anatomic variations.

With the patient in upright position, under anesthesia with 10 per cent cocaine, sinuses are injected using a 16 gauge needle for the puncture. Lipiodol is diluted with two parts petrolatum. After injection, until the oil is seen returning over the inferior turbinate, a moist piece of cotton is placed in the region of the inferior meatus and the patient sent to the X-ray Department, where films are made in all the standard positions, with progress films to check the emptying time. In the normal antrum, the opaque shadow will be the size and shape of the bony contour of the sinus, pathologic variations shown will be thickened membrane, polyps, and other

tumor growths. The emptying time is being given increasing attention.

Lipiodol examination agreed as to the presence of pathology in 96 per cent of the operated cases, while sinus washing was dependable in only 56 per cent.

W W WATKINS, M D

The Radiography of the Accessory Nasal Sinuses A New Standardized Technic for the Exact Projection of All the Accessory Nasal Sinuses, Together with the Demonstration of Fluid Levels H Graham Hodgson Brit Jour Radiol, September, 1931, IV, 421-431

Since the use of "nose-chin" or "forehead nose" positions obviously will not give constant relationship of various bony landmarks of the skull in sinus radiography, the author has resorted to the use of a specially constructed upright head clamp attached to a vertically mounted Bucky diaphragm. A large metal protractor is used for obtaining constant angles between the central ray from the tube and the orbito-meatal line.

Six positions are routinely used: (1) The occipito-frontal, with the orbito-meatal line perpendicular to the film and the rays centered over the external occipital protuberance (petrous bones thrown into orbital spaces, hence projection closely simulates the Granger position) for maxillary sinus study, (2) the occipito-mental, with the head tilted backward 45 degrees, which throws the petrous bones inferior to the antra and shows the anterior ethmoid cells projected above the posterior ethmoids, (3) the vertico-mental view, with the head tilted back to the maximum and the tube now tilted downward so that the central ray will pass exactly vertically through the vertex of the skull, for sphenoid study, (4) and (5) the right and left oblique views, with the head tilted backward 39 degrees and rotated 39 degrees to right and left, thus projecting the posterior ethmoids into the corresponding maxillary sinus, and (6) the simple true lateral.

By making all examinations with the patient sitting up, low fluid levels in the antra can be readily identified which might be entirely missed with the patient in the prone posture. (Of such cases, 5 per cent may be clinically normal antra, in the author's experience.)

THE PHYSICAL FOUNDATION OF GRENZ-RAY THERAPY¹

By OTTO GLASSER, PH.D., Cleveland Clinic Foundation, CLEVELAND, OHIO

ABOUT six years ago, Dr Gustav Bucky invited me to work with him on the investigation of the physical and clinical foundations of over-soft roentgen rays, which he had just introduced into practical use. We attempted to determine the wave lengths of the soft rays used by Dr Bucky and to devise practical methods of measuring the quality and quantity of these rays, publishing the results in various papers, including those in the *American Journal of Roentgenology and Radium Therapy* (1), and also in Dr Bucky's book (2).

Although considerable progress has been made in the past few years (3) in the clinical application of Grenz rays, the physical foundations have essentially remained the same. In the following presentation, therefore, some of the old data will necessarily be repeated and the few new developments will be added.

During the past few years the name "Grenz," or border, rays has been used more and more in the literature to designate roentgen-ray beams of an average wavelength of about 15 to 25 Ångstroms, or of half value layers of 0.015 to 0.03 mm of aluminum. Although from the biologic and clinical points of view the term "borderline rays" has its justification, it must be emphasized here that physically these rays form

only a small part of the large spectrum of roentgen rays which has been known for many years.

GRENZ-RAY APPARATUS

A Grenz-ray apparatus is shown in Figure 1. The main transformer, the filament transformer, and the Grenz-ray tube are contained in a separate shock-proof box (B) which is suspended on a stand and can be easily adjusted. The tube acts as its own rectifier. The switchboard (A) contains the autotransformer and resistance control, a milliammeter, a voltmeter, and also a water pump which forces water through the cooling device of the tube. One side of the transformer, usually that which supplies current to the water-cooled electrode, is grounded.

Well known European types of Grenz-ray apparatus are manufactured by Siemens-Reiniger-Veifa, of Berlin, Sanitas, of Berlin, Koch and Sterzel, of Dresden, Seifert, of Hamburg, and Sommer, of Vienna. These types are all practically the same, that is, the control board, the transformer, and the tube are all mounted on one easily movable stand.

GRENZ-RAY TUBES

In previous publications we described the commercial tubes (manufactured by C H F Muller, of Hamburg, and by Siemens-

¹Read by A. W. Erskine, M.D. for the author as part of the Symposium on the Grenz Ray before the Radiological Society of North America at the Seventeenth Annual Meeting at St. Louis Nov. 30-Dec. 4, 1931

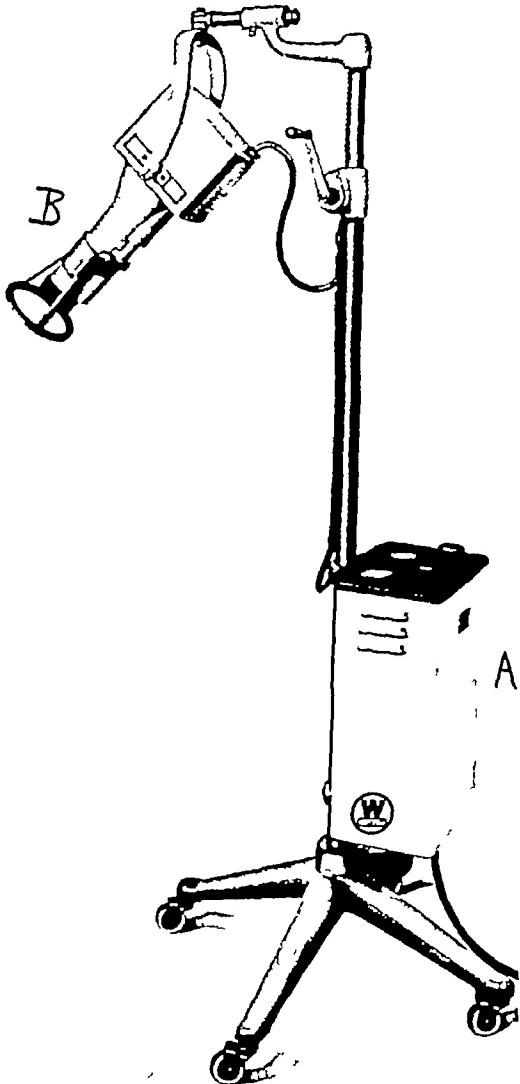

Fig 1. Westinghouse Grenz-ray apparatus. (A) switchboard, (B) transformer and Grenz-ray tube

Reiniger-Verfa, of Berlin), which are still in use to-day (Fig 2, B and C). We also described a tube made entirely of lithium glass, which was constructed in the laboratories of the Cleveland Clinic Foundation. At that time we called attention to the fact that this tube did not yet compare favorably with the commercial Grenz-ray tubes, since the transmission rate of the lithium glass used by us was less than that of the Linde-

mann glass used in the commercial tubes. We, therefore, abandoned the construction of lithium glass tubes and turned to another method in which we attempted to avoid the use of the Lindemann window. It must be remembered that the materials of which the Lindemann window is composed, namely, boron, beryllium, and lithium, are of low atomic weight and, therefore, easily permit the transmission of very soft rays. On the other hand, the Lindemann window must be rather thin (about 0.3 mm.) and, since it is slightly hygroscopic, it is not stable. Since it deteriorates in time unless it is carefully protected by a covering of lacquer, an attempt was made to obtain the same radiation transmission with a more stable window. Following the idea of the thin glass window used by Slack in his cathode-ray tube, we built a Grenz-ray tube with the same type of window (4). The tube itself, with the exception of the window, is built on the same principles as that made by the C H F Muller Company (Fig 3). The window is a very thin bubble of glass which is drawn into a larger glass sphere. According to our tests, the filtering action is about the same as that of the Lindemann window of the Muller tube, but the glass window is more stable and does not deteriorate with time. This construction easily prevents damage to the window and also offers good resistance to the atmospheric pressure.

Shortly after the construction of our tube and the publication of our article in *Strahlentherapie*, an advertisement of the Westinghouse X-ray Company appeared in the *Journal of the American Medical Association* (June 1931, XCVI, 7), describing a new Grenz-ray tube, built on the same principle as ours, on which scientists of the Westinghouse X-ray Company had been working independently for some time. This Westinghouse Grenz-ray tube (Fig 4), the Siemens, and the Muller tubes are the only commercial Grenz-ray tubes on the market at the present time.

SPECTRUM OF GRENZ RAYS

Grenz rays are roentgen rays of a wave length in the neighborhood of 2 Å U, which are produced by the special tubes just described. Because of the low potential used

Grenz rays produced at various voltages as calculated by Kustner (9) are shown in Figure 5. Additional spectral distributions of Grenz-ray beams have been reported elsewhere (1, 2, 6, 9). It is interesting to study the spectral distribution as well as the

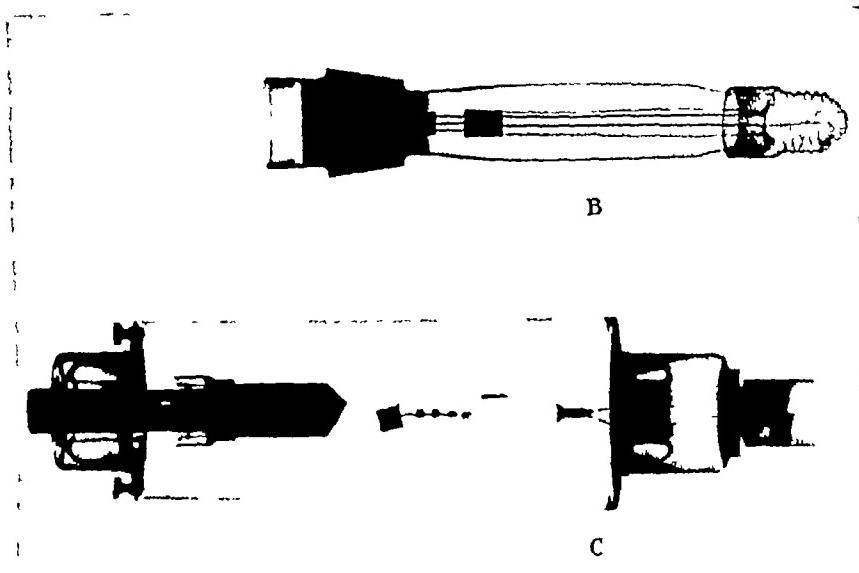

Fig 2 (B) Müller Grenz-ray tube, (C) Siemens Grenz-ray tube

(around 10 KV), the spectrum is limited to about 1 Å U at the short wave end. These short wave lengths have very characteristic properties, described in detail in earlier publications (1-8), which are important in therapy and must be discussed briefly here.

As Grenz rays are extremely soft, their quality and quantity depend very much upon the thickness of the glass or Lindemann glass window, and also upon the layer of air between the tube and the skin, or measuring instrument. The spectral distribution of the Grenz-ray beam, and therewith its quality, on the one hand, will change with various thicknesses of windows and with various focal skin distances, the relative intensities of Grenz-ray beams, on the other hand, will not follow the law of inverse squares of distance.

Curves of the spectral distribution of

rapid decrease in intensity for decreasing voltages. The absorption of Grenz rays in a Lindemann window and in air can be calculated for various wave lengths by means of the following formula (9)

$$\mu_{\text{air}} = 0.00331 \lambda^3 + 0.00022$$

$$\mu_{\text{Lindemann}} = 5.0 \lambda^3 + 0.04$$

where μ is the coefficient of absorption and λ the wave length in Ångstroms. These absorption coefficients permit the calculation of the absorption of the window and of air for various wave lengths.

TABLE I

| K.V | Thickness of Lindemann windows in millimeters | | |
|-----|--|-------|-------|
| | 0.04 | 0.20 | 0.40 |
| 6 | 40.7 | 0.074 | 0.013 |
| 8 | 118.0 | 34.3 | 0.14 |
| 10 | 256.0 | 100.0 | 49.2 |

These data show the great influence of the thickness of the tube window and air

layers upon the qualitative and quantitative distributions of the rays. It follows, therefore, that in order to obtain a correct estimate of the quality and quantity of Grenz rays at a given point, for instance, for the application of a certain dose, it is necessary that this determination be made at the point of the application of the rays. We shall, therefore, employ the half value layer in aluminum to indicate the radiation quality, and the number of roentgen units per minute to indicate the intensity of the radiation. In addition we shall specify the kilovoltage,

stated, it is advisable to supplement the direct method of determination of quality

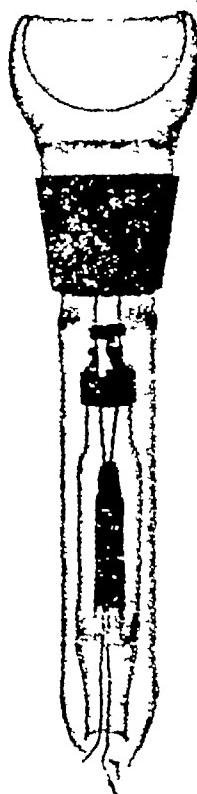

Fig. 3 Grenz-ray tube with Slack window

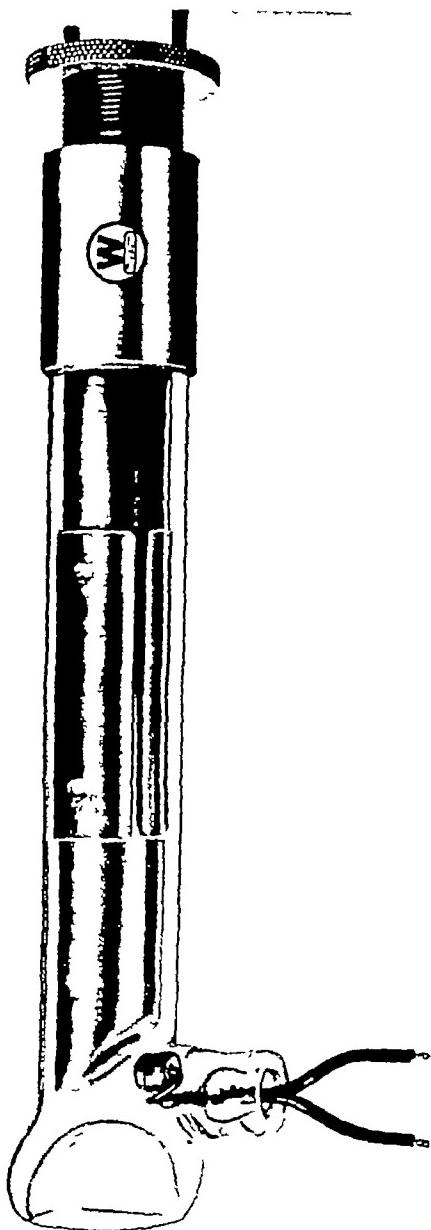

Fig. 4 Westinghouse Grenz-ray tube

the milliamperage, the tube, the target material, and the focal distance.

DETERMINATION OF QUALITY OF GRENZ RAYS

(A) *Indirect Method*—As we have just

by the so-called indirect method, which consists in giving the secondary voltage and current and specifying the tube, target material, and focal skin distance used. The switchboards of all types of Grenz-ray

apparatus mentioned above are equipped with a kilovolt meter, that is, a voltmeter which is connected across the primary of the transformer. The voltmeters are calibrated in kilovolts in the factory by various methods. Whenever feasible, it is advisable

gap. In order to avoid mistakes, secondary voltages should always be given in peak and not in effective voltages. The secondary current is read on a milliamperemeter which is also mounted on the switchboard of the Grenz-ray apparatus.

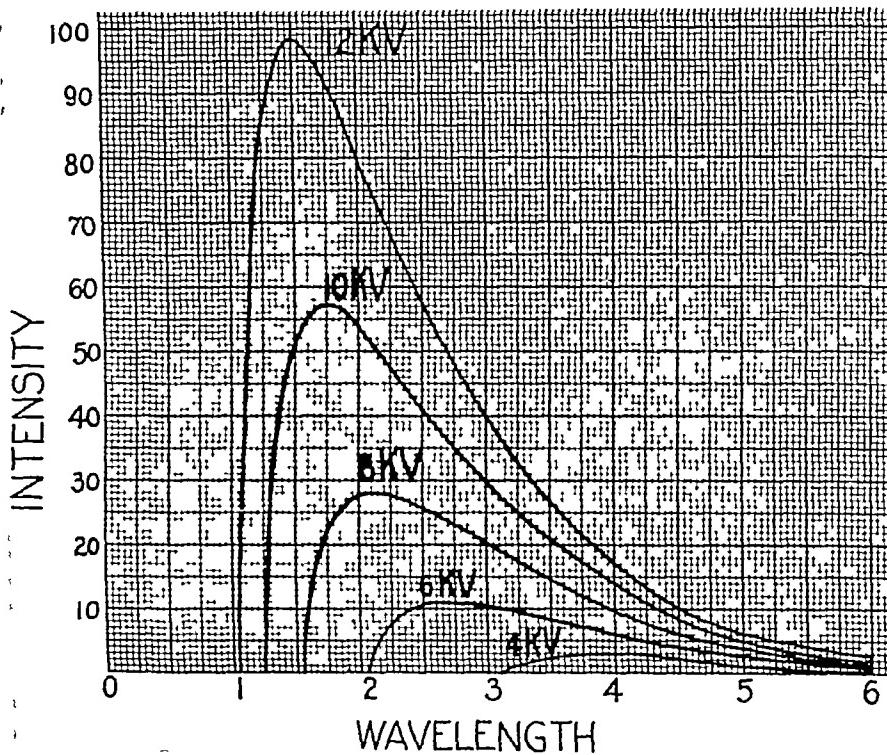

Fig 5 Spectrum of Grenz-ray beams produced at various voltages (Kustner)

to recalibrate these meters from time to time by means of sphere gaps or spark gaps. Better than sphere gaps are electrostatic voltmeters which are reliable and can be easily procured for the voltages used in Grenz-ray therapy. It is not sufficient, however, to connect the gap right across the terminals of the Grenz-ray tube since in practically all Grenz-ray apparatus the negative phase of the current is not suppressed. This negative phase usually is higher than that which reaches the tube and must, therefore, be excluded by means of a valve tube which must be included in the secondary circuit connected in series with the sphere

(B) *Direct Method*—In addition to the data described in the preceding paragraphs it is advisable to indicate the radiation quality by direct means. A number of years ago we suggested the use of the half value layer in aluminum to specify radiation quality in Grenz-ray therapy. This half value layer can be determined satisfactorily by means of the ionization dosimeter which will be described later. In our measurements we used pure aluminum foil of 0.0125 mm thickness as an absorbent material. Cellophane, as well as other substances, has been suggested for this purpose. We found, however, that aluminum was supe-

rior to other materials since it can be obtained in uniform thickness and does not show the variations in absorption due to impurities or irregularities in composition inherent in most other materials. Further-

from the focus to the chamber. For the sake of comparison, in addition to the curves obtained with the Muller Grenz-ray tube at 4, 5, 6, 8, 10, and 12 K.V., an absorption curve is illustrated which is ob-

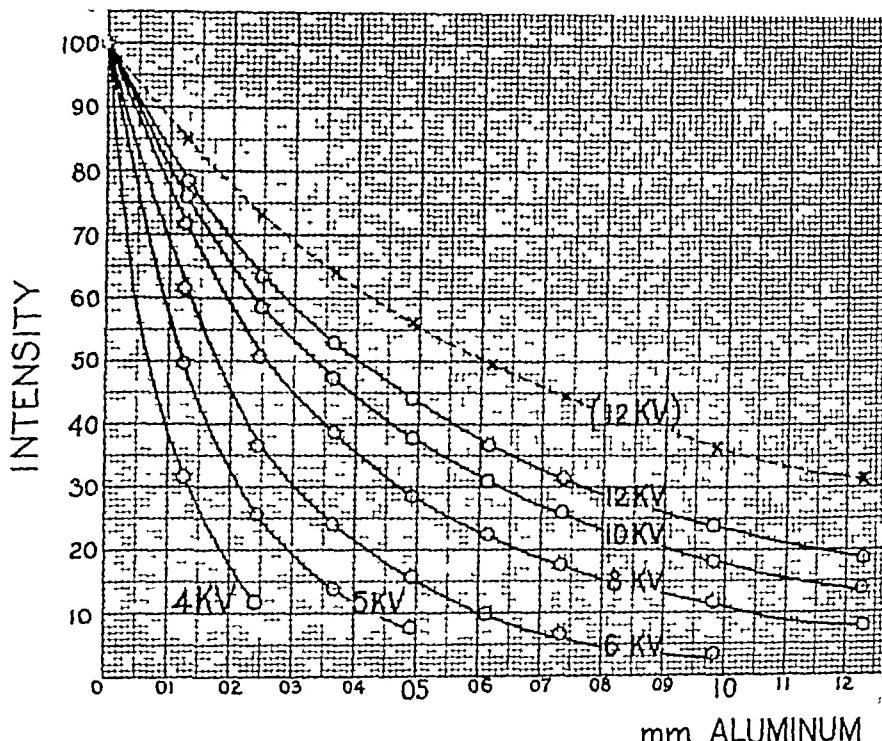

Fig 6. Absorption curves for Grenz rays produced at various voltages.

more, some of the other materials are hygroscopic and, therefore, change with time.

Complete absorption curves on Grenz rays produced at various voltages have been described (1, 2), and the more important data are again reproduced (Fig 6). The various intensities were measured with a specially constructed ionization chamber, made of goldbeater's skin and having a volume of 1 cubic centimeter. This chamber measures the radiation intensity independently of the wave lengths over the range used in Grenz-ray therapy. The curves were obtained with a Muller tube, the distance from the window to the chamber being 4 cm, that is, 9.6 cm

tained by means of an ordinary Coolidge tube operated at 12 kilovolts. As we have stated, these curves hold only for the special tubes with which they have been measured; they may be quite different for other tubes. Furthermore, the quality distribution measured would be different if the measurements had been made at greater distances since the air would act as a filter and "harden" the Grenz-ray beams. We have previously discussed this effect and further extensive experimental data regarding it were recently presented by Meyer (10), using filters of 0.01, 0.013, 0.018, 0.025, 0.031, and 0.035 mm aluminum and a Sie-

mens integral dosimeter with a Grenz-ray chamber. This author also called attention to the fact noticed by others (3, 6, 11) that, due to the filtering effect of the sputtered tungsten on the window of the tube, Grenz-ray tubes harden with use. For this reason, it is necessary to repeat dosage measure-

ments on Grenz-ray tubes at least after every 100 hours of use.

It must be mentioned here that some authors believe that the half value layer method of indicating radiation quality for Grenz rays is not necessary, and that indirect factors indicating the quality are

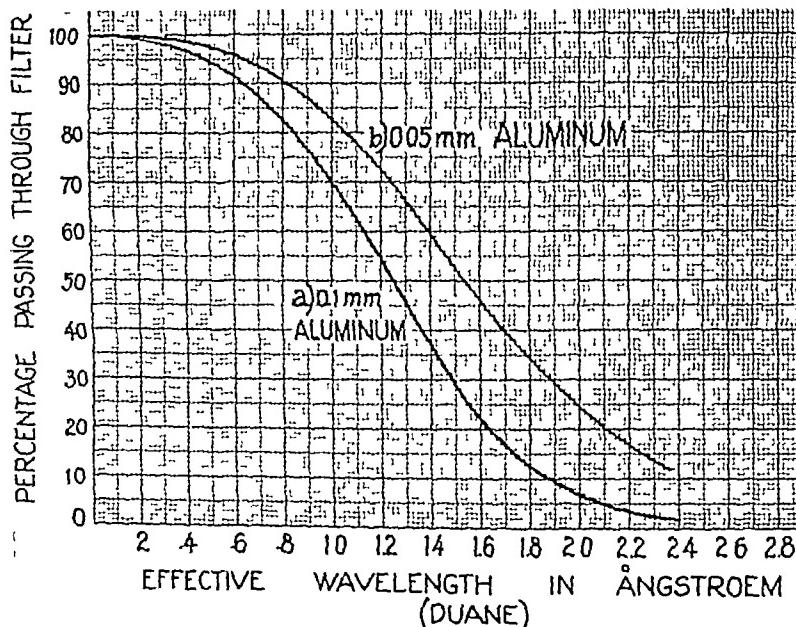

Fig 7 Curves for the determination of the effective wave length for Grenz rays (Duane)

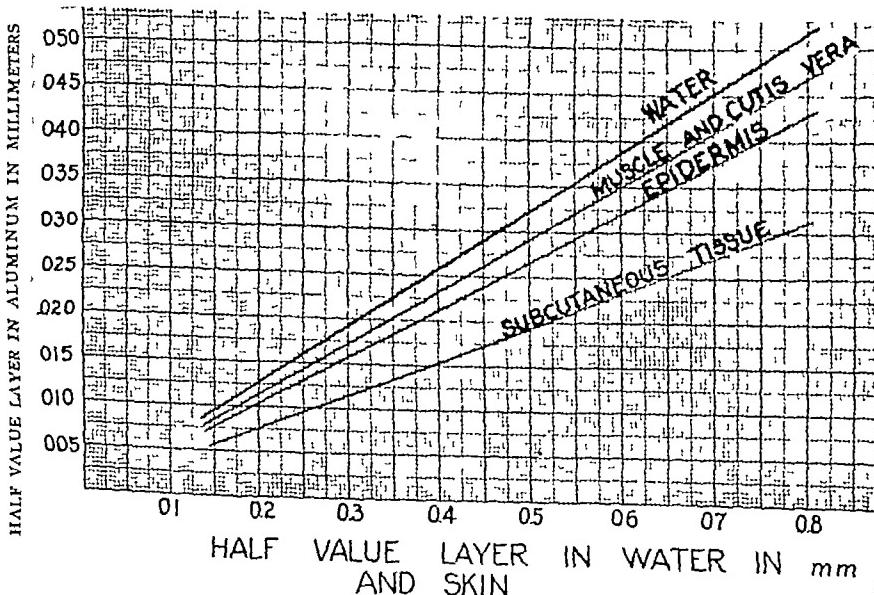

Fig 8 Half value layer in aluminum as opposed to half value layer in water and various parts of the skin

entirely sufficient. However, on this point opinions are divided and controversies have arisen (12).

Berger (13), who at first was against the use of the half value layer, has since con-

tinued to use it and has recommended it as directly calibrated in respective thicknesses. In our opinion, the determination of the half value layer is indispensable in Grenz-ray therapy.

Another method of indicating radiation quality is the effective wave length method suggested by Duane (14). This has also been discussed previously and various data have been reported (1, 2) on the effective wave lengths of Grenz-ray beams (Fig 7). We shall, therefore, not go into this question again especially since, in 1931, the International Standardization Committee at the Third International Congress of Radiology suggested that the roentgen-ray beams be characterized by the half value layer.

ABSORPTION OF GRENZ RAYS IN THE HUMAN SKIN

Formerly we presented half value layers for various layers of the human skin in combination with the half value layer in water and aluminum. The most important data in this connection are contained in Table II, which gives an idea as to how far the Grenz rays of various half value layers penetrate into the skin (Fig 8).

TABLE II—HALF VALUE LAYER IN ALUMINUM AS COMPARED WITH HALF VALUE LAYERS IN WATER, MUSCLE, CUTIS VERA, EPIDERMIS, AND SUBCUTANEOUS TISSUE (IN MILLIMETERS)

| Alu minum | Water | Muscle, cutis vera | Epi- dermis | Subcu- taneous tissue |
|--------------|-------|--------------------------|----------------|-----------------------------|
| 0.007 | 0.12 | 0.13 | 0.14 | 0.20 |
| 0.0125 | 0.20 | 0.22 | 0.24 | 0.33 |
| 0.0175 | 0.28 | 0.31 | 0.34 | 0.46 |
| 0.0250 | 0.39 | 0.43 | 0.47 | 0.64 |
| 0.0335 | 0.52 | 0.57 | 0.62 | 0.86 |
| 0.0400 | 0.62 | 0.68 | 0.74 | 1.02 |

It is interesting to compare the absorption of the Grenz rays in skin with that of roentgen rays usually employed in dermatology.

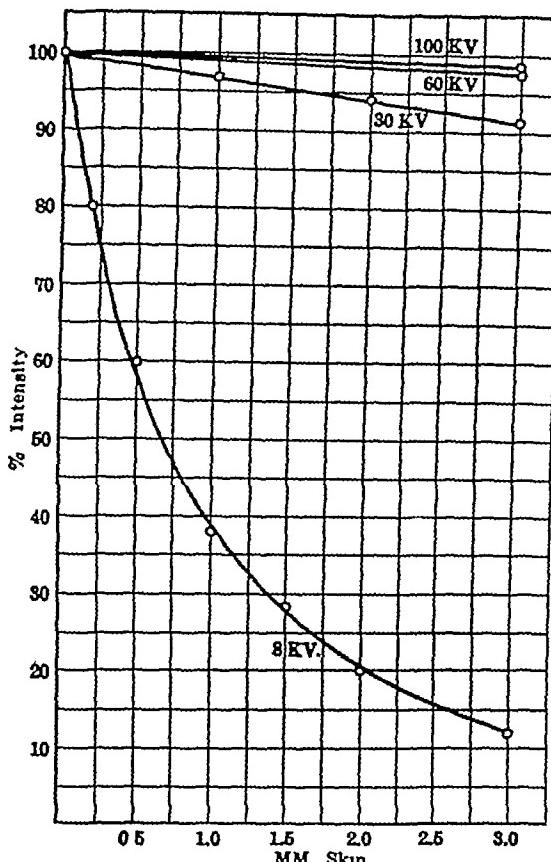

Fig 9. Comparison of the absorption of Grenz rays and harder roentgen rays in the skin.

structed a practical little apparatus to measure it. The apparatus consists of an aluminum foil of 0.01 mm thickness which can be rotated around its axis in a small cylinder, the latter being placed between the Grenz-ray tube and the ionization chamber. The Grenz rays, which first pass through a small diaphragm, must penetrate different thicknesses of aluminum foil, depending upon the angle between the foil and the path of the rays. A pointer connected to the foil permits the reading of the angle on the outside of the apparatus on a scale which

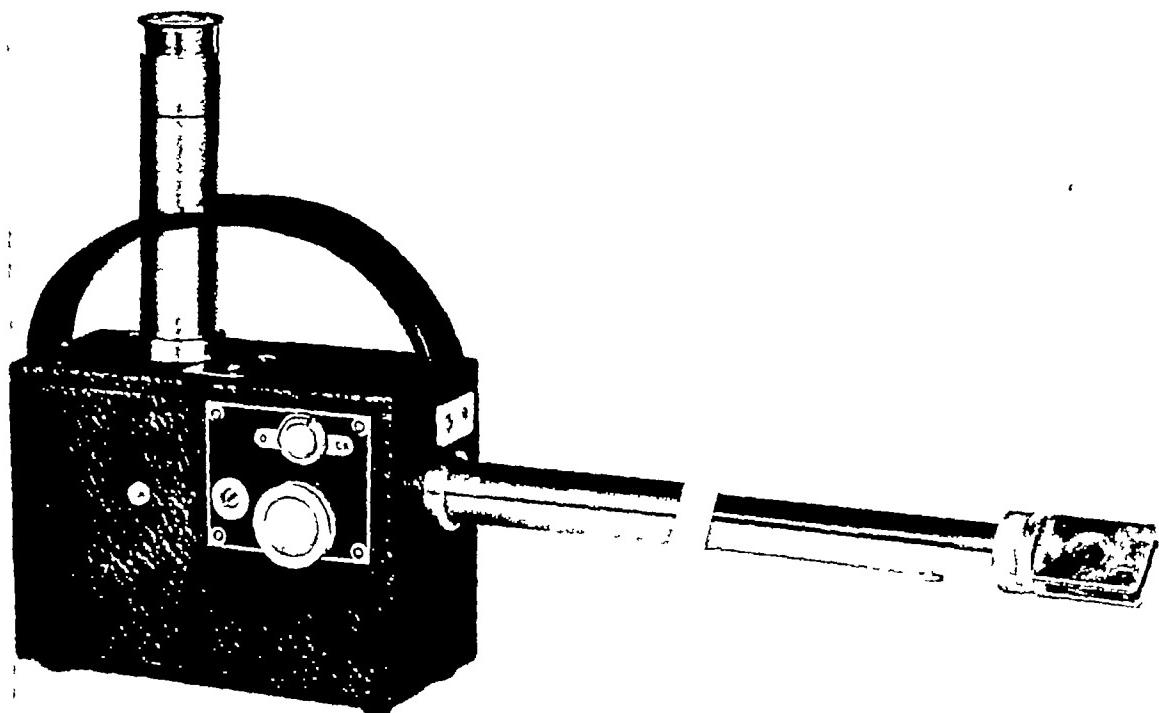

Fig. 10 Victoreen r meter with Grenz-ray chamber

Only a very low percentage of roentgen rays produced at about 100 KV are absorbed by 1 mm of skin, while over 50 per cent of Grenz rays produced at 10 KV are absorbed by 1 mm of skin. This is illustrated in Figure 9, taken from Bucky's book (2).

DETERMINATION OF THE QUANTITY OF GRENZ RAYS

(A) *Indirect Method*—The indirect method of measuring the quantity of Grenz rays by means of the milliamperemeter has been found to be unsatisfactory. The intensity delivered by various tubes for the same number of milliamperes varies widely. The Grenz-ray apparatus also must be calibrated at various voltages for various milliamperages, since the secondary current changes if the voltage is changed. It is, therefore, advisable always to use the same milliamperage for a given voltage. It is still better, however, to measure the quantity

of radiation by the direct method at the point of application.

(B) *Direct Method*—The quantity of Grenz rays is best determined by, and expressed in, the international roentgen unit, the definition of which, as well as the methods of determination, has been described frequently. A few years ago we modified our apparatus for the determination of the r unit in order to use it for the soft Grenz rays (1). Since that time we have calibrated in roentgen units specially constructed dosimeters with small ionization chambers and our calibration compares favorably with that of others. Originally we used 1 cc chambers built entirely of goldbeater's skin. However, we found that this construction was not stable enough for practical purposes and changed to a small metal ionization chamber with windows of goldbeater's skin (Fig. 10). It may be used in connection with any dosimeter, in the illustration, for instance, it is

connected to a Victoreen r meter. This instrument has proven to be very practical and satisfactory for dose measurements with Grenz rays as well as with roentgen rays, since the intensity of Grenz rays may be

employed, all absorption measurements described above, and the dose measurements to be described later, were made by means of our calibrated goldbeater's skin chamber. Photographic films have been suggested

measured at the point of application of the rays.² Similar instruments have been constructed by Kustner, in Gottingen, by Siemens, in Berlin, and by Strauss, in Vienna.

Since it was found to be sufficiently accurate on account of its independence of the wave lengths within the range of Grenz rays

for dosage measurements in Grenz-ray therapy (15), but the difficulties involved would seem to be too great to permit of accurate results. This observation is borne out by a controversy between the originators of the method and Reisner (16). Another dosage method which we have used with good success is the photometer (17). DOSE MEASUREMENTS ON GRENZ RAYS IN PRACTICAL USE

In his latest papers, Bucky suggests the use of Grenz rays of half value layers of

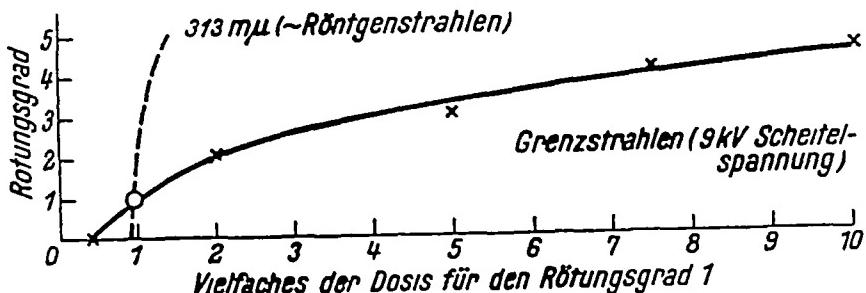

Fig 12 Comparison of the degree of redness of the skin after application of increasing doses of roentgen rays and of Grenz rays (Hausser and Schlechter) Rotungsgrad degree of erythema Vielfaches der Dosis für den Rötungsgrad I multiple of the dose to produce one degree of erythema

to a considerable degree, therefore, only direct determinations of the radiation quality and quantity at the site of application are found to be satisfactory. These data should be accompanied preferably by an indication of the kilovoltage, the milliamperage, the type of tube, the target material, and the focal skin distance.

The absorption of Grenz rays in aluminum foil of 0.125 mm thickness has been determined for different conditions of radiation and the half value layers of this radiation are found to be between 0.04 and 0.01 mm of aluminum.

Data for translating half value layers of aluminum into half value layers of air, water, muscle, and various parts of the skin are given.

A small ionization chamber of goldbeater's skin, which is practical for dosage measurements in Grenz rays and is calibrated in roentgen units, is described. This chamber may be connected to any ionization dosimeter and the radiation intensity of Grenz rays may be measured independently of the wave lengths over the range used in Grenz-ray therapy. By means of this goldbeater's skin chamber the intensity of Grenz rays has been measured in r per minute for a number of radiation conditions, having been found to vary between about 400 r per minute and 0.5 r per minute.

The threshold erythema dose for Grenz rays is in the neighborhood of 250 r units. The increase of the physiologic effect of Grenz rays upon the skin with increasing dosages is much smaller than it is for roentgen rays.

In Table IV are presented various Grenz-ray intensities in roentgen units

Figure 11 shows more data on Grenz-ray intensities for various focal distances and various voltages as published recently (10). The data show that the intensity decreases rapidly with decreasing kilovoltage and increasing distances. We have stated previously (1, 2) that it is difficult to fix erythema doses for Grenz rays and have made the suggestion that the value of 250 r units be accepted as a threshold erythema dose. Further experiments have shown that this value is approximately correct. Haussner and Schlechter (21) presented data on measurements of erythema doses with Grenz rays as compared to erythema doses produced with roentgen rays and have shown that the increase in the biologic reaction with increasing doses is much slower for Grenz rays than for X-rays (Fig. 12). Finally, attention must be called to the difficulty in radiating larger skin areas with the ordinary type tube, since at 4 cm distance the diameter of the irradiated area is only about 4 centimeters, and there is a marked decrease in intensity in this area from the center toward the periphery. For practical treatments careful planning (22) of the combination of various areas has to precede

the treatment for a typical case this is illustrated in Figure 13.

SUMMARY

Grenz rays are soft roentgen rays having a wave length of from 1 to 3 Ångstrom units. They are produced in tubes with Lindemann glass or specially constructed windows of ordinary glass with voltages of from 6 to 10 kilovolts.

High tension apparatus and tubes for the production of Grenz rays are described.

Grenz rays are so soft that they are absorbed in the window of the tube and air

to a considerable degree, therefore, only direct determinations of the radiation quality and quantity at the site of application are found to be satisfactory. These data should be accompanied preferably by an indication of the kilovoltage, the milliamperage, the type of tube, the target material, and the focal skin distance.

The absorption of Grenz rays in aluminum foil of 0.125 mm thickness has been determined for different conditions of radiation and the half value layers of this radiation are found to be between 0.04 and 0.01 mm of aluminum.

Data for translating half value layers of aluminum into half value layers of air, water, muscle, and various parts of the skin are given.

A small ionization chamber of goldbeater's skin, which is practical for dosage measurements in Grenz rays and is calibrated in roentgen units, is described. This chamber may be connected to any ionization dosimeter and the radiation intensity of Grenz rays may be measured independently of the wave lengths over the range used in Grenz-ray therapy. By means of this goldbeater's skin chamber the intensity of Grenz rays has been measured in r per minute for a number of radiation conditions, having been found to vary between about 400 r per minute and 0.5 r per minute.

The threshold erythema dose for Grenz rays is in the neighborhood of 250 r units. The increase of the physiologic effect of Grenz rays upon the skin with increasing dosages is much smaller than it is for roentgen rays.

Electron Particles Again Break up into Waves—Repetition by a modified method of the epoch-making experiments which first proved that electrons can behave as waves, has been reported by Dr C J Davisson and Dr L H Germer, who won fame some years ago by their pioneering experiments

A stream of electrons moving at high speeds was directed at a nearly glancing angle towards an etched metal surface, and caught on a photographic plate where the diffraction rings formed showed that the electrons behaved like light waves. Previously untried metals and a new method devised by Prof G P Thomson, of the Imperial College of

Science and Technology, in London, were used in the recent experiments. Patterns of about twenty rings were obtained in the new experiments of Dr Davisson and Dr Germer from the metals gold, tungsten, molybdenum, cobalt, nickel, chromium, and platinum. The arrangement of the rings was characteristic of the known structure of the metals.

For some metals, etching with acid or standing in the air caused a change in the pattern.

A narrow pencil of light rays directed at a fine grating or a pencil of X-rays hitting a crystal surface produce similar "diffraction" patterns, it was explained, because of their wave-like nature.—*Science Service*

TREATMENT OF SUPERFICIAL FUNGUS INFECTIONS WITH THE LONG WAVE LENGTH ROENTGEN RAYS (GRENZ RAYS) FURTHER OBSERVATIONS¹

By MAURICE DORNE, M.D., and CLEVELAND WHITE, M.D., CHICAGO, ILLINOIS
From the Departments of Physiotherapy and Dermatology of Northwestern University
Medical School

INTRODUCTION

THE prevalence of the superficial fungus infections (ringworm) is now generally recognized, even to the extent of being accorded second place (1) in the order of incidence of the most common skin diseases. This steady increase in prevalence during the past few years has been considered by many to be apparent only because of our better knowledge of the disease, and, as a result, our greater skill in recognizing its characteristics. However, a careful survey of the statistics from various countries is rather convincing proof that this increase is actual.

The increasing recognition of the importance of the superficial fungus diseases has stimulated research and observation in all of its clinical and laboratory phases, resulting, with the exception of therapy, in numerous valuable advances. Every dermatologist in particular, and every clinician in general who treats these cases, has his own favorite remedy, with the result that innumerable drugs, almost every available therapeutic physical agency, and various combinations of different methods have met with but partial success, which has tended to reveal the refractoriness to treatment of this disease.

The rapidly accumulating literature on Grenz-ray therapy, even up to now, has failed to reveal any concerted effort in the treatment of these infections, regardless of the fact that they are primarily localized in the epidermis and that most of the radiation of Grenz rays is absorbed by the epi-

dermis and upper layers of the derma. It was felt that, if Grenz rays offered any possibilities in dermatology, one excellent opportunity to determine their possibilities was in this particular field, and so it was decided to give Grenz-ray therapy a thorough clinical trial.

ETIOLOGIC ASPECTS

Research into the etiologic aspects of the superficial fungus infections has revealed the fact that the manifold cutaneous expressions may be the result of the action of all three classes of micro-organisms, *Hypomyces*, yeasts, and bacteria (2), with the yeast assuming as much importance as the others.

Efforts to classify fungi satisfactorily have resulted in considerable confusion, different workers often using different bases. Therapy has suffered as a result of this, for a simple classification based on the major morphologic characteristics might be of far greater value to the clinician and lead to better therapeutic results.

For practical purposes we have classified the fungi into two groups, namely, *Hypomyces* and yeast-like fungi. In the latter group, hyphae, which usually are of the round-cell yeast structure, may be present both microscopically and in culture. This classification is used advisedly, for Draper (3) has demonstrated that the yeast forms will grow mycelia by certain changes in the media.

Predisposing factors in these fungus infections have attained a position of importance, as is reflected by the special attention given them. Hyperhidrosis is now gen-

¹Read by Dr. M. Dorne as part of the Symposium on Grenz-ray Therapy before the Radiological Society of North America, at the Seventeenth Annual Meeting in St. Louis Nov. 30-Dec. 4 1931

erally admitted as an important predisposing factor, Levin and Silvers (4) obtaining cultures of apparently pathogenic fungi from the sweat in five of eight cases. As pre-existing intertrigo and plantar dysidrosis may predispose to infection with fungi, these possibilities must not be overlooked in therapeutic management. A much disputed point at present is the possible etiologic relationship of yeast forms in various types of dermatitis. One of us (5) has performed a series of successful inoculations of fungus cultures on their respective hosts, indicating a possible pathogenesis in the syndrome known as seborrheic dermatitis, especially of the exudative type and in certain types of infantile eczema.

X-RAY RESULTS AND ATTENDANT DANGERS

Practical skin therapy with X-radiation has been developed by dermatologists such as Sabouraud, Pusev, MacKee, and others. If the radiation is judiciously applied, it is an extremely useful agent in dermatologic practice, being now considered by many as the most useful and successful single remedy available for the treatment of skin diseases. While it is true that X-radiation has proven itself almost specific in the treatment of various cutaneous disorders, it has failed almost completely in others. It cannot be considered a panacea for all skin diseases.

Superficial fungus infections have proven themselves even more refractory to irradiation than to other forms of therapy. Occasionally the infection is permanently cured, very often after the subsidence of the acute symptoms no further improvement is noted, and recurrences are common. It is more or less generally agreed that the majority of the cases will do better under intelligent antiparasitic treatment than under irradiation. Nevertheless, X-radiation is often of value as an adjuvant.

According to MacKee (6), dermatomycosis of the acute vesicular or vesicopustular

and chronic intertriginous types responds much better to properly administered dermatologic treatment. While this is also true of the hyperkeratotic type, some cases do very well under fractional X-ray treatment. Fractional doses are advisable because

(a) Inflamed tissue is hypersensitive to X-rays

(b) The susceptibility is increased by the previous use of strong topical remedies

(c) It has been found that, if the eruption will yield to X-rays, it will respond to small doses.

If the eruption does not disappear as a result of such treatment over a period of from four to six weeks, it is unlikely to be favorably influenced by further treatment.

Filtered radiation is not believed to be more efficacious than are unfiltered X-rays.

EXPERIENCES WITH THE GRENZ RAYS

As stated in our previous communication (7), we employed a special generator for long wave length roentgen rays, designed by the General Electric X-ray Corporation, which delivered a maximum of 12 KV and 12 milliamperes. This was used to activate a specially constructed modified Coolidge tube, made by Muller of Hamburg, in which the Lindemann glass window was situated on the under surface, the entire tube being encased in a metal water jacket.

With this particular apparatus we were able, within twenty-four hours, to produce a mild red blush on the flexor surface of the forearm of a young brunette adult, employing the following factors: 8 KV, 6 ma, 3 inch skin-tube distance, and one minute exposure.

Having determined the erythema dose with our particular apparatus (8 KV, 6 ma, 3 in., 1 min.), we decided to use the fractional method of treatment, adopting one erythema dose as a working unit. Treatments were divided into one-quarter units, or fraction thereof, given at weekly intervals, four treatments constituting a

series. This method of procedure was decided on in view of the fact that we had limited our work to the treatment of the superficial fungus infections. We used such fractional doses at weekly intervals, so that there could hardly be any question as to the safety of the dosage. A few cases have been demonstrated by several dermatologists in which damage to the skin has been produced by erythema doses of Grenz rays. In cases in which large areas were involved, necessitating repeated focusing at each treatment, the dosage was reduced one-half. In several instances, as in the treatment of the nails, the dosage at each treatment was doubled.

In several of our patients, a single one-quarter unit exposure provoked a reaction which was manifested by an aggravation of the original lesions. In most instances these reactions subsided spontaneously within forty-eight hours with a resultant improvement in the lesions. In one instance, the reaction occurred after the second treatment, the first treatment apparently having improved the condition. As the dosage employed in the treatment of all these patients was identical, it would seem that the reactions induced were the results of individual tolerance.

In several instances following a series of treatments, there were recurrences of the original lesions. These were always milder than the original condition and responded promptly, as a rule, to the one or two additional treatments.

The first patient treated was a male, 33 years of age, who had a tinea cruris of five years' duration. The lesion disappeared entirely with one treatment of a quarter unit to each area. The next three cases failed to respond, even after three treatments had been administered. At this point in our investigation, a complete check-up of our apparatus was made, revealing the fact that our machine was functioning properly. Following this experience it was decided

that a clinical diagnosis alone was not sufficient indication for this type of treatment and routine smears (the extemporaneous potassium hydroxide preparation) and cultures (Sabouraud's dextrose media) were included in every case. As a result of this routine examination we soon learned that the cases which were positive for *Momilia* and yeast-like fungi responded with good results, while those in which the infections were of hyphomycetic origin showed very little, if any, improvement.

In our original communication (7) we reported 30 cases, to which we now wish to add 22 more. In this latter group our experience has been identical with that in the former group reported.

Two of the patients in this latter group exhibited erosio interdigitalis blastomycetica, the lesions in both instances involving the third interspace on both hands. Potassium hydroxide preparation and cultures revealed yeast. In one instance, topical applications consisting of 0.5 per cent methyl-violet aqueous solution was applied to the lesion on one hand once a week and a 0.25 unit of Grenz ray was given to the lesion on the other hand once a week. It was very interesting to note that improvement occurred in the lesions after two treatments by both methods, the improvement being somewhat more marked in the lesions treated by topical applications.

However, in this connection, the important observation was the fact that yeast was recovered from the lesions and there was a prompt response to therapy. In our original communication we reported an instance of a woman, aged 59 years, with similar lesions, in whom the potassium hydroxide preparation revealed large branching hyphae, but cultures were negative. In this case there was no improvement after four 0.25-unit treatments with the Grenz ray and the patient thought the condition was aggravated if anything.

| Case | Age | Sex | Areas of involvement | Clinical diagnosis | Mycologic findings KOH —cultures | Treatment with Grenz rays | Clinical results |
|------|-----|--------|--|--|--|---------------------------|--|
| 1 | 26 | Male | Intragluteal fold | Pruritus ani | KOH and cultures +++, yeast-like fungi | 0.25 unit | Cleared of symptoms in 72 hours |
| 2 | 31 | Male | Fingers left hand | Epidermomycosis | KOH and cultures +++, yeast | 0.25 unit 0.25 unit | Cleared but recurred in 3 weeks, after further treatment cleared entirely |
| 4 | 38 | Female | Intragluteal fold | Pruritus ani | KOH and cultures negative | 0.25 unit | No improvement, did not return |
| 5 | 31 | Male | Palm of right hand, right fingers | Epidermomycosis | KOH and cultures ++, yeast-like | 4—0.25 | All cleared |
| 6 | 30 | Male | Both axillæ marked, genitocrural, slight | Epidermomycosis | KOH ++, yeast-like | 3—0.25 | Five months previously received 4 X-ray treatments to axilla and 2 to the genitocrural region, but with no improvement. Markedly improved after this treatment |
| 7 | 26 | Male | Fingers and both hands to wrists | Dermatitis venenata with secondary superimposed mycotic dermatitis | KOH ++, yeast-like | 9—0.25 | All cleared |
| 8 | 50 | Male | Fingers and hands with toxic eruption from hands on neck | Dermatitis venenata with secondary superimposed mycotic dermatitis | KOH ++, yeast | 4—0.25 | All cleared |
| 13 | 20 | Female | Scalp, face, neck, axillæ, genitocrural, lower abdomen | Seborrheic dermatitis and mycotic dermatitis | KOH ++, yeast | 8—0.25 to all areas | Cleared after 3 treatments, but recurred. Additional Grenz therapy did not help much, other treatment given |
| 14 | 13 | Female | All fingers and both hands | Epidermomycosis | KOH ++, yeast | 4—0.25 | Marked improvement. Did not return |
| 15 | 25 | Female | Palms and index and middle fingers of the left hand | Dermatitis venenata with secondary superimposed mycotic dermatitis | KOH ++, yeast | 3—0.25 | All cleared |
| 17 | 42 | Female | Left thumb and index, right index and middle fingers | Epidermomycosis | KOH ++, yeast | 3—0.25 | Improved Did not return |
| 18 | 13 | Female | Scalp, face, neck, arms | Seborrheic dermatitis and epidermomycosis | Repeatedly negative for fungi | 7—0.25 | Very marked improvement. Much treatment preceding Grenz therapy |

(Continued on next page)

| Case | Age | Sex | Areas of involvement | Clinical diagnosis | Mycologic findings KOH —cultures | Treatment with Grenz rays | Clinical results |
|------|-----|------------------|---|--------------------------------------|---|---------------------------|--|
| 21 | 42 | Male | Feet and generalized eruption | Epidermomycosis and epidermomytid | First KOH and cultures contaminated. Later KOH and cultures +++ for yeast | 7—0.25 | All cleared |
| 22 | 11 | Female | Dorsum of toes and feet | Epidermomycosis | KOH and cultures +++ for yeast | 1—0.25 | Marked improvement |
| 23 | 42 | Female, pregnant | Toes, both feet, finger nails | Epidermomycosis | KOH and cultures +++ for yeast | 2—0.25 | Improved |
| 24 | 40 | Female | Third digital interspace of right hand | Erosio interdigitalis blastomycetica | KOH and cultures +++ yeast with fermentation | 4—0.25 | Markedly improved |
| 28 | 14 | Female | Toes of left foot | Epidermomycosis | KOH and cultures +++ for yeast | 5—0.25 | Entirely cleared |
| 29 | 40 | Female | Web between middle and ring fingers, right and left hands | Erosio interdigitalis blastomycetica | KOH and cultures +++ for yeast | 3—0.25 | Right hand treated with methyl-violet, left with Grenz rays. Right hand much better, both improved |
| 30 | 20 | Male | Toes and feet | Epidermomycosis | KOH +++ for yeast | 1—0.25 | Improved |
| 32 | 13 | Male | Toes and feet | Epidermomycosis | KOH negative cultures +++ for yeast | 2—0.25 | Improved |
| 34 | 24 | Male | Both feet | Epidermomycosis | KOH negative cultures — <i>Monilia</i> | 1—0.25 | Improved |
| 35 | 30 | Female | Fingers | Epidermomycosis | KOH and cultures +++ for <i>Monilia</i> | 2—0.25 | Marked improvement |
| 36 | 38 | Female | Toes, left foot | Epidermomycosis | KOH and cultures negative | 2—0.25 | Improved |

This substantiates our original observations—that good results were obtained in the patients who presented infections due to yeast-like fungi, while the infections of hyphomycetic origin showed very little, if any, improvement.

Experiences with occupational dermatoses complicated by secondary superficial fungus invasion are too meager to permit any fair evaluation at this time.

CONCLUSIONS

An experience of 22 more cases is added to a previous report of 30 patients who had dermatoses which were considered to be of superficial fungus infection and who were treated with Grenz rays used in fractional doses.

With such dosage, those infections due to yeast-like fungi responded quite uniformly to therapy, while those of hyphomycetic

origin showed very little, if any, improvement.

Further investigation is being actively pursued to determine the full worth of the above observations.

We wish to thank A. W. Stillians, M.D., and J. S. Coulter, M.D., for their many kindnesses in making it possible for us to study these cases and to have access to departmental facilities. We also wish to thank Miss Bertha Culka who has aided us greatly by performing all of the culture work.²

Photographs Record Speedy Atomic Hearts
—World record speeds of hydrogen atomic hearts, pushed along by the pressure of 1,000,000 volts, have been photographed, investigators at the Department of Terrestrial Magnetism of the Carnegie Institution of Washington have announced to the American Physical Society. Their speed was 13,400 miles per second. The high-speed protons, as the hydrogen atom hearts are called, were allowed to plunge into a moist atmosphere in a Wilson cloud chamber and snapshots were taken of the tracks made in the cloud by the rushing atomic projectiles.

The three physicists who did the work, Dr M. A. Tuve, Dr L. R. Hafstad, and Odd Dahl, won the thousand-dollar prize of the American Association for the Advancement of Science, 1930-1931 meeting, for previous high voltage work.

Million-volt protons had been produced and

measured by magnetic means in the same laboratory last year, but this is the first time their paths had been photographed. The speeds, of which the photographs are evidence, are the greatest yet obtained for artificially speeded protons. Protons of somewhat higher speed are produced when naturally produced alpha particles from radium are allowed to bombard paraffin. About one proton is given off for each million alpha particles. Artificial production by the Carnegie Institution method gives much larger quantities of the speedy protons than could be obtained even if large amounts of radium were used.

A high voltage tube of special design was used with a Tesla coil to produce the minute but relatively massive particles, but the three experimenters are now working with the electrostatic generator devised by Dr R. J. Van de Graaff as a better source of even higher voltage electrical current.—*Science Service*

GRENZ-RAY THERAPY¹

By ALFRED REISNER, M.D., FRANKFORT-ON-MAIN, GERMANY

From the Radiological Institute, University of Frankfort-on-Main, Prof H Holfelder,
Director

CREDIT is due to Bucky, who was the first to carry out systematically the idea of using roentgen rays of long wave length (Grenz rays or borderline rays) in the treatment of disease. Since he has published his good results in order to induce other clinicians to give this method a trial, many articles of a more or less critical nature have been written on the subject. An analysis of these publications must include only such papers as are based on accurate physical data, *i.e.*, definite indication of the quality and quantity of the radiation. It is also necessary to ascertain that roentgen rays of long wave length were actually used, in other words, rays produced at a potential not to exceed 10 KV, corresponding to a half value layer in aluminum of 0.03 millimeter. If this limit is exceeded it seems quite possible that the blood vessels of the skin may undergo injury similar to that following exposure to ordinary roentgen rays, particularly if high doses were used. In that case one deprives oneself, of course, of the great advantage of long wave length therapy, namely, the lessening of the danger of late injuries.

A number of late injuries observed can in all probability be explained by this fact or are due to an inaccurate determination of the quality. It is important in this connection to mention the result of an experiment which Fuhs conducted on his own skin. He exposed an area to 4,500 r which two and one-half years later showed very fine telangiectasis in a slightly atrophic skin. The latter had been exposed, however, to

sun rays rather frequently during the summer months.

We are using a half value layer of 0.02 mm Al which is produced on our apparatus with a potential of 10 KV and a tube current of 10 milliamperes. The longer wave lengths in the spectrum are made useful by not exceeding the focal skin distance of 10 cm for local treatment and 15 cm for general body exposures. Epilation was not observed in doses up to 5,000 r, given in one sitting.

The question of the exclusive character of the biologic action of Grenz rays when compared to that of ultra-violet rays and ordinary roentgen rays has never been explained satisfactorily. Holthusen denies a fundamental difference and classifies Grenz rays with the remaining roentgen spectrum. Politzer and Zakovsky did not see any difference between the effect of Grenz rays and that of ordinary roentgen rays on the mitosis of cells. At this point I would like to refer to two observations made by Hummel. He found that Grenz rays in doses up to 10,000 r did not decompose cholesterol or its fatty acid esters in certain solutions, while ordinary roentgen rays do. Nor was an effect seen if cholesterol dissolved in blood serum was exposed to Grenz rays *in vitro*. In my own erythema tests on human skin I noticed that the first visible erythema appeared following doses of from 240 to 480 r, and that up to doses of 2,400 r and more the reaction takes its usual course. If, however, a dose of 4,800 r was applied, a very marked erythema appeared immediately which developed within three days to a pillow-like swelling, led to an intense blue-red discoloration, remained unchanged for al-

J. Van de Graaff as a better source of even higher voltage electrical current.—*Science Service*

eral years in order to ascertain if these cases are permanently cured and if late injuries will appear. In a critique of Grenz-ray therapy one must not forget that, in ordinary roentgen therapy, it is necessary to approach the toleration of the tissue in order to obtain a therapeutic effect. On the other hand, we should remember that other treatment methods are available in *lupus vulgaris*, as, for instance, the Finsen light ointments, and the ultra-violet lamp, from which permanent results can be obtained without injury to the skin.

In the treatment of carcinomatous skin lesions, Grenz-ray therapy is, in our opinion, contra-indicated. X-ray deep therapy and radium treatment lead here to excellent results in so high a percentage of cases that it does not seem justifiable to change from a long proven method to a new and apparently less effective one. Considering the rapid loss of radiant energy when Grenz rays are used, due to the high absorption, even very intense doses will not permit of homogeneous irradiation, which is essential in the successful treatment of skin carcinoma.

Excellent experimental investigations have been carried out by Krasso, Mylius, and Erggelet concerning the effect of Grenz rays on the cornea and lens. When applying the doses used in therapy no injury of the cornea or the lens could be seen even after prolonged periods of observation. When compared with roentgen or ultra-violet rays, the advantages of Grenz rays in the treatment of inflammations of the cornea are obvious. There is no danger of injury to the deeper layers of tissue in the eye and the therapeutic procedure is not only not painful but sometimes is even analgesic.

Bucky also reported good results in local skin diseases treated by general body exposure to Grenz rays. However, none of the clinicians who repeated this work has been able to confirm his claims, although one might expect results in treatment of the

universal eczema with exudative diathesis which is seen in children. A regression in hypertrichiasis following general body exposure could not be brought about in our cases, this is also at variance with Bucky's statements. We have not been able so far to verify the appearance of pigmentation in cases of vitiligo of several years' duration as reported by Bucky and Buschke.

Bucky explains the results by postulating an effect of the Grenz-ray irradiation on the vegetative nervous system and also indirectly on the glands of internal secretion. Great interest was created by the communication of Bucky that polycythemia rubra was improved following general body exposure to Grenz rays, this has been confirmed recently by Schilling. It is remarkable that, while we may be certain these rays cannot reach the bone marrow, a pathologic process originating in the bone marrow and, therefore, usually treated by X-ray deep therapy, is influenced by Grenz rays. It is only possible that an indirect effect can take place *via* the change in the skin. Schilling investigated the findings of Bucky very thoroughly. He could not confirm the constancy of the leukocyte drop following Grenz-ray exposure, but, on the contrary, sometimes saw an increase of the leukocytes. Following irradiation, a definite bradycardia appeared, lasting from 20 to 25 minutes, which was interpreted as being due to a stimulation of the vagus. In patients with hypertonia of various origins there was always a definite drop in the blood pressure 30 minutes after the treatment which, however, lasted only from one to one and one-half hours. In the normal individual the blood sugar dropped, the same reaction was noted in diabetics, while patients with toxic goiter showed an increase. The basal metabolism was not influenced at all. According to the experience of this author, Grenz-ray therapy was of benefit in asthenic patients, in asthma in polycytemia, and sometimes in toxic goiter.

most three weeks, and developed then into pigmentation without producing blisters or ulceration. A skin area of the same size exposed to roentgen rays of short wave length (1,000 r) showed definite blistering after four weeks. This peculiar course of the erythema reaction corresponds neither to the skin reactions seen following ultraviolet exposure nor to those seen after exposure to roentgen rays of short wave length. The former usually disappear much more quickly, while the latter reach their maximum much later or, if they appear immediately, soon lead to blistering or ulceration. A therapeutic effect of Grenz rays on rickets was not observed (Rominger).

From a theoretic standpoint, there are two points of advantage in the treatment of skin diseases by roentgen rays of long wave length. One is the almost complete absorption in the upper layers of the skin which has been proved by absorption measurements, the other is the protection of the deeper layers of the tissue. In addition, there is also the wide margin of safety between the therapeutically effective dose and the injuring dose, which decreases with increasing wave length. In a series of cases of eczema and neurodermatosis in which the lesions were symmetric, we carried out the treatment by exposing one side to Grenz rays and the other side to ordinary roentgen rays. While in the overwhelming majority we saw, in accordance with the observations of Fuhs and Konrad, Spiethoff, and others, an even regression, sometimes there was a preponderance of the effect of Grenz rays. Our single doses very seldom exceeded 240 r and we usually did not have to apply more than 480 or 720 r as a total dose (measured in air). The same can be said in regard to skin diseases during childhood. Rominger states that the universal dry types of eczema, accompanied by considerable pruritus, are the field for Grenz-ray treatment. In all exudative and crustal types of eczema of the

head and face, improvement was seen following Grenz-ray therapy. Psoriasis responds in the same manner as it does following ordinary roentgen therapy, in view of the great absorption of Grenz rays it is absolutely necessary to remove the scales before the exposure. The advantage of Grenz rays in this disease lies in the fact that relatively large areas of the skin can be irradiated without danger, while, if ordinary roentgen rays are used, the possibility of a blood injury increases with the number of exposed fields.

Even if we assume equal therapeutic effects of Grenz rays and ordinary roentgen rays, preference should be given to the former because of the protection of the deeper non-diseased tissue. It is for this reason that Grenz-ray therapy is so suitable for the treatment of skin lesions of the scalp, of the lids of the scrotum, and of the cheeks.

Another type of skin lesion yielding well to Grenz-ray therapy is the dilatation of superficial blood vessels. A nevus flammeus disappeared after 500 r, given during two exposures. Caution is indicated in irradiating acne rosacea in the face. After a very conservative dose of 240 r, a reddening and swelling of the face appeared immediately following irradiation and lasted about eight days, being accompanied by intense itching and burning. As in any other type of radiation therapy, it is imperative to feel one's way in order to arrive at the proper dose and it is always advisable to start with a very small amount of radiant energy.

In tuberculous skin diseases, a heavier dosage is necessary. Most suitable for Grenz-ray therapy is the ulcerating type of erythema induratum Bazin. The publications of Spiethoff show, to judge from illustrations accompanying them, excellent results in lupus vulgaris. The doses used are sometimes extremely high, reaching 25,000 r. It seems advisable however to wait sev-

ranged to build up an apparatus in which to generate the energy to operate them. We have treated a number of superficial skin lesions of the fungus or yeast-like type, but we did not make a microscopic diagnosis in all of these cases. While we have received very satisfactory temporary results from the Grenz ray in some of these lesions, in others we did not see very much improvement. We have made no cures whatever.

At this time, I cannot say if all of our cases were of the hyphae mycetic type. In fact, I do not recall that at that time we made any diagnoses, microscopically, of the yeast-like type, although we studied several, but we did not find the organism. We tried the Grenz ray in psoriasis, but could not see that there was any more benefit from this wave length than from the shorter therapeutic X-rays. In fact, I might say the same thing in regard to hyphae mycetic infections. We finally had to go back to the use of various chemicals.

It is possible that the matter brought out by Dr Dorne can be explained on the basis of the selective action of this special band of rays. That the rays in the roentgen- and gamma-ray fields have no selective action, all acting alike, is, I think, generally conceded by most men working in those fields to-day. Dr Brackett, of the Smithsonian Institution, is not quite convinced that this is so, being rather inclined to think that there is a selective action. However, when we get into the ultra-violet and the visible fields, we are in fields in which there is a very decidedly selective action. In the infra-red field, we see a very selective action. It is possible that in the borderline field we may have a selective action that explains some of the results which are reported from the use of Grenz rays, both locally and constitutionally.

Dr Reisner refers to the treatment of polycthemia and some other constitutional troubles. While I have been inclined to ridicule any beneficial action from these rays in such diseases, I realize that we have to be careful in making judgments.

In treating the whole body, would not the Grenz ray, at a distance of 50 centimeters, be almost entirely absorbed by the air?

Perhaps we cannot figure on any direct depth action of the rays in the skin to account for constitutional results. We must remember that very definite constitutional results, in rickets, etc., are obtained from ultra-violet rays which do not penetrate deeply into the skin. It is just possible that there is a similar action from the Grenz rays.

Dr Reisner stated that, in treating psoriasis, it was necessary to scrape the scales off in order to get results, because of the filtration of the scales. He mentioned 10 KV, but throughout the paper he has not specified whether they were using 10 KV or less. With 8 KV, I got enough penetration through my thumb nail to damage the matrix severely, with 10 KV, I think the damage would have been much more serious. Certainly, using X-rays of 8 KV, the nail did not give much protection to the matrix.

In the case of nevus flammeus, I was much surprised at the author's results with a single dose of about 240 r, however, he has not stated the size of the birth mark or the age of the child. Those factors are very important in the treatment of nevus flammeus by other methods.

When he treats lupus vulgaris with 2,500 r, he is giving a hundred times the erythema dose. I would hesitate to use that much in lupus vulgaris for fear of stimulating malignant epithelial growth.

DR ARTHUR MUTSCHELLER (New York City). In this symposium, so much valuable material has been presented that it would be impossible to discuss each and all of the phases that have been brought out. I think, however, one point was noticeable throughout all these papers, which I believe should be clearly kept in mind for the future.

Dr Glasser brought out the point that there is considerable difference in the various kinds of windows. Theoretically, of course, the composition of the Lindemann glass would be such that it would transmit the long wave length rays better than any other kind of glass. However, the Lindemann windows are not blown, and the thickness of these windows cannot be regulated. Rather, they

It is not indicated, however, in spastic conditions of the gastro-intestinal tract or in any type of anemia. Bucky also reported good results in Grenz-ray therapy of duodenal ulcer and in gastritis, which were confirmed by Levy, Kestle, and Gertz. Most striking in these cases was the relief from pain. Bucky based this treatment of gastro-intestinal conditions on the observation that, following burns of the skin, hemorrhages in the gastro-intestinal canal are sometimes observed. It seems evident that, up to now, our knowledge of the efficacy of Grenz-ray therapy in the treatment of internal diseases is limited; it must be tried out on a large number of cases before we arrive at a conclusion.

SUMMARY

From a study of the world literature and from our own experience with X-rays of long wave length, we may sum up the present situation in this field as follows:

1 The basis for successful Grenz-ray therapy is exact dosage.

2 For the treatment of superficial skin diseases, Grenz-ray therapy offers a valuable addition to our therapeutic armamentarium.

3 While the therapeutic effect is approximately the same as that of ordinary roentgen rays, sometimes it seems slightly superior.

4 The advantage lies in the fact that the deeper layers of tissue are well protected and that the therapeutic dose can apparently be administered without danger of immediate or delayed injuries.

5 In the treatment of local disease, the value of general body exposures to Grenz rays is a very much debated problem.

6 A final judgment as to the effect of Grenz rays on internal diseases cannot be passed at the present, but further investigations in a large number of cases are necessary and seem to be worth the effort.

7 Injuries following Grenz-ray therapy

can apparently be avoided if very soft rays are used and if the smallest dose required for the therapeutic result is administered.

DISCUSSION

DR. ROLLIN H STEVENS (Detroit, Mich.)
It is some four or five years since we received our first Lindemann tubes, and Dr. Pohle ar-

ods we have used, with the idea of not condemning unnecessarily Grenz rays or Bucky's work, until they have been given a very thorough trial

It is true that not enough cases have been treated, nor has the time been long enough really to determine the end-result

At the April meeting of the New York Dermatological Society, Dr George M MacKee presented a case of telangiectasia caused by Grenz rays, treated about three years before presentation to the Society. This has been reported in the November, 1931, issue of the *Archives of Dermatology and Syphilology*, page 926. At this same time Dr Eller stated that he had had six similar cases which developed after three years. I believe that heavy dosage is probably the cause of these reactions. It is my impression that we are the first to concentrate on the fractional doses and I feel that it is important for us to give this a fair trial.

As to the difference of intensity varying with the distance, we noted that immediately upon starting our work It was about ten months or a year before we actually treated anybody. We were not familiar with the apparatus, so we worked out a number of problems in an effort to determine various factors

All our treatments are given alike for distance, in order to avoid the loss of intensity occasioned even by a difference of a fraction of an inch. We constructed a small gauge, by screwing a little plug of wood into the center of a piece of aluminum, which fit snugly against the water jacket surrounding the tube. The tip of the wood measured exactly three inches from the center of the tube. All our skin-tube distances are measured by this means.

As to the treatment of psoriasis and the removal of scales, I think the *modus operandi* is similar to the following when Bucky and Eller first reported their cases, they included a large series of epitheliomas of the eyelids in which they got their best results. In the discussion of that paper, Dr Pusey stated that it was his impression that the rays reduced the epithelioma, layer by layer. Shortly after this, in 1929, Herxheimer and Uhlmann working

in Germany, performed histologic examinations in a series of cases in which the patients were treated with these rays, demonstrating that the effect was limited to the epidermis and did not involve the cutis. The changes they reported occurred following small doses of the rays which, nevertheless, completely sufficed to produce therapeutic results. In the end the small doses reach the deeper layers of the skin by routine radiation. They decided that in this manner they could determine the practical boundaries of the application of this kind of ray. It is my feeling that this may, in a way, explain the question as related to psoriasis. With probably one or two exceptions, we have not attempted to treat psoriasis, and these only as a matter of setting off our routine with the fungus infections.

As to nevus flammeus, in their newly printed book on Grenz rays, Conrad and Fuhs recommend 1,000 r units at five-week intervals. Others advise even three or four times that dosage at longer intervals. These, in my estimation, are rather large doses and just the thing we are trying to avoid until we know more about the sequelæ from Grenz rays. We have just started to treat cases of this type.

Of course, there is much work to be done. Earlier I made the statement that practically every dermatologic entity—there are few exceptions—has been treated by this method by the different workers, with varying results. The impression one gains is that, in many instances, enthusiasm and over-confidence have biased the results, while in other instances prudence and ultra-conservatism have prejudiced the results.

I think that if we follow a conservative course and give the Grenz rays a good trial, they may prove to be of value.

We are continuing our work and are starting on a parallel series of treatments. The cases will all be of the superficial fungus infections. Diagnosis will be made in the same way and similar cases will be treated in parallel groupings. X-ray, Grenz ray, and ultraviolet ray. We hope to be able to add something more to the work already done.

DR ERNST A POHLE (Madison, Wisconsin) I wish only to emphasize one point

are pressed in a mould, and, usually, in order to counteract the effect of possible deterioration by moisture, these windows have been made thicker and thicker. As a result, as a medium for the transmission of X-rays or Grenz rays Lindemann glass has become less and less effective.

Some of the results described, and the doses that are used for certain effects, clearly point out that fact. Dr Glasser found it better to use lithium glass. At the same time that Dr Slack developed the drawn-in window, he also had, independently, the same idea and found better results could be obtained with a drawn-in thin glass window. In other words, the thinness of the window seems to be a distinct advantage over the apparently more favorable atomic composition of the Lindemann window, the constancy of the tubes with drawn-in windows is so far superior that they ought to be the type to be used exclusively in the future.

Comparison of some doses or rather some intensities that are emitted from thin window tubes and some of the tubes with Lindemann windows, shows a very striking difference. Ordinarily, with a given tube current and voltage, the radiation emitted from some of the Lindemann window tubes imported from Germany is approximately one-third of that obtained with tubes of the drawn-in window. Thus we have been measuring with 8 KV and 8 ma, at a distance of 10 cm, an average intensity of 350 r per minute. This is just about three times, or even more, the intensity that is ordinarily measured with any of the Lindemann window tubes.

One further point of great importance, I believe, has not been brought out in either of the two text-books now available on the subject. I am referring to that of Fuhs and Conrad and of Bucky. These writers refer to the inverse square law, and in a casual way indicate that probably the inverse square law is not obeyed by Grenz rays, failing, however, to give any specific data. Measurements we have made point out that there is a very considerable difference or divergence between the inverse square law and the actual measurements, and that these differences should be clearly kept in mind.

Just to give one example, let us assume that we designate the radiation intensity at 10 cm distance, 8 KV, and 8 ma as unity. Taking 15 cm, we should theoretically have 44 per cent of that. In reality, we measure only 25 per cent. Or, going to the other extreme, at 7 cm distance, a lesser distance, instead of measuring about twice the intensity, we are measuring 26 times the intensity.

It practically means that, if we use the inverse square law and work at a shorter distance, we shall over-dose, and if we are working at a longer distance, we shall under-dose. The difference, of course, is due to the absorption of the rays in the air layers. I believe, therefore, it falls upon the manufacturer of tubes to supply a correct table of radiation intensities for various distances.

There are a great many more points that could be discussed. There is in particular one while the name "Grenz ray" is probably highly appropriate we should not forget that these rays are still roentgen rays, and, though they appear to have a specific action of their own that specificity is due entirely to their definite physical properties.

Furthermore, it does appear as very important that alongside of the correct quantity dosage the correct control of the voltage would be a very important question. For instance, the reports of the Frankfurt (Germany) laboratory, I believe, are always on 10 KV, and it seems that even with very small doses they produce a distinct effect upon the vascular system. But if the voltage is only 2 KV lower it seems that very much larger doses can be given without producing the same pronounced effects on the blood vessels.

I am merely mentioning this to point out that the control of voltage is a very important factor and if the tube voltages are properly adjusted the safety of the use of the Grenz rays is considerably increased.

DR MAURICE DORNE (closing). In our investigations the results obtained are not by any means conclusive. Rather, they are suggestive and we have written these papers with the idea that probably we could stimulate more work among the radiologists, the physicists and the dermatologists, according to the meth-

ROENTGEN THERAPY IN BONE METASTASIS OF CARCINOMA¹

By K W STENSTROM, PH D, and L G ERICKSEN, M D

From the Cancer Institute, University of Minnesota, University Hospital,
MINNEAPOLIS, MINNESOTA

BONE metastasis from carcinoma and its treatment have been discussed repeatedly in a general way (1, 2) and numerous case reports can be found in the literature (2, 3, 4, 5). Such publications have made it clear that bone metastasis may respond in a remarkable way to roentgen therapy and that the patient may be relieved from severe pain for relatively long periods. A more definite impression of what may be accomplished should be obtained from a report of all carcinoma patients treated for bone metastasis. In an attempt to do that we have gone over our treatment records of carcinoma of the breast, prostate, cervix and corpus uteri, and thyroid. Hypernephroma and melanoma have also been included in this survey. The records have been collected since July, 1926, when high voltage therapy was introduced at the University Hospital.

It should be kept in mind that patients seldom come to a cancer institute until the disease is far advanced. A routine procedure to discover bone metastasis has not been carried out, as a rule, as it may occur in almost any bones of the body and a complete roentgenologic study would be impracticable. The pelvis is, however, almost always examined roentgenographically in carcinoma of the prostate. Pain is the most common symptom which leads to the diagnosis of bone metastasis. In three instances the diagnosis was made in spite of the fact that the X-ray films were negative and in four others the diagnosis was made without any X-ray film. On the other hand, in some instances, metastatic bone lesions causing neither pain nor other clinical symptoms

have been discovered on X-ray films. It is, therefore, evident that many patients may have had bone metastases which were never discovered.

In Table I the total number of patients who have been treated with high voltage roentgen rays is given and also the number of those with known bone metastasis. The occurrence of bone metastasis has not been expressed in percentages as the number of patients is too small to give reliable figures in this respect. The patients who are known to be dead are grouped separately, the others are referred to as alive, though some of them probably are dead by this time.

It is well known that bone metastasis in carcinoma of the prostate is very common. Table I shows that more than one-half of our patients (22 out of 38) had bone involvement. Carcinoma of the breast comes next with almost one-third of the patients (49 out of 156) in the metastatic group. Bone metastasis in carcinoma of the body and cervix of the uterus has been recorded in only 3 out of 165 patients. The occurrence seems to be more frequent in carcinoma of the thyroid (1 out of 4), in hypernephroma (5 out of 16), and in melanoma (1 out of 12). This is in agreement with the statements of other authors.

Carcinoma of the breast gave rise to both osteoclastic and osteoblastic types of metastasis in 11 cases, to osteoblastic only in 3 cases, and to osteoclastic in 30. In five cases the type was not determined. Which bones become involved seems to be mainly a matter of chance and may be seen in Table II. In comparing this table with that of W S Handley (7) on the frequency of carcinomatous bone metastasis, we find there is some difference. This undoubtedly

¹Presented before the Semi annual Meeting of the Minnesota Radiological Society Minneapolis Minnesota, October 25 1930

which has seemed to be prominent throughout the entire discussion, namely, the importance of actually measuring the dose under the same conditions as you use for treatment. Although Dr Mutscheller's suggestion is a good one, I would much rather see the radiologist place

his ionization chamber at that distance from the focus of the tube, when he wishes to determine the surface dose, not only every 100 hours, but every 25 hours of tube life, in view of the changes apparently occurring in this type of tube

STUDY SUGGESTS NEW LINE OF CANCER RESEARCH

A suggestion for new methods of research into the cause of cancer and of certain obscure blood diseases is one of several important lessons to be learned from a study of radium dial painters' cancer, it appears from a lengthy report on this occupational disease made by Harrison S Martland, M D, medical examiner of Essex County City Hospital, Newark, N J, to the *American Journal of Cancer*.

Dr Martland reviewed the cases of the radium dial painters, and showed that cancer does occur in radio-active persons. The cancer in these cases developed from the constant bombardment of each victim's body by the alpha particles emanating from the radium stored in her bones, he explained. This suggests new methods for producing experimental cancer. But, more important, it suggests that, since very small amounts of radium taken into the bodies of watch dial painters quickly produced cancers, the occurrence of other forms of cancer in man may be the result of much smaller amounts of radio-active substances present in the body over much

longer periods of time. These amounts would be too small to measure or even to detect by present methods.

Dr Martland considers less than one-half of a microgram of radio-active substance dangerous. He emphasized in the report what an infinitesimal amount of radio-active substance is necessary to destroy life.

"A milligram of radium bromide is not much larger than a small grain of sand," he explained in this connection. "One microgram is only one-thousandth as large, is invisible, and cannot be detected by any known chemical method. It is necessary to have only ten micrograms, or one hundred thousandth of a gram, distributed over the entire skeleton to produce a horrible death years after it has been ingested."

"This is interesting when it is recalled that the fatal dose to man of the toxin produced by *Bacillus tetani* (the germ of tetanus or lockjaw), one of the most powerful soluble poisons known, is twenty-two hundredths of a milligram or about one three-hundredth of a grain," he added.—*Science Service*

outcome was unknown in six. Of the other patients, representing mainly the osteoclastic group, partial or complete relief of pain was obtained in 28, no relief in one, the results were not known for 22, seven patients were not treated for the bone metastasis, and one never had any pain. The relief from pain usually came within a week after the treatment, lasting from a couple of weeks to more than one year following one series of treatments. When the records were made, an analysis of results in bone metastasis was not considered and the notes are, therefore, incomplete in this respect. It may be mentioned, for example, that a patient improved after treatments without definite reference to the bone metastasis. That is the reason the results are put down as "not known" for some of the patients.

The relief of pain is undoubtedly due to improvement of the lesion itself as has been recently pointed out by Borak (11) of Vienna. Borak emphasized the relative sensitivity of bone metastasis as compared to the primary lesion and to other metastasis, considering this due to the fact that no epithelium is present in the bone and therefore the growth changes somewhat its character. He ascribes the pain to pressure on the periosteum or nerves surrounding the bone. If epithelial tissues become involved in this region, then the resistance to radiation ought to increase and this would explain why it sometimes is very difficult to influence the growth. Borak seems to believe that often the metastatic lesion of bone is healed completely. Unfortunately X-ray films were made only exceptionally after treatment in our group of patients. The impression obtained from these was, however, that complete healing is a rather rare occurrence. In 12 cases of mainly the osteoclastic and in four cases of mainly the osteoblastic type, X-ray films were made both before and a reasonable time after treatments. Nine of the former and one of

the latter showed a definite improvement. In at least one case the lesion seemed completely healed and the bone practically normal at the last X-ray examination. The patient grew worse, however, due to progression of other metastases.

When all the patients with bone metastasis are considered together, it seems that the benefit from the treatments is of rather short duration. This is in many cases due to the fact that the original lesion, as well as metastasis to glands and other organs, continued and soon brought the patient to a helpless condition, or death. In spite of this it seems that the treatments, as a rule, have been worth while. They have made it possible to reduce the use of drugs (such as morphine) and in many cases have enabled a bedridden patient to become ambulant, e.g., Case No. 396. The benefit obtainable has been emphasized by some exceptionally good results.

CARCINOMA OF THE BREAST

A T., No. 396, age 46 years. In 1923 the patient noticed a lump in the left breast. Radical amputation of the breast was performed at that time at the Mayo Clinic, following which the woman received post-operative X-ray treatment to the breast in two series there and at Aberdeen, South Dakota. One year later, at the Mayo Clinic, radium was inserted in the glands of the neck and locally to the breast. She reported to the University Hospital in December, 1927, with metastasis to the pelvis and spine. She had been unable to walk and had been confined to her bed for one month because of pain in the pelvis and hip. At this time she received a series of four treatments over the pelvis, anterior and posterior, amounting to a 120 per cent erythema dose to the tumor. She returned in March for check-up and more treatment, at which time she was able to walk and was free from pain in the pelvis. She had also gained 25

can be explained by the fact that his statistics were based on postmortem findings, while in this survey the metastases were substantiated by X-ray examination. Unless each bone is sectioned in an autopsy one is very apt to overlook bone metastasis, hence, many metastatic lesions may have escaped discovery. Though it seems fairly well established that carcinoma may spread to the bones through both superficial and deep lymphatic channels (4, 8), it is probable that the cells are quite often transplanted by blood (8, 9, 10). An example is seen in the patient (No. 702, Table III-A), with primary lesion in the right breast and with demonstrable metastasis limited to the left calcaneum, carpus, and ulna. Biopsy, taken of the calcaneum, showed metastatic adenocarcinoma.

Carcinoma of the prostate gave rise to both osteoblastic and osteoclastic metastasis in five patients, to osteoclastic in only one, and to osteoblastic in 16 patients. The bones involved may be seen in Table II.

Three cases of carcinoma of the cervix and body of the uterus gave rise to osteoclastic metastasis, represented in the pelvis, femur, dorsal, and lumbar spine. One case of carcinoma of the thyroid showed osteoclastic metastasis in the dorsal spine, right and left femur, and right ribs. Four hypernephroma patients had osteoclastic metastasis with irregular distribution. One patient with melanoma developed osteoclastic metastasis to a rib.

It is interesting to observe that bone metastasis sometimes occurs quite early, in some of the patients pain in one or more bones was the first symptom of metastasis anywhere in the body (10). In 14 of the patients no other metastasis was found. The time that elapsed between the operation on the primary lesion and the first treatment for bone metastasis is given in the tabulations. The shortest interval from a radical mastectomy to treatment of bone metastasis was one month and the longest interval ten

years. We may conclude from this that it is apt to become noticeable almost any time, and a careful check-up of the patients is needed. The sooner the bone metastasis receives roentgen-ray treatment, the better results and the more prolonged palliation we may expect.

TREATMENTS

The treatments were carried out with high voltage, the usual factors being 200 KV, 30 ma, 1 mm copper plus 4 mm aluminum filter, and 60 to 70 cm target-skin distance. As a rule the treatments consisted of a full erythema dose (our erythema producing definite reddening and pigmentation) to the skin immediately above the involved bone. Sometimes the treatment was given at one sitting, but more often it was divided into two seances, given on the first and third day, with 10 per cent added to make up the loss in time. Sometimes the bones were irradiated from two sides and then usually in four fractional treatments. The dose given to the lesion in the bone never was less than 80 per cent or more than 120 per cent of our erythema dose. The treatments were in many instances repeated after about two months. The greatest number of series of treatments given to any one area was four.

The aim of the treatments was mainly to relieve pain and the results in this respect are shown in Column 4 of Tables III-B and IV-B, and Column 3 of Tables V-B and VI-B. The length of time the patients have been followed after treatments of bone metastasis can be found in the last column. As was to be expected, the osteoclastic type of metastasis responded to treatments much better, as a rule, than the osteoblastic type. Partial or complete relief of pain was however, obtained in 10 cases of carcinoma of the prostate which is to be considered mainly as representing the osteoblastic type. Six of these patients had no relief and the

of pain in the back, right hip, and shoulder for which he received treatment. He was given a series of treatments over the hips, pelvis, and spine at the time but his condition was not very good—he had hematuria. He has not been heard from since May, 1929 (22 months), but is undoubtedly dead.

SUMMARY

1 The records of patients treated with high voltage roentgen therapy since July, 1926, have been investigated in regard to metastatic carcinoma to the bones. A statistical survey has been made of carcinoma of the prostate, breast, thyroid, cervix and corpus uteri, and of hypernephroma and melanoma.

2 Metastases to the bones were found to be common in carcinoma of the prostate and breast. They may occur at any time and in any location and one should watch out for symptoms, especially pain, which indicate such lesions.

3 Carcinoma of the uterus and cervix does not as a rule give rise to bony metastasis but occasionally it may. Other investigators have found the incidence of bone metastasis relatively high in cases of carcinoma of the thyroid, hypernephroma, and melanoma. Our records show an agreement in this respect, though the number of patients reported is small.

4 The tables show which bones were found to be involved, the means of diagnosis used, whether metastasis was of the osteoblastic or osteoclastic type, the time interval between radical operation of the primary lesion and first treatment of bone metastasis—also between this treatment and the last time the patient was seen, number of complete treatments, and improvement of pain and of the lesion as shown by X-ray films.

5 Most of the patients, particularly those exhibiting the osteoclastic type of metastasis, benefited by the treatment. Though the improvement was of rather short duration for the group as a whole, it was quite remarkable in some few instances. It seems that the roentgen treatments have been of very definite value in reducing the amount of drugs needed for pain, in getting patients out of bed, and in restoring some of them to useful lives for as long as two years.

TABLE I

| | ALIVE | | DEAD | | TOTAL | |
|---------------|-------|-----------------|-------|-----------------|-------|-----------------|
| | Total | Bone metastases | Total | Bone metastases | Total | Bone metastases |

| Carpus | 1 | |
| Ulna | 1 | |
| Total number of times bone regions involved | 115 | 45 |

pounds in weight in four months. Between the time of admission in December, 1927, and the time of death in March, 1930 (27 months), the patient received six series of deep X-ray treatments to the pelvis, entire spine, and right shoulder girdle and was kept very comfortable as far as pain was concerned. Her physical condition kept up very well. On November 9, 1929, she fell, sustaining a pathologic fracture of the femur, and was confined to her bed. She died March 31, 1930. Information received from a sister seemed to indicate that the patient had had chest involvement and intercurrent pneumonia.

A H, No. 69.—The patient had had a radical breast amputation in January, 1924, remaining fairly well until the Fall of 1925, when she began having pain in the right hip and back. In May, 1926, she had received a series of deep X-ray treatments at St. Barnabas Hospital, St. Louis, Mo., with resulting relief of pain. In June, 1926, she began to have severe pain in the head and neck and X-ray films showed metastasis to the thoracic and cervical vertebrae. She was not able to move about at all except in a wheel chair. X-ray films made at the University Hospital in September, 1926, revealed multiple metastases to the pelvis, femora, lumbar, dorsal, and cervical spine, with several vertebrae almost entirely destroyed. The patient received a series of deep X-ray treatments at this time, as well as in November, 1926, with marked relief, and was able to walk about as usual and to do all her own work. After this series of X-ray treatments she entered a Christian Science Home and so gave all credit to "divine healing." She remained well until January, 1928, when she was forced to remain in bed again. She died in April, 1928 (16 months), but was faithful to Christian Science to the end.

CARCINOMA OF THE THYROID

C D, No. 48958, age 72 years. The

patient, who had had thyroid enlargement for 10 years, noticed that the gland had increased markedly in size in the 6 months preceding examination. She complained of weakness, dyspnea, and a feeling of pressure. Thyroidectomy in July, 1929, revealed a malignant melanoma. She received a series of prophylactic X-ray treatments to the neck region in July, following operation, and in January, 1930. In March, 1930, the patient developed pain in the dorsal spine. X-ray examination revealed multiple osteoclastic metastases of this region. A series of deep X-ray treatments over this region afforded relief. In June pain developed in the left hip, but was relieved by treatment. In August, she complained of pain in the right ribs and dorsal spine, receiving another course of treatment with relief. Because of pain in the pelvis, the woman is at present receiving a course of treatments in that region and has already been relieved completely. It is interesting in this case to note that the patient experienced relief within two days of the first treatment. Her physical condition is very good and there is no sign of any local or glandular recurrence (7 months).

CARCINOMA OF THE PROSTATE

C T, No. 41166, age 66 years. Onset occurred in the latter part of May, 1927, with dysuria and dribbling. The patient became progressively worse until August, 1927, when he came to the University Hospital where his case was diagnosed as carcinoma of the prostate. He received radium implants into the prostatic gland. At this time, he complained of pain in the right femur and radiograms revealed osteoblastic metastasis to the right femur. He then received a course of deep X-ray treatments to the pelvis and the right femur, with relief of pain although the X-ray plate showed progression of the bone lesion following treatment. In November, 1929, he complained

TABLE III-B—CARCINOMA OF THE BREAST, LIVING—26 OF 104 CASES

| X-ray No | Time from operation to treatment | No of treatments | Pain | X-ray | Time followed |

tion, together with surgery, in selected cases, is the treatment of choice for hypertrophic scar and keloid.

Keloid, like scar tissue, arises from the corium and, also like scar tissue, is generally due to trauma. It has a predilection for certain portions of the body, the region of the sternum being most frequently infested. Next in order come the lobes of the ears and in those individuals who are susceptible to this scourge it may come anywhere that trauma breaks the skin.

Keloid is the nightmare of the plastic surgeon. Many times when he has done a very commendable piece of remodeling he is abashed, and sometimes criticized, for a condition over which he has no control, except possibly through the use of the prophylactic dose of X-rays given prior to the operation. This procedure, which was first used by Dr. Pfahler, is useful to a degree, although nothing seems, in some instances, to stop the formation of keloid in those susceptible to it.

Dr. H. L. Updegraff, reconstructive plastic surgeon, with whom I have been associated in the treatment of these conditions, uses the pre-operative prophylactic suberythema dose more and more in his work and thinks it has decreased to a great degree the number of keloids encountered. It is our opinion that if a scar is closely watched, and at the first indication of keloid is irradiated with monthly suberythema doses over a period of three or four months, this lesion will not become large and unsightly, yielding much more rapidly than in those cases in which no check is made at all or made only when the condition has become unbearable to the patient. Of course, the more recent a keloid is, the more easily it is righted.

H. Lyons Hunt, in *American Medicine*, sums up the treatment of keloid as follows: Until the advent of roentgen rays and radium, both surgery and medicine failed

numerably in producing a fair percentage of cures. Excision, thiosinamin, injection of formalin or of creosote oil, massage and pressure, introduction of digestive secretions such as bile, pancreatic juices, etc., all had their advocates but not cures, so it seems of little use to spend time in discussing this at any length. Of those pioneering in this field, William, Allen, Degravins, Pusey, Allen, Wickham, Hahn, Edwards, Taylor, and a few others did commendable work, but their technic varied and it was left to the roentgenologist to work out his own.

Of late we have used the following technic which seems to give very good results: 90 KV, 4 ma, giving 650 r units through 1 mm aluminum. This last is added to take care of the variation in tubes which has been worked out so nicely by Dr. A. W. Erskine, of Cedar Rapids. The dose may be repeated every month until recovery is complete or no further benefit is observed. We have been giving the equivalent of the above, but spaced out in weekly treatments, and in this way feel that we have retained patients who would otherwise have felt they were neglected. No reactions have been experienced at any time and the results have been satisfactory.

One such dose is given pre-operatively if operation is to be done and at monthly intervals, as above stated, following operation.

In those cases which are resistant to the X-ray, success has been had with the use of the water-cooled ultra-violet ray. Just what action ultra-violet has on these tissues is debatable, but the fact remains that the results are quite good, and the element of safety in its use is the factor that recommends it. In persons of the negro race, whose skin is so resistant to all forms of treatment, it can be pushed to success in cases in which other forms of treatment have failed or in which it would be unwise to push the X-ray further. Of course one must keep in mind the slowness with which

X-RAY TREATMENT OF KELOIDAL AND HYPERSTROPHIC SCARS¹

By BENJAMIN H SHERMAN, M.D., HOLLYWOOD, CALIFORNIA

K ELOID, first described by Alibert, is derived from two Greek words meaning "scar-form." Keloid, although it generally starts in an injured area, tends to spread from this area into the surrounding tissues in a claw-like shape. While it is a moot question as to just why it forms in one scar and not in another, some disputing that there is a so-called keloid individual, still the fact remains that keloid attacks some individuals while others who have undergone like injuries, whether from operation, burns, or what not, show no sign of this disease. There seems to be no real reason to burden the mind with the etiology of keloid, as the primary cause is unknown, aside from the fact that it is more prone to attack darker and thicker skinned individuals, the syphilitic and the tuberculous, following injury.

Burns about the mouth, eyelids, nose, neck, etc., may completely change the patient's looks or expression, generally to his detriment, and may interfere with function—this is especially true when they occur about the tear ducts or angles of the mouth.

Hypertrophic scar and keloid have a common etiology—trauma, yet their histologic structures are far separated. Hypertrophic scars tend to proliferate, but they do not extend beyond the border of the injury, while keloids tend to grow out in claw-like formations over healthy tissue, converting it into a formidable dermatologic problem.

Pathologically keloid is essentially a fibroma, arising out of the corium with small round cells that group themselves around the blood vessels, which, in the older keloid, become less numerous. The bundles of fibrous tissue run parallel to the long axis of the tumor, no glands follicles, or elastic

tissues are present in the growth, having been crowded out by the fibrous tissue.

There seems to be no distinction pathologically between the so-called true and false keloid, or new and old keloid, except that the cells are fewer in number in the latter and the blood vessels are somewhat atrophied.

Before beginning treatment of keloid or scars in general, better results will be obtained in all cases if one will take into consideration the following points:

- 1 Is syphilis a factor in this individual case?
- 2 Is tuberculosis a factor?
- 3 Does the individual have an obsession regarding this particular scar or keloid?

In the first instance it is to be insisted upon that a Wassermann be made regardless of age, social standing, or "previous condition of servitude," for obvious reasons. In the second instance these conditions in the tuberculous yield much less rapidly to treatment, and in the third instance those individuals who have an obsession as to their condition are apt to multiply their troubles many fold, it being a condition of the mind rather than a deformity of import. Although it may seem very small to us, to them it is of vast importance, and if it does not yield promptly they become most discouraged and in some cases have even committed suicide. One should be very guarded in his prognosis, never promising the patient relief, but, rather, giving him hope in other ways, for it is in this obstinate type of case which it takes months sometimes to relieve that patients are apt to become discouraged and to seek other treatment.

It seems to be the opinion of the profession generally that some type of irradia-

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting at Los Angeles, California, Dec. 1-5, 1930.

sponges, also cut to size. Then firm pressure approximating 30 mm of mercury should be applied until the area has healed. X-ray in suberythema, one-fourth doses every week until healing has entirely occurred offers a better result than any other method I have found to date.

DR SHERMAN (closing) I would like to make a statement about the treatment of these conditions, which probably accounts for patients' remaining with us until results were obtained. Instead of the monthly suberythema dose, they were treated at weekly intervals, dividing the doses so that the results were equivalent. In this way, patients retained their interest and also felt that we were interested in them and doing something for them.

The massive dose, so to speak, I think is probably best applied to those small hard lesions such as are frequently seen on the face.

Surgery was used in those cases in which the lesion was large, possibly one or two inches across and five or six inches in length, and it was thought best to remove a portion of the lesion, or, if possible, all of it, leaving a small linear scar instead of the rough contour which remains many times, especially following a burn. In some of these cases in which it was possible to remove all of the keloid, irradiation was used with good results as a prophylactic measure.

Some workers report good results with the use of radium, but it is probably the best rule to use such agents as you are most accustomed to in getting the desired result, in other words, it is best to use those agents the specific action of which you understand.

Success in treating these patients will depend upon your judgment as to which agent to use, be it X-ray, radium, or surgery, alone or in combination, that will best suit the particular case.

these conditions yield to any form of treatment, running as they do over a period of months. The radiologist must be sure to inform the patient that it will be months before appreciable relief can be had, and, too, the physician should not be influenced by sentiment to push the X-ray beyond the normal limits of dosage.

Radium is very acceptable for use in places inaccessible to the X-ray.

CONCLUSION

Prognosis should be guarded in every case of keloid or scar, be it ever so small or recent, being particularly cautious as regards the syphilitic type, the tuberculous, of erosions on the face, hard lesions, and lesions in the dark-skinned races.

The X-ray should not be pushed to the point of producing telangiectasis, in these instances, it would be better to use a less destructive wave length.

In the formation of scars there is a wide diversity of reactions. In some extensive injuries, whether lacerations, bruises, or burns, there are bound to be mutilating scars with contractions, while in others with the same extensive injury the deformity is surprisingly light. As a general rule, given the amount of surface involved together with depth of tissue involved, we can make a fairly accurate determination of the amount of scar tissue to be expected.

Probably the most important item in the treatment of these conditions is caution-caution in the application of whatever mode of treatment is used, fearlessness in calling upon the plastic surgeon when he is needed, for dividing responsibility may help in cases in which failure impends, and especially caution in the prognosis as it may save embarrassment later.

DISCUSSION

DR. T. M. BURROWS (Pasadena, Calif.) I think one should emphasize a point brought out by the speaker the importance of treating the cause of the keloid as well as the keloid

itself. In 200 cases of various benign and other lesions of the face which I removed with the circle knife, I noticed that scar formation was invariably associated with focal infection in the mouth or elsewhere. When these focal infections are treated successfully at the time or before the operations on the face, the scars are practically invisible. In cases having large keloids such as are found to occur in negroes we treated the focal infections, removed the keloids surgically, and treated the wound with X-rays or radium. This method has given very good results if the accompanying focal infections have been treated successfully.

A considerable number of patients refuse to have their teeth or tonsils removed. One woman had a malignant tumor on the end of her nose which I removed with the knife but an unsightly hypertrophic scar developed. She had chronic tonsillitis. The tonsils were removed after the scar developed and the scar disappeared within four weeks after the removal of the diseased tonsils.

Another point of interest is that circular open wounds leave the smallest scars on the face, while on the neck, the wound must be closed carefully or a scar will form.

DR. HOWARD L. UPDEGRAFF (Hollywood, Calif.) Keloid is the plastic surgeon's Sphinx. In spite of intensive observation and study by a great number of skilled observers, the why and wherefore of keloidal occurrence remains a mystery. It is almost a platitude that keloid occurs most frequently in the colored race. However, most of us are dealing with the white race and we see keloids entirely too often for our mental comfort.

The most efficacious means seems to be a combination of surgery and radiation. As a reconstructive surgeon, I have practically abandoned skin grafts on old keloidal bases. The surgical removal of hypertrophied scar tissue and definite keloidal growths must include all of the involved tissue—well into the subcutaneous layer.

These areas should be dressed with aero-form gauze (parresine mesh impregnated with 3 per cent ointment) cut to the size of the excised area. This should be covered with gauze

was instituted, except when repeated tapings of the joint failed to effect a cure

In Group 2, the arthritics, the prognosis is even better since the process is acute, the pain usually subsiding after a period of from four to six weeks under any form of therapy X-ray treatment was used only in the polyarthritic cases, for the relief of pain

It is in the osteo-arthritis (Group 3) that the prognosis is usually not favorable. Here the inflammatory process is chronic and refractory to treatment, the pain is severe, and lasts for months, or even a year. There is usually stimulation to the production of osteophytes at the borders of the articulating surfaces, permanently damaging the joint, so that, even with apparent cure of the ailment, recurrences are frequent. It is in this type of gonorrhreal joint complication, the type that has lasted more than a period of six weeks and has not yielded to the usual measures—rest, immobilization, attack of the urethral source of infection, vaccine, foreign protein injection, intravenous potassium iodide, or baking and massage—that X-ray treatment was instituted. The results, although they did not solve the problem, appeared somewhat better than those obtained with other measures, so that for the past few years it has become the practice at these hospitals to refer the difficult cases of gonorrhreal arthritis almost exclusively to the X-ray department for treatment.

Technic of Treatment—In the arthroses and arthritides, the treatment was Type "A," namely, 125 KV, 4 ma, 24 inch distance 0.25 mm copper, 1 mm aluminum and 2 cm of wood as filters, 20 cm area, 30 minutes every other day, alternating the anterior with the posterior, the internal with the external surface of the joint or joints, until each surface received four exposures over a period of from five to six weeks. At the completion of the series there was faint browning of the skin in light-haired individuals.

In the osteo-arthritis the treatment was Type "B," consisting of 155 KV, 4 ma., 24 inch distance, 0.5 mm copper, 1 mm aluminum, and 2 cm of wood as filters, 30 minutes every other day, alternating the anterior with the posterior, and the internal with the external surface, until each area received four exposures over a period of from five to six weeks. At the completion of the treatment there was slight browning in brunets and definite mild erythema in blonds. In some blonds, treatment was stopped a week or so earlier on account of the erythema.

Results—It is somewhat difficult to interpret exactly the results obtained, especially in view of the fact that the course of treatment was fully six weeks, and that time in itself was a very important factor in the treatment and final outcome of the disease. To obtain some notion, then, of its true efficacy, the average stay in the hospital of the 35 arthritic cases receiving X-ray treatment was compared with 35 others that had not received this treatment. Although these two groups are not strictly comparable (those receiving X-ray treatment being generally more severe), the treated cases showed an average stay of eight weeks as compared to nine weeks for the untreated. Only 3 of the 35 failed to obtain some relief from pain before the end of the second week of treatment.

Recurrence—The tendency to recurrence was determined by communicating with all the other United States Public Health Service Hospitals with reference to re-admission at a later date of the treated cases. From the reports of 23 of these hospitals up to July, 1931, and from our own files, we find 12 recurrences in the 35 cases treated, indicating a definite tendency in that direction.

In view of the lack of specificity in the action of X-radiation on gonorrhreal joints the expense both as to personnel and apparatus necessary for this type of treatment, and the recurrences within a 5-year period

THE X-RAY TREATMENT OF GONORRHEAL COMPLICATIONS IN MALES¹

By FRANK LIBERSON, M.D., Roentgenologist to the United States Public Health Service Hospitals, New York City

THREE is little that is definite in the literature on the therapeutic value of X-radiation in gonorrhreal complications. Wetterer, 1921, was probably the first to treat this subject in any comprehensive manner (1). His results in the inflammatory complications of gonorrhea—epididymitis, prostatitis, adenitis, etc.—were encouraging indeed, especially when treatment was instituted at an early date. His observations, however, were purely clinical there being no mention made of control groups or attempt to follow up the patients after treatment to determine recurrence of the complaints or ailments. Later workers, Fried (2), 1925, Grynraut (3), 1926, Sordello (4), 1926, Guhrauer (5) 1927, Martenstein (6), 1927, Gunsberger (7) 1928, Samek (8), 1930, and Kloekorn (9), 1930, corroborated in the main Wetterer's findings, using, however, much smaller doses, as is the modern trend generally. These observations, too, lack the scientific certainty that control groups and a follow-up system assure. A review, then, of the entire literature leaves some doubt as to the exact efficacy of X-ray therapy in the individual gonorrhreal complications.

The present study of the effect of filtered radiation in gonorrhreal complications began in 1925 at the United States Marine Hospitals at Staten Island and New York. It was not an outgrowth of any particular aim at scientific completeness, but, rather of a search for a more effective means of dealing with those cases refractory to the usual method of treatment at the time. After about one-half year's attack on these complications by means of X-ray with some meas-

ure of success, we began to deal similarly with the severer types of complications before they were considered refractory to the present date we have treated, controlled, and followed up a sufficient number of cases to give us some notion of its effectiveness. This series consists of 44 cases of painful heel, 35 of gonorrhreal arthritis, 20 of gonorrhreal adenitis, 12 of gonorrhreal epididymitis, and 8 of unyielding chronic gonorrhreal urethritis, treated during the period from January, 1925, to July 1931.

GONORRHEAL ARTHRITIS

(35 cases)

This is probably the most important complication of gonorrhea from the therapeutic point of view, especially in the severer mono-articular forms, since it is apt to be refractory to the usual treatment.

Roentgenologically, three types are commonly met with:

1 Simple arthrosis with swelling of the peri-articular joint space or tendon sheaths, or of the joint proper, with X-ray evidence of synovitis.

2 Arthritis in which there is slight diminution in joint space and some disuse atrophy (but no bony changes as seen by the X-ray) with or without effusion.

3 Osteo-arthritis, in which there is haziness over the joint, generalized peri-articular infiltration, diminution in joint space, and subsynovial bone absorption with or without periosteal reaction.

In the simple arthroses (Group 1 above) the prognosis for recovery within a period of from three to four weeks is good under any form of treatment or even without any. In those cases no X-ray treatment

¹Published by permission of the Surgeon General United States Public Health Service

These uniformly favorable results tend to show that X-ray therapy of the gonorrhreal heel makes for a shorter stay in the hospital and a more permanent result than the operative treatment, which is marked by prolonged pre-operative and convalescent care, and the frequency of recurrence (11, 12)

GONORRHEAL ADENITIS (BUBO)

(20 cases)

Our 20 cases of gonorrhreal bubo may be divided into three groups 8 were in the presuppurative stage, 6 in the suppurative stage (but were not incised at the time X-ray treatment was instituted), while 6 were operated upon and were draining

The first group (the presuppurative) was composed of cases that developed while the patient was in the hospital under treatment for posterior urethritis or some other gonorrhreal complication The X-ray treatment was Type "A," 125 KV, 4 ma., 50 cm distance, 0.25 mm copper, 1 mm aluminum, one-half hour every other day until three treatments were given (approximately two-thirds of an erythema dose) In six of these eight cases suppuration did not occur The other two suppurated, were incised, and progressed very much like the suppurating cases

In the second group (the suppurative, non-incised), the stay in the hospital was not shortened, the average being about 26 days, but the wounds were cleaner The treatment here was as above, two-thirds of an erythema dose being given in a five-day period

In the draining and incised cases, the treatment was repeated three weeks later, the results being cleaner wounds The stay in the hospital was shortened in some cases, but lengthened in an equal number, as compared with the untreated cases Our conclusion, then, after one year's trial, was that in cases of suppuration, with or without drainage, the value of the X-ray is insignif-

icant In the non-suppurative cases it has some value

GONORRHEAL EPIDIDYMITIS

(12 cases)

In the treatment of gonorrhreal epididymitis we were at first reluctant to use X-radiation because of the possible temporary sterilization that may follow its use All the patients consented, however, some even welcomed the possibility of sterilization The treatment consisted of 125 KV, 4 ma., 50 cm distance, 0.25 mm copper, 1 mm aluminum, every other day for three periods, alternating the front and back with the side of the epididymis (two-thirds of an erythema dose being given in five days) The treatment resulted in diminution or entire disappearance of the pain after five days, and some diminution of the swelling The average stay in the hospital, however, was three weeks, only one or two days less than the control groups This form of therapy was, therefore, discontinued the following year

UNYIELDING CHRONIC URETHRITIS

(8 cases)

Although it is not strictly a complication of gonorrhea, unyielding chronic urethritis with acute exacerbations is included as one of the end-results of gonorrhreal infection The treatment consisted of two-thirds of an erythema dose given to the perineum on three alternate days, using the same technic as for epididymitis, but shielding the testes Pain on micturition and also the discharge were diminished On the other hand, the fact that strictures were more numerous than in the control cases led us to abandon X-radiation as a routine procedure

SUMMARY

Deep X-ray therapy in the treatment of the various complications of gonorrhea in

in about one-third of the cases, it is recommended that X-ray therapy be employed only in the most severe cases, or those in which alleviation of pain is the main desideratum

GONORRHEAL PERIOSTITIS

(44 cases)

Periostitis, or spur-formation with an inflammatory soft-tissue infiltration over the spur, is the cause of the painful heel in gonorrhea. The treatment of 31 of these cases has been reported in a recent paper in the *Journal of Urology* (10).

From the roentgenologic viewpoint there are two readily distinguishable types of spurs.

The soft type, which is under 2 mm in size, is very difficult to see on a dark X-ray film, and leaves a smooth periosteal border after resorption. It is generally found in young adults with a history of gonorrhreal infection not more than one month before the appearance of the pain. The treatment suitable to this type of spur is Type "A" therapy, consisting of 125 KV, 4 ma, 24 inch distance, 0.25 mm copper, 1 mm aluminum, and 2 cm wood as filters, one-half hour every other day, alternating the internal lateral and the external lateral with the plantar surface of the os calcis. This treatment is continued for six weeks, each surface getting one treatment a week. At the completion of the full course of treatment, there is the faintest browning of the skin in very light-skinned patients.

The other type of spur, which is over one month in developing, or recurs after operative procedures, appears radiographically as

- (1) A simple bony projection with a sharply defined, dense, soft-tissue area over the spur
- (2) An irregular bony projection with erosion posterior to it

- (3) An irregular bony projection with erosion and periosteal tipping of the plantar surface, seen also in the region of the attachment of the tendo achillis

The treatment for this kind of spur is Type "B," consisting of 155 KV, 4 ma, 24 inch distance, 0.5 mm copper, 1 mm aluminum, and 2 cm wood as filters, one-half hour every other day, alternating the internal and external with the posterior surface of the os calcis for six weeks. At the completion of treatment there is a definite browning of the heel. In light-skinned patients we have to stop one or two weeks before the completion of a full course of treatment.

The results of the X-ray treatment of gonorrhreal spurs are uniformly encouraging. Of the 44 patients who had X-ray treatment to the gonorrhreal heel, 41 left the hospital with no complaint referable to it. They were able to jump from a height of 30 inches and land on the heels without feeling any discomfort. The other three patients were discharged without improvement—one for disciplinary reasons after only one treatment, another, after three treatments. A third had four weeks of treatment, but left the hospital against advice before a definite erythema was produced. Of the 41 cases, one had to have two courses of treatment before he was able to stand the test of jumping from a height of 30 inches without discomfort.

Although nothing definite can be said about the frequency of recurrence, we can state after a perusal of our follow-up files and the reports of 23 other hospitals of the United States Public Health Service that although 12 of the treated cases were readmitted for other conditions, not a single one who was fully treated complained of pain in the heel. One patient did have a recurrence of the pain three months after treatment, but the pain was atypical being mostly in the tendo achillis.

THE APPARENT THERAPEUTIC EFFECT OF THE ROENTGEN RAY UPON THE CLINICAL COURSE OF ACUTE MASTOIDITIS (PRELIMINARY REPORT)

By RAPHAEL SCHILLINGER, M.D., BROOKLYN, N.Y.

THE clinical course of acute mastoiditis appears to take a turn for the better after exposure of the infected mastoid to the roentgen ray. The turn is marked by a syndrome of favorable action, characterized by a drop in temperature, absence of pain and insomnia, diminution in the amount of discharge, and a change in the character of the discharge from purulent to mucopurulent. The frequency of this observation, and the surprising regularity with which it is induced, leads one to believe that a therapeutic action is exerted by the roentgen ray upon the infected mastoid. A compilation of statistical data of cases definitely diagnosed as acute mastoiditis, both clinically and by X-ray examination, which were subsequently cured without operative interference, and of others, which were operated

upon, is given in this report, as a result of which certain conclusions and recommendations are made.

LITERATURE

We fail to find any case reports in the literature, describing intentional therapeutic use of the roentgen ray in acute mastoiditis. Granger (1) mentions a favorable effect on infants who present signs of infection and occlusion, but not of softening and destruction, which effect was incidental to the making of the roentgenograms. Many of these went on to resolution and cure, which prompts Granger to believe that neither mere hazard nor coincidence was responsible.

In closing his discussion of his paper, Granger says, very significantly "After seeing from 50 to 60 patients with mastoiditis

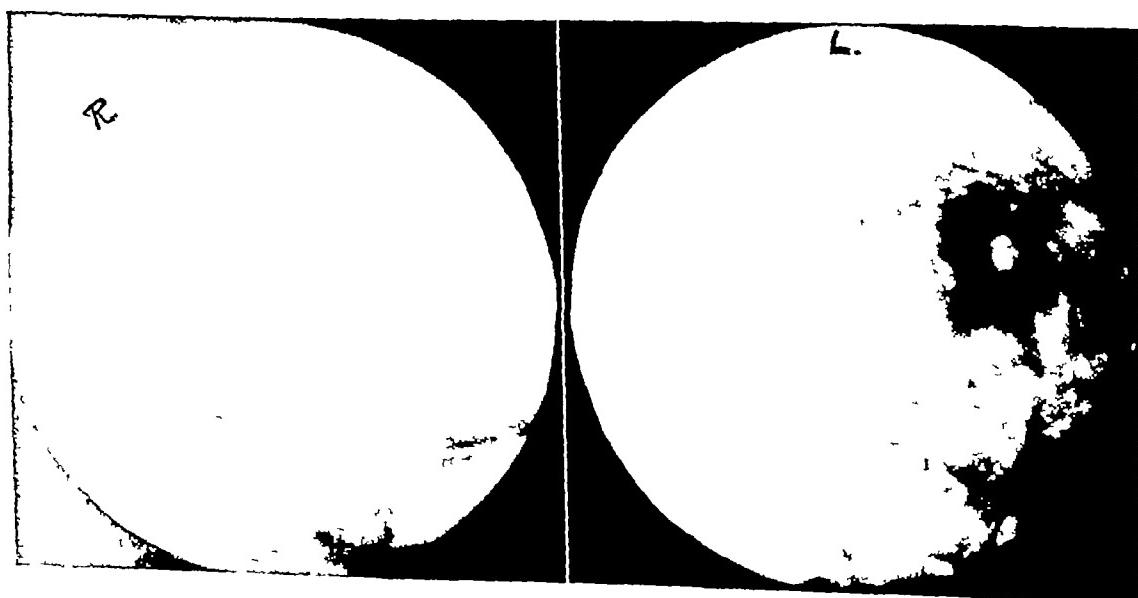

Fig 1 Case 6, Table I—Scarlet fever otitis media, followed by mastoiditis. The plate shows the left mastoid occluded, with softening and destruction of some trabeculae in the posterior border cells. The ear returned to normal three weeks after the second exposure.

119 males was studied over a period of six and one-half years, with special consideration for recurrences and for comparison with untreated control groups. In the order of efficacy, X-ray therapy appears uniformly effective in the painful heel due to periosteal spur, it has a limited field of usefulness in the treatment of refractory gonorrhreal joint complications, especially for the relief of pain, but in gonorrhreal epididymitis, adenitis, and urethritis the results were not significant.

To Study Cosmic Rays with Balloon-borne Instruments—Balloons bearing automatic recording instruments, floating free to heights hitherto unattained in such studies, are planned for the further investigation of cosmic radiation by Dr Robert Andrews Millikan, of the California Institute of Technology. The launching place for these unmanned explorers of upper air has not been announced, except that it will be in a different latitude from that used for similar experiments in 1922, when Dr Millikan and his colleague, Dr I. S. Bowen, sent up recording balloons from Kelly Field, Texas.

In these tests ten years ago, one of the balloons reached a height of 15.5 kilometers, or 9.6 miles. Dr Millikan hopes to send this year's balloons to greater heights, carrying their feather-weight equipment of recording electroscopes, barographs, and thermometers

into regions where the blanket of air is far less dense and correspondingly more penetrable to the cosmic rays.

Investigations at great heights, as well as under great depths of water, have been considered of much importance in the study of cosmic radiation. With other rays, there is a difference in their penetrating power, depending on their wave length—the shorter the wave length, the "harder" and more penetrating the radiation. The same rule may be presumed to hold for cosmic rays. Dr Millikan has stated as a result of his earlier studies that he has been able to distinguish a cosmic-ray "spectrum" of several wave lengths. Possibly the higher ascensions planned for this year will carry his instruments out into a region where they can pick up "softer" rays of greater wave length, that are stopped by the deep atmospheric blanket that surrounds the earth.—*Science Service*

was given on each of the two succeeding days and a third therapy dose was given a week later. Recovery was uneventful, function returning to normal after the second therapy dose.

Fig. 3 (center) Case 17, Table I.—The two large areas of coalescence are here outlined.

Fig. 4 (below) Case 17, Table I.—Twenty months later, Nature's effort at repair is quite evident. The two coalesced areas are now the site of early sclerosis. The ear is perfectly normal in function and appearance.

without bone destruction get well with fractional doses of the X-rays, one cannot feel that it is an accident."

The same author, in a previous paper (2), makes the same comment about improvement incidental to making the roentgenograms, and adds that, after a period of from two to five days of watchful waiting "If the condition shows no sign of clearing up, or if the clinical examination indicates that it has become worse, other radiographs are made, and invariably these show signs of softening or destruction."

We are heartily in accord with the observations and statements made by Granger, who deserves much credit, more particularly because his observations are those of a radiologist and not of an otologist. From the otologist's point of view, we can add experiences similar to Granger's, and also state that, in many cases, even though softening and destruction did take place, if the clinical picture was improved by repeated X-ray exposures, postponement of operation was allowed, and eventually complete recovery without operation was made in approximately 85 per cent of our cases.

Desjardins (3) gives a very comprehensive summary of the various explanations of the mode of action of irradiation on inflammatory conditions, referring to favorable effects of the roentgen ray upon many, including otitis media. He strikes a very important note in speaking of treatment by irradiation in saying, "Even now, however, this method of treatment is not used as widely as it might be, probably because its value is not generally realized."

In the hope that this report may act as a guide and stimulus for the use of X-irradiation in acute ear infections, and more partic-

ularly for acute mastoiditis, we respectfully offer our experiences.

AUTHOR'S CONTENTION

That a certain percentage of all cases of acute mastoiditis recover without any special therapy is undoubtedly true. That a favorable effect on acute mastoiditis is exerted by the roentgen ray is also true. The use of irradiation on cases of acute mastoiditis in which operation is indicated will, in a large majority, cause resolution and cure without operation. We have observed what we believe to be a therapeutic effect on a number of cases of acute mastoiditis, even those with evidence of bone destruction, and we dared to subject some of them to repeated X-ray exposures in an effort to answer the following questions:

1. If a favorable effect on the symptoms of acute mastoiditis is seen after exposure to the roentgen ray for diagnostic purposes, could this effect be repeated by subsequent exposure, when, and if, the original symptoms recurred?

2. If, in a case of acute mastoiditis we have diagnostic plates which allow us to temporize, would it be possible to observe the progress of the bone disease on serial plates, and, if the progress was that of increasing bone pathology, in spite of persistent benefit symptomatically, might we expect resolution of the infection, without loss of valuable time?

Such questions were evolved from curiosity aroused by cases which showed unexpected benefit following diagnostic exposure to the roentgen ray, of which a few representative histories are given here as examples.

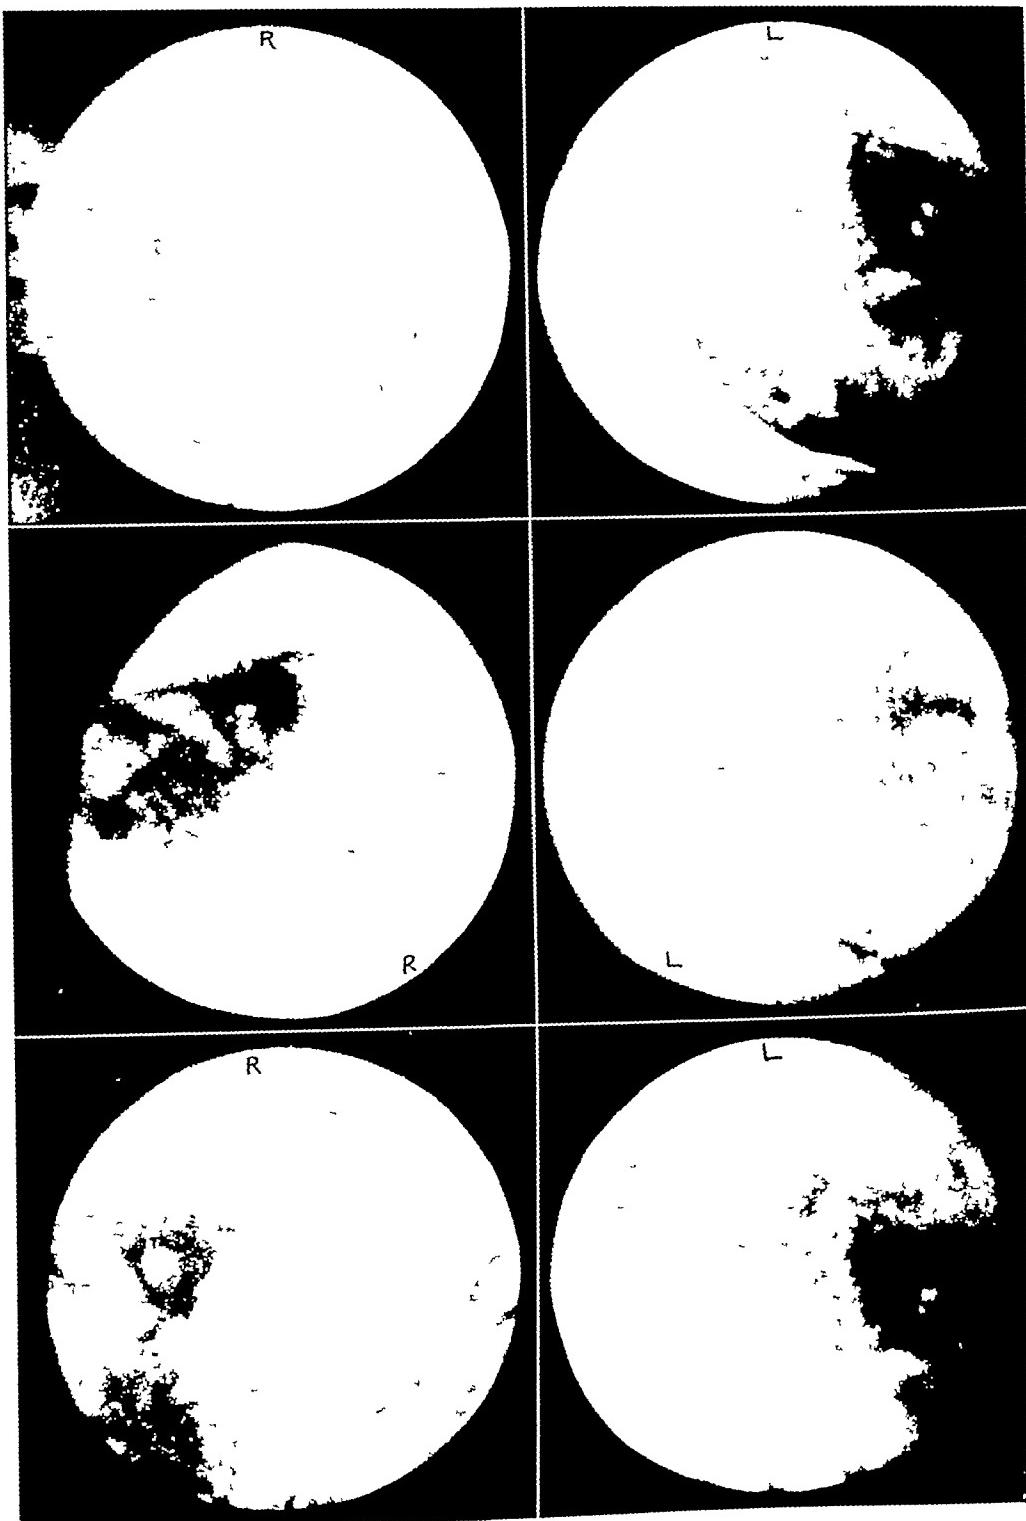

Fig 2 (above) Case 17, Table I—Twenty-four days after incision of the drum, two large areas of coalescence in the right mastoid, peri-antral clouding, and general fuzziness were noted. A therapy dose

(Continued on next page)

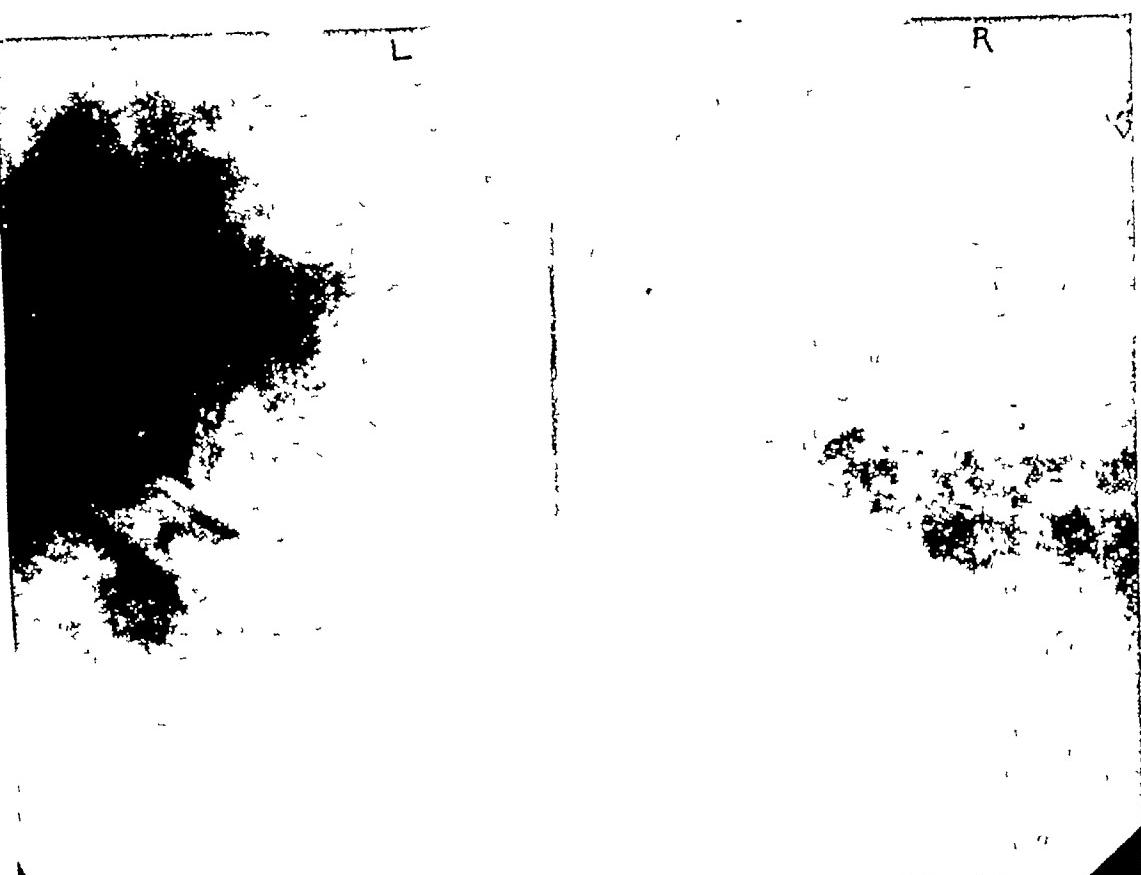

Fig 6 Case 24, Table I.—There is marked clouding of the right mastoid, with softening and probably destruction. The otoscopic picture was that of severe mastoiditis, for which several otologists indicated operation, as we also did. Recovery was prompt after the second exposure.

April 5, the drum, canal, and function having returned to normal.

B P, age 40 years, Oct 1, 1924. The patient complained of sharp pains in both ears, especially at night. Both ears had been discharging for nine weeks, following spontaneous perforation. Diagnostic plates of the mastoids were made, and the pain disappeared at once. Two days later the ears were dry.

SCOPE OF WORK

We have observed a large number of cases with histories such as the three described above. Many were cases of severe otitis media, while others, beyond any question, were surgical mastoiditis. For lack of control cases, this report will not concern itself with the large number of cases that

received but one roentgen-ray exposure. We shall deal exclusively with those cases observed in our office practice that have been examined roentgenographically on two or more occasions, and either resolved to the state of being cured, or else came to operation.

A series of 38 cases is tabulated, each one of which presented, at one time or another, a sufficient combination of cardinal symptoms, otologic signs, and laboratory findings, along with roentgenographic evidence to indicate mastoidectomy. There is considerable difficulty involved in the preparation of a table or chart that will permit the description of all the signs and symptoms in each case. Therefore, we have tabulated the significant treatment data and made comments wherever they were deemed advisable. Certain factors common to all the cases on

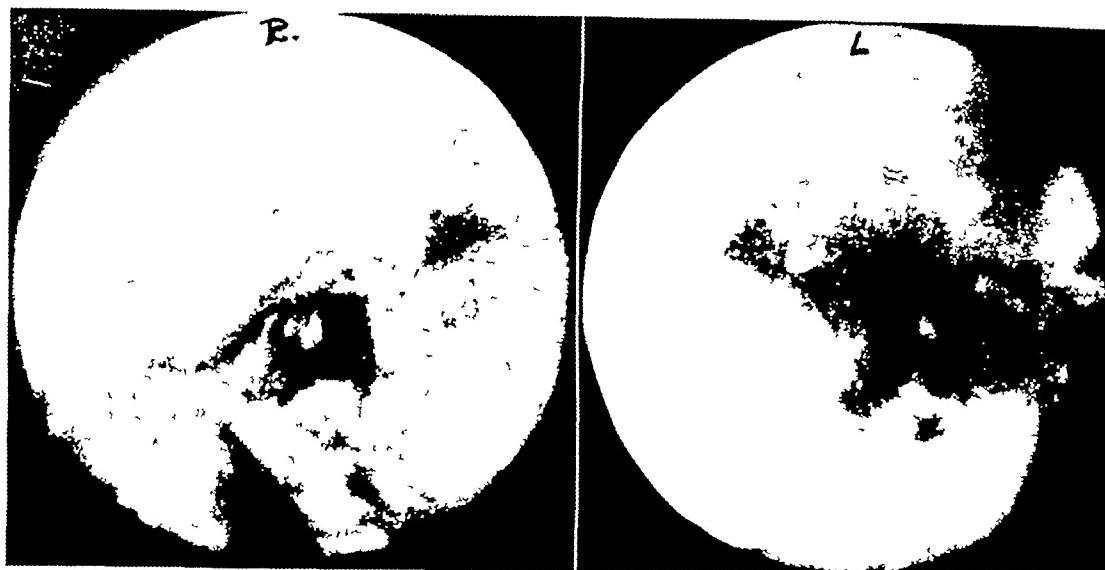

Fig 5 Case 23, Table I.—This plate shows marked clouding of the mastoid in an infant. The clinical picture of mastoiditis was severe. The ear returned to normal five days after the second exposure.

Mrs P F, age 32 years. Paracentesis of the right drum was performed April 12, 1923. A week later the patient developed severe mastoid pain, headache, insomnia, and a temperature of 103° . The discharge was purulent and profuse. The drum was puffy and red, and the canal fundus was contracted. On April 19, the patient was hospitalized for operation. The urine was negative. The blood count showed 4,500,000 red blood cells, 14,800 white blood cells, and 80 per cent polymorphonuclears. X-ray examination showed a large cellular mastoid, markedly云ed, with softening of many cell walls. The temperature, pain, and headache disappeared immediately after X-ray exposure. Because myocarditis made this patient a poor risk, and on account of the favorable turn in the clinical picture, operation was deferred. Otoscopic examination the next day showed general improvement. Four days later insomnia and pain reappeared, and the temperature rose to 101° . The mastoids were again examined roentgenologically. The right one showed more softening than before, but the temperature, pain, and insomnia promptly

disappeared following this second exposure, and discharge diminished considerably. The patient was sent home from the hospital on April 30, with the following otoscopic findings: scant discharge, no fundus contraction, drum pink and flat, no tenderness. Office examination on May 5 showed the right drum healed and normal in color and position and the patient felt perfectly well. Three weeks later the ear function was normal.

I M, age 10 years, March 17, 1924. There was a history of discharge from the right ear for one month, which had been more profuse a few days preceding examination. The drum was red and puffy, and there was marked sagging of the posterior superior canal wall and marked tenderness over the entire mastoid cortex. Diagnostic plates were made, showing marked clouding of a cellular mastoid. Operation was advised, to be performed the next day, but the patient was so markedly improved over night that operation was deferred. The pain and tenderness disappeared, the canal picture improved, and the patient was discharged from observation and treatment on

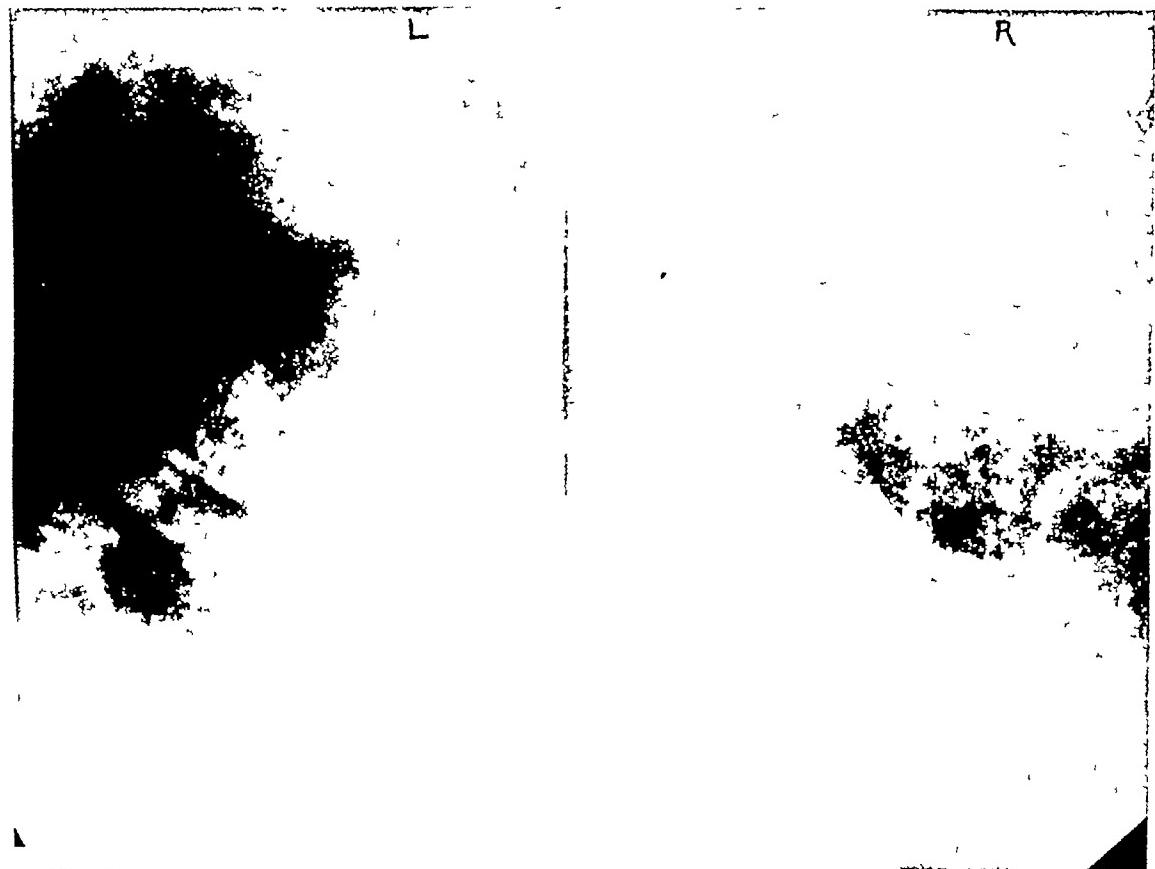

Fig 6 Case 24, Table I.—There is marked clouding of the right mastoid, with softening and probably destruction. The otoscopic picture was that of severe mastoiditis, for which several otologists indicated operation, as we also did. Recovery was prompt after the second exposure.

April 5, the drum, canal, and function having returned to normal.

B P, age 40 years, Oct 1, 1924. The patient complained of sharp pains in both ears, especially at night. Both ears had been discharging for nine weeks, following spontaneous perforation. Diagnostic plates of the mastoids were made, and the pain disappeared at once. Two days later the ears were dry.

SCOPE OF WORK

We have observed a large number of cases with histories such as the three described above. Many were cases of severe otitis media, while others, beyond any question, were surgical mastoiditis. For lack of control cases, this report will not concern itself with the large number of cases that

received but one roentgen-ray exposure. We shall deal exclusively with those cases observed in our office practice that have been examined roentgenographically on two or more occasions, and either resolved to the state of being cured, or else came to operation.

A series of 38 cases is tabulated, each one of which presented, at one time or another, a sufficient combination of cardinal symptoms, otologic signs, and laboratory findings, along with roentgenographic evidence to indicate mastoidectomy. There is considerable difficulty involved in the preparation of a table or chart that will permit the description of all the signs and symptoms in each case. Therefore, we have tabulated the significant treatment data and made comments wherever they were deemed advisable. Certain factors common to all the cases on

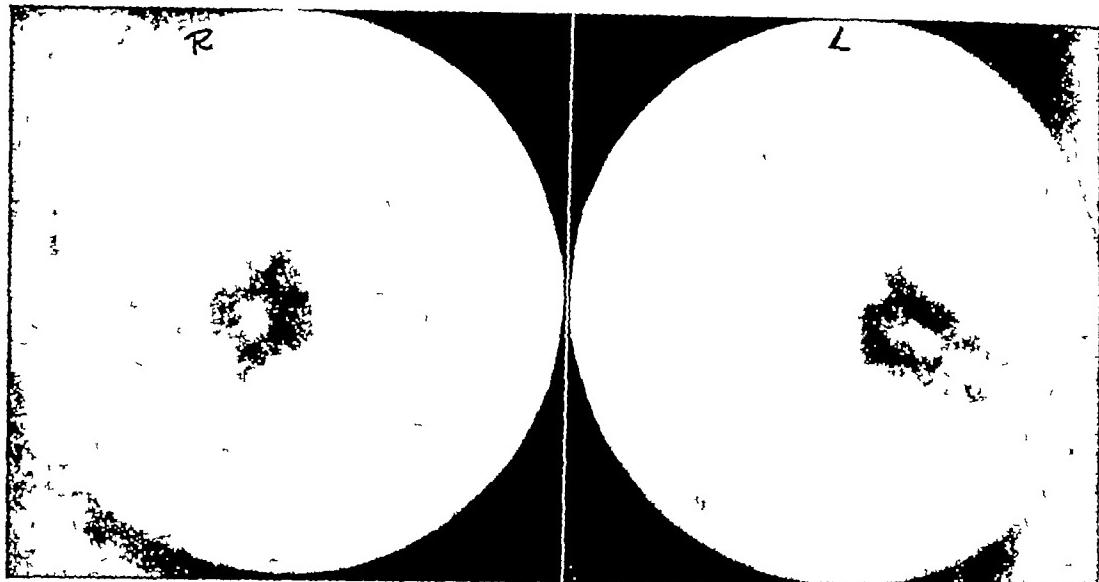

Fig 7 Case 25, Table I.—The right mastoid, infantile cellular type, is markedly occluded. The ear became normal five days after the second exposure.

the day of the first X-ray exposure may be described here.

All cases in this series presented red, puffy drums, the amount of edema of the drum membrane varying from a marked bulge to a nipple which hung from the roof to the floor of the canal, obscuring the rest of the drum. In all but 11 cases the canal fundus was contracted. The middle ear discharge could be increased in quantity by finger pressure on the internal jugular vein in all but 13 cases. There was exquisite tenderness over the entire mastoid cortex in 20 cases. There was exquisite tenderness over the antrum and tip in 11 cases, and marked tenderness over the antrum in seven. There was marked periosteal thickening in one case. There were pain and headache in 28 cases, and insomnia in all but seven. In the 38 cases, the sexes were equally represented. The nutrition was good in 17 cases, fair in 20, and poor in one. The ear infection resulted from the following diseases:

| | | | | | | | |
|---------------|---|---|---|---|---|---|----------|
| Rhinitis | — | — | — | — | — | — | 23 cases |
| Grippe | — | — | — | — | — | — | 5 cases |
| Tonsillitis | — | — | — | — | — | — | 3 cases |
| Scarlet fever | — | — | — | — | — | — | 2 cases |
| Measles | — | — | — | — | — | — | 2 cases |
| Pansinusitis | — | — | — | — | — | — | 1 case |

Swimming was the etiologic factor in one case, and, in the last case, irrigation of the nose for ozena set up the ear infection. The right mastoid was involved in 17 cases, the left, in 19 cases, and both mastoids in two cases. In only three cases had there been previous ear disease.

COMMENTS

Case 7.—The patient entered the hospital for operation, but X-ray examination there relieved symptoms. The ear cleared up and function returned to normal.

Case 10.—The patient developed a nipped drum, pain, and insomnia, accompanied by a profuse discharge, two weeks after the first exposure. The second exposure cleared all symptoms and within 48 hours the ear was dry.

Case 17.—The patient slept well after the first exposure, but retained sagging and tenderness until after the second exposure. X-ray film made 20 months later showed sclerosis in the coalesced area (Figs 2, 3, and 4).

Each X-ray exposure means two plates each side

T—Therapy dose

T*—Therapy dose plus two plates each side

P—Paracentesis

S—Spontaneous perforation

F—Fourth exposure

b—Bilateral

p—Portable X-ray apparatus used

Case 20.—The portable X-ray apparatus was used at the patient's home on account of his temperature (104°), severe pain, and

insomnia, which were unrelied by opiates. Remarkable relief followed the X-ray exposure.

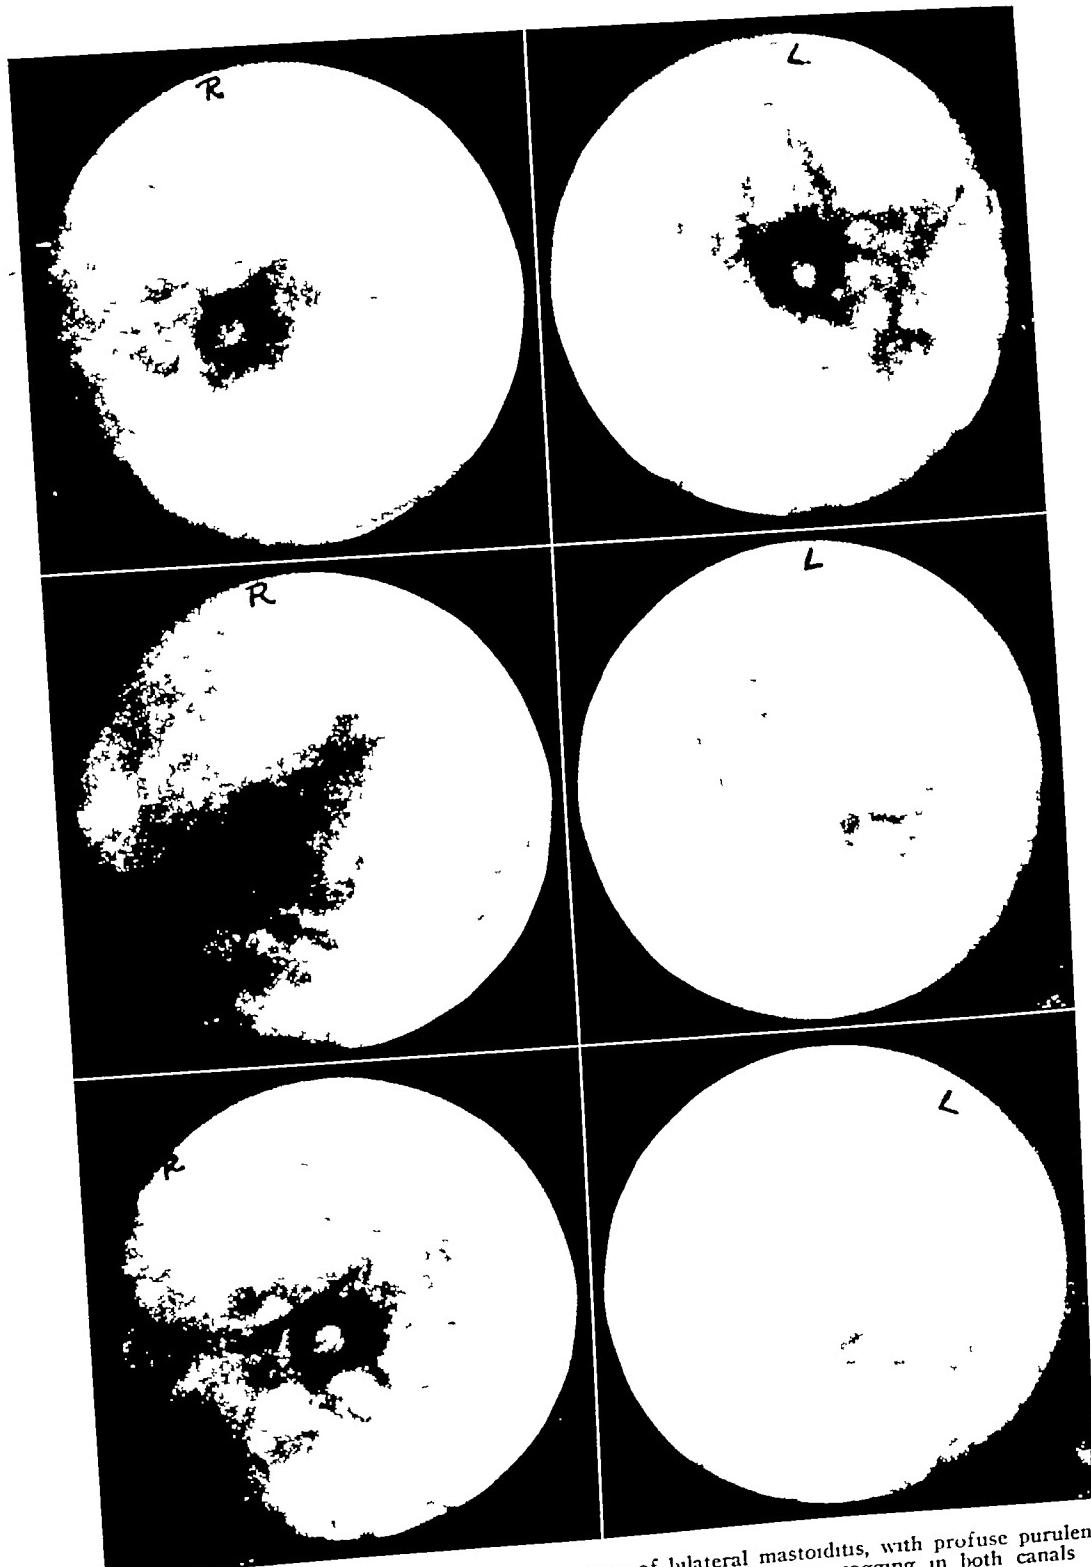

Fig 8 (above) Case 32, Table I.—This is a case of bilateral mastoiditis, with profuse purulent discharge from both ears. Both drums were red and nipped, and there was sagging in both canals. *(Continued on next page)*

and insomnia, and exquisite tenderness over both mastoids were among the symptoms. The morning temperature on the day of exposure was 103° , while that on the day following was 100° . The right mastoid is occluded throughout, fuzziness of the cell walls denotes softening. The left mastoid is smaller, of the infantile type, the peri-antral region is clouded and the cells are occluded. Aeration was present only in one large posterior cell. The emissary vein is visible on both sides, being more clearly so on the right.

Fig 9 (center) Case 32, Table I—Eleven days after Figure 8 was made. Just prior to this exposure, the right ear showed a profuse discharge, an increase in discharge on jugular pressure, a nippled edematous drum, and a marked sagging of the posterior and superior canal walls. The temperature was 101° . Periosteal thickening was present. The left ear was nearly dry and the drum almost normal in appearance. The temperature dropped to 99.8° after this exposure. This plate shows, in the right mastoid, increased bone pathology, destruction being evidenced by several areas of coalescence. The emissary vein is more prominent than before. The left mastoid shows increased aeration and less clouding in the peri-antral region, with beginning definition of the peri-antral cells.

Fig 10 (below) Case 32, Table I—Nineteen days after Figure 9. The ears were dry and the drums had returned to normal. The temperature was normal and the patient slept, played, and ate well. The plate shows better aeration in both mastoids, which is more evident in left. Cell definition is becoming clear in the right mastoid. Evidently, the otologic signs of recovery precede the X-ray signs by a considerable period of time.

Case 30—A streptococcus hemolyticus infection was present. The white blood count was 15,000. The same disease occurred in the other ear three weeks later, resolution and cure taking place after three X-ray exposures.

ANALYSIS OF TABLE I

In all cases, each X-ray exposure was followed by relief of the pain, tenderness, and insomnia within 24 hours. In all cases the temperature dropped to normal or close to normal within 24 hours. In all cases the discharge was lessened, and was changed from purulent to mucopurulent. Four cases showed sagging after the first exposure, five showed sagging after the second exposure, but in all these cases it cleared up subsequently. Ten cases received a therapy dose, the average time for cessation of discharge following the therapy dose being six days. There were no complications of any kind subsequent to any of the X-ray exposures.

Interval between first and second exposures—average number of days, 3-4

Interval between second and third exposures—average number of days, 5

Interval between third and fourth exposures—average number of days, 3

Subsequent to the first exposure, 25 ears were dry within two weeks, 15 were dry in from two to six weeks.

Subsequent to the second exposure, 31 ears became dry within two weeks, nine required two weeks or more to become dry.

CONTROL CASES

A series of seven cases is now presented in Table II, all of which came to operation after two or more roentgen-ray exposures. Incidentally, they were all females.

DISCUSSION

The cases which were operated upon deserve discussion individually for their special features.

Case 1 The child had been ill with whooping cough for five weeks. Earache and temperature of 105° for three days indicated paracentesis. A mild pneumonia followed for about eight days. Diagnostic X-ray films, made 20 days after paracentesis had been performed, showed moderate clouding of the right mastoid. This exposure was followed by less discharge and restful sleep. A week later, there was pain, accompanied by temperature of 100.2° . The periosteum was thickened, the drum red and swollen. A second X-ray exposure showed softening and destruction. The posterior superior canal wall was sagging, the discharge was increased on jugular pressure. Upon operation, the findings were bone softened, no free pus, several coalesced

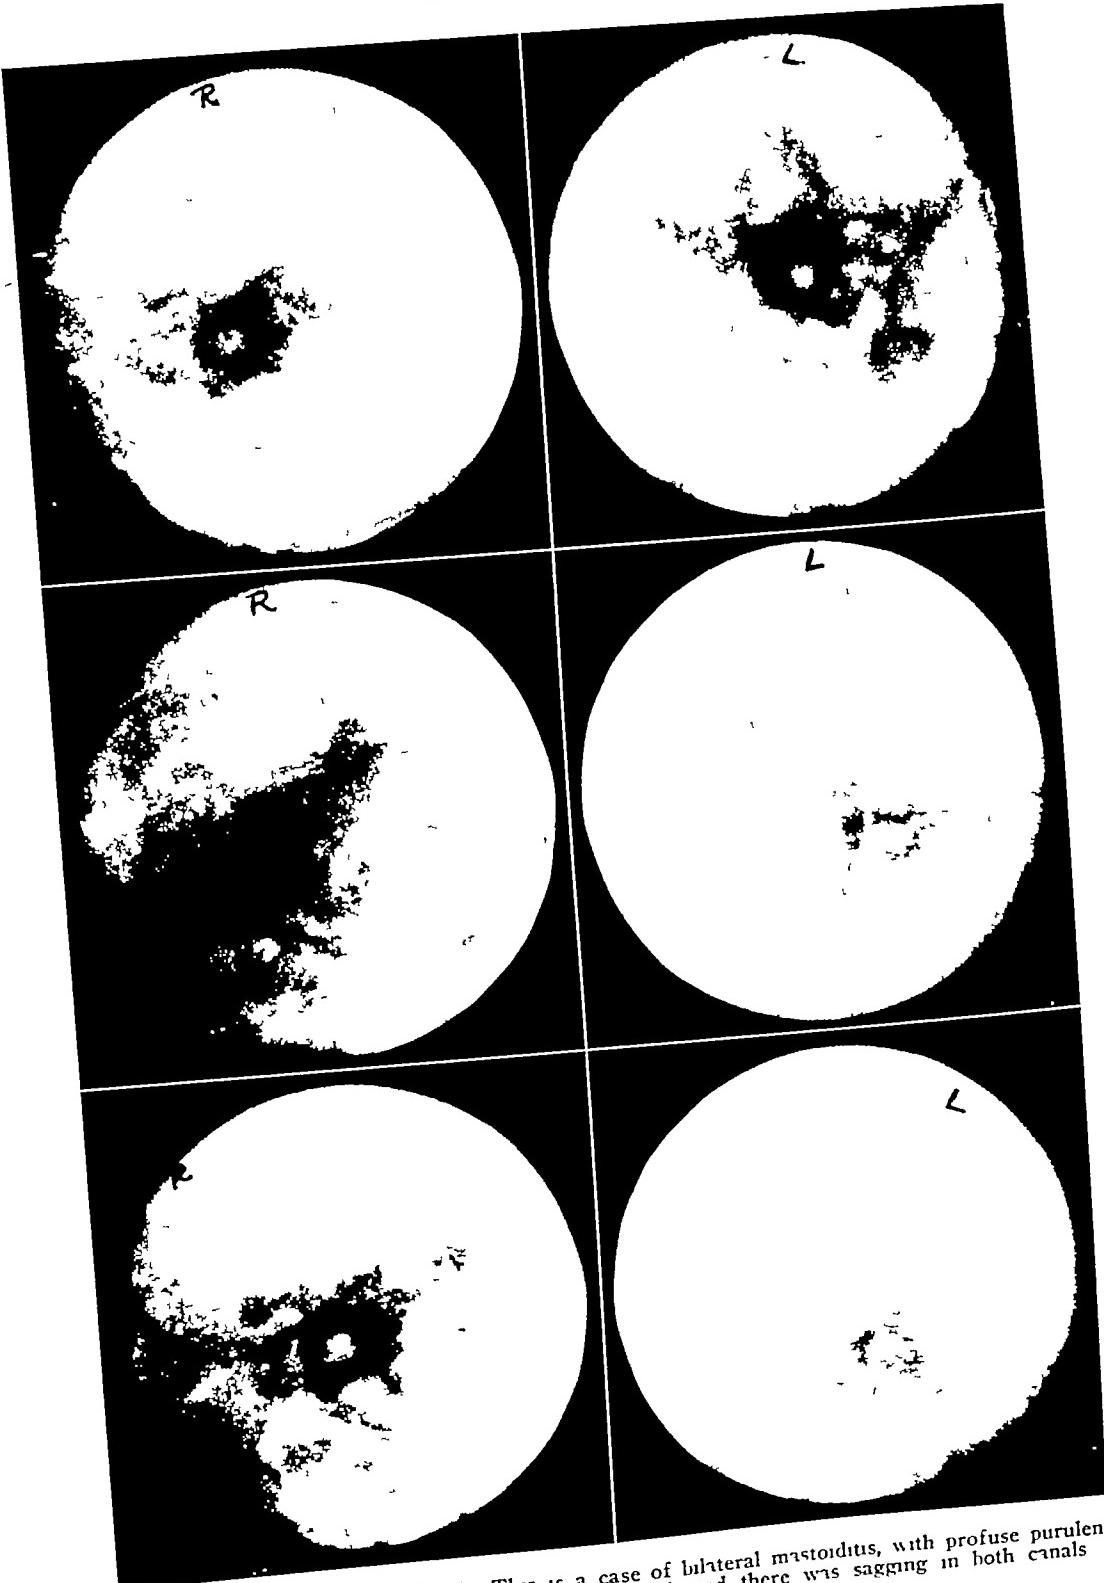

Fig. 8 (above) Case 32, Table I.—This is a case of bilateral mastoiditis, with profuse purulent discharge from both ears. Both drums were red and nippled, and there was sagging in both canals. Pain

(Continued on next page)

Fig 11 Case 34, Table I—Scarlet fever the plates were taken at home with portable apparatus Note that the left mastoid cells are completely occluded and the sinus plate prominent, with softening throughout, also there is dilatation and prominence of the emissary vein

paracentesis X-ray examination showed clouding of the left mastoid. She reacted well to this exposure, but the nose was discharging profusely in spite of regular maxillary antrum irrigations. Subsequent X-ray examinations of the mastoid showed destruction. The patient slept well and felt well, but ran a low-grade temperature; therefore, operation was performed to relieve the low-grade sepsis. Free pus was found in several large coalesced areas. Recovery was uneventful.

Case 6 This patient became very septic after a follicular tonsillitis, running a saw-tooth temperature between 100 and 105°. X-ray examination showed occlusion of both mastoids five days after incision of the drums. She did not react favorably to the first exposure, and a second exposure four days later showed destruction in the right mastoid. Operation was performed on the right mastoid. The temperature dropped from 104° to normal and stayed normal thereafter. The left ear continued to discharge, but became dry 11 days after a third exposure, or 40 days after incision. This

was a case of acute fulminating mastoiditis which did not show any effect from X-ray exposure and was relieved only by surgery. Both ears showed about the same severity of infection, and we feel that the recovery of the left ear was due to early intervention on the right side as well as the final touch of the third X-ray exposure.

Case 7 A young woman, who was poorly nourished, was very septic following a severe tonsillitis. Saw-tooth temperature, pain, and insomnia were unrelieved by X-ray exposure. The patient exhibited a drawn, anxious facies. No one could deny surgical help in this case of true fulminating, septic mastoiditis. The streptococcus hemolyticus was recovered from the mastoid wound.

These seven cases constitute the total number upon which we have operated subsequent to two or more X-ray exposures.

DOSAGE

As early as 1924 we had noted favorable changes in the clinical course of acute mastoiditis following roentgenographic exami-

TABLE II—CASES OF ACUTE MASTOIDITIS WHICH CAME TO OPERATION,
FOLLOWING TWO OR MORE ROENTGEN-RAY EXPOSURES

| Case | Age | Paracentesis or spontaneous perforation | Duration of earache before paracentesis or perforation, days | Temperature range before first X-ray exposure | Duration of discharge before first X-ray exposure, days | Interval between first and second X-ray exposures, days | Interval between second and third X-ray exposures, days | Interval between first X-ray exposure and operation, days |

P—Paracentesis

S—Spontaneous perforation

L—Left side

b—Bilateral

areas filled with polypoid granulation tissue. Microscopic examination of this tissue showed fibroblastic granulations throughout. One cannot say whether or not this child would have recovered with more roentgen-ray exposures. Recovery after mastoideectomy was rapid and uneventful.

Case 2 The child reacted very well to both exposures, but, on the day of the second exposure, developed the Griesinger sign, which indicated interference with the sinus circulation. Operation was performed, and a large perisinus abscess was found, the sinus lying close up to the antrum. The white count before operation was 22,000, with 94 per cent polymorphonuclears (Fig. 12).

Case 3 This young woman was septic, and remained septic, due to a streptococcus hemolytic infection. Insomnia and pain were influenced by the X-ray exposure for only about ten hours. Her temperature varied several times a day, ranging from 101° to 103°. The tenderness was always

exquisite along the posterior border of the mastoid, and, when operation was performed, we found pure pus confined solely to several large posterior cells. Recovery was very prompt.

Case 4 The woman had had a discharging ear for one month. The drum healed and she felt well, but came to us for a check-up. The drum was normal in appearance, but the canal fundus was markedly narrowed. X-ray examination showed several areas of destruction. The patient slept well and had no temperature. Six days later she experienced pain behind the ear, and an evening rise in temperature. Roentgenographic examination again showed the same areas of destruction. Operation was advised and performed, disclosing a large perisinus abscess with granulations on the sinus about 2 cm in length. Recovery was rapid.

Case 5 One week postpartum, this patient required paracentesis of her left drum. She had a very severe tonsillitis and pan-sinusitis. Pain and insomnia continued after

- (d) Lessened quantity of discharge
 - (e) Change in the character of the discharge from purulent to mucopurulent
- 2 When, and if, the original symptoms recur, another exposure to the roentgen ray is given, then, in the great majority of cases, the syndrome of favorable action recurs, after this manifestation, resolution of the mastoid infection may be expected

3 Third and fourth exposures to the roentgen ray may be necessary in the more stubborn cases to secure resolution of the infection, especially in cases which show increasing bone pathology on X-ray examination, providing each exposure is followed by the syndrome of favorable action

4 A dosage ranging from between that required for making two plates of each mastoid to a 25 per cent erythema dose seems to be optimum for the apparent therapeutic effect Such dosage is considered one exposure

5 From experiences described herein and otherwise, we deem it advisable to attempt roentgen-ray therapy for acute mastoiditis under the following circumstances

- (a) when there is edema over the mastoid, or perforation of the cortex,
- (b) when there is extensive destruction of the mastoid process as shown on the roentgenogram,
- (c) when, in acute fulminating mastoiditis, roentgen-ray exposure fails to induce the syndrome of favorable action,
- (d) when the patient is diabetic, and there is evidence of bone destruction, even though the clinical picture is mild,
- (e) when the Griesinger sign is present, indicative of perisinus abscess or sinus thrombosis,
- (f) when the roentgenogram shows a cellular mastoid with the sigmoid sinus extending more anteriorly than usual, so that it impinges upon the antral

region, plus a marked clouding or softening The strong possibility of perisinus abscess formation should lead one to operate

- (g) when there is lowered resistance and low-grade sepsis, and serial plates show progressive destruction, and when further toxemia might seriously impair the recuperative power of the patient,
- (h) where there are symptoms of sinus thrombosis or phlebitis, meningitis, labyrinthitis, or brain abscess

CONCLUSIONS

1 If exposed on two or more occasions, acute mastoiditis, without bone destruction, frequently resolves under the influence of the roentgen ray

2 If exposed on two or more occasions, acute mastoiditis, with bone softening and destruction, may resolve under the influence of the roentgen ray

3 The roentgen ray exerts an influence upon acute mastoiditis which we have termed a syndrome of favorable action In most cases, this influence is followed by resolution of the infection, and it is, therefore, considered a therapeutic agent In some cases, even though this influence is experienced, operative interference is indicated

RECOMMENDATIONS

1 It may be advisable, as a prophylactic measure against mastoid disease, to treat acute otitis media by X-radiation at the end of the first week of discharge, and at three-day intervals thereafter, for three exposures, all told This formula is chosen arbitrarily from our experience at the present time

2 Once again, a plea is made for closer co-operation between the roentgenologist

Fig 12 Case 2, Table II.—Note the prominent lateral sinus in the right mastoid plate. The anterior sinus wall lies close to the antral region. Operation, which was indicated on account of the Griesinger sign, disclosed a large perisinus abscess.

nation. Prior to this date, only one plate of each mastoid was taken at each roentgen-ray examination, but, from this date on, two plates of each side were made at each roentgenographic examination. It is only since this change in routine that the favorable results herein reported were observed. For this reason we believe that the amount of irradiation incidental to making one plate of each mastoid is below the dosage required to produce the favorable effect.

The amount of irradiation used on the above cases may be judged from the following statement of technic employed on a standardized X-ray machine:

For diagnostic plates Ma, 30, time, one-third second to two seconds for each plate, depending on the age of the patient, focal distance 25 inches, gap, 4 inches, Law position, cone, 3 inches, two plates each side.

The therapy dose mentioned, and marked "T" in Table I, is 25 per cent of an erythema dose, given as follows Ma, 7.5,

time, 50 to 90 seconds, focal distance, 16 inches, gap, 6.5 inches, Law position, cone, 3 inches, one fiber filter. The pathologic ear is placed nearer the tube, as it then receives the greater amount of irradiation.

We have used this "T" dose in a few cases to determine whether or not it offers a more rapid resolution of the pathologic process; it was also used in cases that exhibited more severe clinical symptoms.

SUMMARY

1 In over 85 per cent of our cases, the roentgen ray caused an apparent change, within 24 hours after exposure, in the clinical picture of acute mastoiditis, affecting the temperature, pain, insomnia, and the amount and character of the discharge. This syndrome of favorable action is characterized by:

- (a) Lowered temperature
- (b) Cessation of pain
- (c) Absence of insomnia

- (d) Lessened quantity of discharge
- (e) Change in the character of the discharge from purulent to mucopurulent
- 2 When, and if, the original symptoms recur, another exposure to the roentgen ray is given, then, in the great majority of cases, the syndrome of favorable action recurs, after this manifestation, resolution of the mastoid infection may be expected

3 Third and fourth exposures to the roentgen ray may be necessary in the more stubborn cases to secure resolution of the infection, especially in cases which show increasing bone pathology on X-ray examination, providing each exposure is followed by the syndrome of favorable action

4 A dosage ranging from between that required for making two plates of each mastoid to a 25 per cent erythema dose seems to be optimum for the apparent therapeutic effect. Such dosage is considered one exposure.

5 From experiences described herein and otherwise, we deem it inadvisable to attempt roentgen-ray therapy for acute mastoiditis under the following circumstances

- (a) when there is edema over the mastoid, or perforation of the cortex,
- (b) when there is extensive destruction of the mastoid process as shown on the roentgenogram,
- (c) when, in acute fulminating mastoiditis, roentgen-ray exposure fails to induce the syndrome of favorable action,
- (d) when the patient is diabetic, and there is evidence of bone destruction, even though the clinical picture is mild,
- (e) when the Griesinger sign is present, indicative of perisinus abscess or sinus thrombosis,
- (f) when the roentgenogram shows a cellular mastoid with the sigmoid sinus extending more anteriorly than usual, so that it impinges upon the antral

region, plus a marked clouding or softening. The strong possibility of perisinus abscess formation should lead one to operate.

- (g) when there is lowered resistance and low-grade sepsis, and serial plates show progressive destruction, and when further toxemia might seriously impair the recuperative power of the patient,
- (h) where there are symptoms of sinus thrombosis or phlebitis, meningitis, labyrinthitis, or brain abscess

CONCLUSIONS

1 If exposed on two or more occasions, acute mastoiditis, without bone destruction, frequently resolves under the influence of the roentgen ray.

2 If exposed on two or more occasions, acute mastoiditis, with bone softening and destruction, may resolve under the influence of the roentgen ray.

3 The roentgen ray exerts an influence upon acute mastoiditis which we have termed a syndrome of favorable action. In most cases, this influence is followed by resolution of the infection, and it is, therefore, considered a therapeutic agent. In some cases, even though this influence is experienced, operative interference is indicated.

RECOMMENDATIONS

1 It may be advisable, as a prophylactic measure against mastoid disease, to treat acute otitis media by X-radiation at the end of the first week of discharge, and at three-day intervals thereafter, for three exposures, all told. This formula is chosen arbitrarily from our experience at the present time.

2 Once again, a plea is made for closer co-operation between the roentgenologist

and the otologist, because such co-operation must be conducive to a better understanding of the treatment of acute mastoiditis, a diminution in the percentage of cases coming to operation, and the development of an optimum dosage formula for the roentgenographic treatment of mastoiditis

Blocks of Millions of Atoms Make Up Solid Matter—The matter that seems to ordinary eyes so solid and unbroken is actually made of blocks, somewhat like a tile floor, each block made of several million atoms, Dr Francis Bitter, of the Westinghouse Research Laboratories, has just established for the first time through magnetic researches

Reporting to the American Physical Society, Dr Bitter described his experiments that upheld the previous theory that contends such block structure in solids exists

A magnetic powder was suspended in a liquid which was allowed to evaporate on a shiny surface of the metal cobalt. As the liquid evaporated a regular lace-work appearance was produced by the grouping of the particles. As these deposits were arranged in the form of hexagons, the Doctor concluded that the blocks of the metal itself had just

this hexagonal arrangement. Magnetization of the cobalt specimen changed the pattern to a series of not quite parallel lines, showing that the blocks had become differently arranged under the influence of the magnetic force. Irregularities in the pattern were produced, he believes, by impurities in the metal

This brick or mosaic structure provides the key to some of the most baffling problems about the strength and electrical resistance of solids

Dr Bitter's discovery was not accidental but followed logically from a long series of theoretical investigations in which he studied what would be the consequences of such a block structure in solids

It is of interest, furthermore, that Dr Bitter is the son of Karl Bitter, internationally famous sculptor—*Science Service*

RADIOTHERAPY OF PITUITARY TUMORS

By WILLIAM HARRIS, M.D., and HERMAN SELINSKY, M.D.

From the Departments of Radiotherapy and Neurology of Mount Sinai Hospital,
NEW YORK CITY

THE use of the roentgen ray as a therapeutic procedure in the treatment of pituitary tumors was first instituted by Gramegna and Béclère over twenty years ago. The more recent reports in the literature by Sgalitzer (1), Béclère (2, 3), Heinismann (4) and others are indicative of the widespread and accepted use of this form of therapy.

It is not our purpose to go into the historical difficulties in the treatment of pituitary tumors. It is sufficient to state that glandular and surgical methods have not always been rewarded by gratifying results. Hence, an addition to the therapeutic armamentarium which proves its value is an important contribution.

The early successful efforts obtained with roentgen rays in treating hypophyseal tumors have been amplified by the favorable results noted in this country and abroad, e.g., Bailey (5), Borak, Grant (8), Sgalitzer (1). The experience thus gained enabled the observers to a certain extent also to predicate the type of tumor with which they were dealing by the type of response to the roentgen ray (radiosensitivity). Thus, cystic tumors of the pituitary are known to be highly radioresistant to deep X-ray therapy, while the eosinophilic adenomas respond with fair promptness (Sgalitzer, 1). This observation explains to some degree the great variability in the results obtained.

Our present study is limited to thirteen cases in which the clinical picture of tumor in the pituitary region was manifested by visual disturbances, headache, dyspituitarism, and radiographic changes in the sella turcica.

The salient features of the thirteen cases are best illustrated by the accompanying tabulation.

COMMENT ON TABLE

(A) *Predominating Symptoms*

- 1 Headache in five cases
- 2 Visual disturbances in eleven cases (limitation of fields or diminution in visual acuity)
- 3 Polydipsia and polyuria in five cases
- 4 Acromegaly or adiposo-genital dystrophy in eleven cases
- 5 Menstrual disorders in seven of ten women
- 6 Somnolence in three cases

(B) *Sex and Fertility*

Of the thirteen cases reported above, ten were females. As might be expected, menstrual irregularity or cessation of menses was a frequent symptom, occurring in seven patients. Of the nine married patients in this series, eight had children before the onset of symptoms while the ninth practised contraception. The male patients suffered from impairment of libido and potency.

(C) *Sella Turcica Changes*

All cases except No. 3 and No. 11 showed definite erosion of the sella turcica.

(D) *Type of Dyspituitarism*

Although evidence of a mixed type occurred in some cases, the classification was based upon the preponderant symptomatology. Cases Nos. 1, 2, 4, 6, 9, 12, and 13 were classified as hypopituitarism, while Cases Nos. 3, 5, 7, 8, and 11 belonged to the group of hyperpituitarism. Case No. 10 did not show dyspituitarism but, in view of

TABLE ILLUSTRATING THE SALIENT FEATURES OF THIRTEEN CASES OF TUMOR
IN THE PITUITARY REGION TREATED BY RADIOTHERAPY

| Designation of subject | | | Symptoms | Findings | Treatment | Results | Date of last examination | Notes |
|----------------------------------|-----|-----|---|---|---|--------------|--|---|
| No | Age | Sex | | | Operation | Radiotherapy | | |
| 1737 I Adm Dec., 1925 | 29 | ♀ | Headache, failing vision, polydipsia, polyuria, transitory hemianesthesia, somnolence. Onset, 8 years | Hypopituitarism, obesity, optic atrophy, hemianopsia, bitemporal hemianopia, visual acuity—10/200 O.D. 20/50 O.D. Sella turcica, enlarged | Subsellar decompression, with intranasal radium application | 4 courses | Vision improved, extremities smaller, less somnolence, polydipsia and polyuria diminished, mentally more alert. Visual acuity 10/15 O.U. Hemianopsia reduced to quadrantic defect | March, 1931 Patient able to do housework |
| 1504 II Adm Oct., 1925 | 31 | ♀ | Progressive loss of vision, amenorrhea, gain in weight, polyuria. Onset, 3 years | Primary optic atrophy, incised sinuses, tolerance, diminished deep reflexes. X-ray of skull, negative | None | 4 courses | Initial improvement only, vision better, menses returned twice (Dec., June, 1926). Recently impairment of vision recurred. Otherwise unchanged. | April, 1931 Patient refused operation, craniopharyngeal pouch cyst. One child |
| 3827 III Adm Mar., 1929 | 26 | ♀ | Aromegaly, hypertrichosis, menstrual irregularity. Onset, 1½ years | Acromegalic features, normal visual fields, sella turcica enlarged, somnolence | None | 1 course | More alert, extremities smaller, tics markedly less pronounced, menses regular but scanty, memory better | December, 1931 Now attends Teachers' Training School |
| 3876 IV Adm Apr., 1929 | 45 | ♀ | Visual impairment. Onset, 2 years | Bilateral optic nerve changes | None | 3 courses | Distinct improvement—(vision better) after each course, has returned to housework | February, 1931 Visual fields slight restriction of left field only now, right hemianopsia. As before, reads better. Menopause at 42. Five children |

| | | | | | | | |
|-----------------------------------|---------|--|--|--|------------------------------|---|----------------------------|
| 3954 V Adm May, 1929 | 42 ♀ | Enlargement of extremities, change in voice and appearance, impairment of vision, amenorrhea Onset, 7 years | Acromegalic features, sella turcica changes, visual fields normal, macroglossia, +15 +15 | None | 3 courses | Mild improvement; vision better, facies less acromegalic, basal metabolism still elevated | January, 1931 |
| 4460 VI Adm Feb., 1930 | 18 ♀ | Blurring of vision, menstrual irregularity Onset, 3 months | Papilledema OD 4 D OS 3 D Obesity, increased sugar tolerance, sella turcica enlarged Visual acuity 10/15 | None | 2 courses | Improved Papilledema receding OD -2 D OS -1½ D Visual acuity 20/20 Menses still irregular | March, 1931 |
| 4750 VII Adm July, 1930 | 30 ♂ | Visual impairment, polydipsia, polyuria, impotence Onset, 1 year | Pallor, dry, coarse skin, scant hirsutes, slight acromegaly, limitation of visual fields, sella turcica changes | None | 1 course | Marked improvement, vision better, disappearance of central scotoma for color, less polydipsia and polyuria, more alert, basal metabolism rose from -29 to -9 | January, 1931 |
| 3848 VIII Adm Mar., 1927 | 51 ♀ | Enlargement of extremities, visual impairment, amenorrhea Onset (1923), 6 years | Acromegalic features, optic atrophy, sella turcica changes, incomplete amaurosis, left VII n palsy | None | 3 courses | Initial improvement only, somnolence gone, mentally more alert, less irritable, vision unchanged | March, 1931 |
| 2990 IX Adm Oct., 1927 | 21 ♀ | Headache, polydipsia, polyuria, amenorrhea Onset, 5 years | Dystrophia adipogenitalis, left homonymous hemianopsia, sella turcica changes, paresis of ext. recti | Transfrontal craniotomy with partial removal of cranopharyngeal pouch cyst | 2 courses prior to operation | Not influenced by X-ray therapy | Prior to death March, 1928 |
| 4762 X Adm Sept., 1930 | 50 ♀ | Diplopia, headache, vomiting, fatigability Onset, 1½ years | Bilateral ophthalmoplegia, sella turcica changes | Exploratory craniotomy Dec., 1930 | 1 course prior to operation | Initial improvement, diplopia, headache, and vomiting disappeared, ophthalmoplegia less marked, then recurrence, operation, exitus | |
| 4059 XI Adm July, 1929 | 49 ♀ | Headache, enlargement of extremities, photophobia, polydipsia, polyuria Onset, 9 years | Acromegalic appearance, hypertrichosis, fundi negative, tongue large, neg X-ray findings | None | 2 courses | No change | November, 1930 |

Reading easier and more distinct, distant objects clearer
Three times pregnant
Patient working
Two children

Postmortem showed right hemiplegia with aphasia 4 months after operation, with exitus (no autopsy allowed)

Seven pregnancies;
menses irregular or late

TABLE ILLUSTRATING THE SALIENT FEATURES OF THIRTEEN CASES OF TUMOR
IN THE PITUITARY REGION TREATED BY RADIOTHERAPY—Continued

| Designation of subject | | Symptoms | | Findings | | Treatment | | Results | Date of last examination | Notes |
|-----------------------------------|-----|----------|---|--|------|-----------|---|---------------|--------------------------|--|
| No | Age | Sex | Operation | Radiotherapy | | | | | | |
| 2709 XII Adm May, 1927 | 56 | ♂ | Headache, visual impairment, impairment of memory Onset, 3 years | Froelich habitus, central scotoma, contraction of color fields, pallor of right optic nerve, marked sella turcica, cringes | None | 3 courses | Marked improvement (a) Disappearance of headache (b) Vision for distance and reading practically normal (c) Potency preserved (d) Memory good Persistence of bitemporal limitation for color | April, 1931 | | Patient is conducting business, 7 children |
| 1690 XIII Adm Jan., 1926 | 20 | ♂ | "Failure to grow" over period of 7 years | Genital infantilism, dwarfism, anisocoria, temporal optic neuritis, marked sella changes | None | 2 courses | No change | October, 1926 | | Patient observed for only 10 months |

the ophthalmologic signs and sella turcica changes, it was suspected clinically of being a possible tumor of the pituitary region

TECHNIC

The technic consisted of a series of nine X-ray treatments given at two- or three-day intervals, each treatment 20 to 40 per cent S E D (skin erythema dose), 860 r units¹ equal to 1 skin erythema dose. Three portals of entry were usually employed, viz, one frontal and two temporal fields. Each field received 1 skin erythema dose. The filter was 0.5 mm Cu and 1 mm Al. The voltage was 180 to 200 kilovolts. Between the series of treatments, an interval of from three to six months elapsed.

In one case (No 1) the X-ray treatment was preceded by a subsellar decompression and an intranasal surface application of radium.

RESULTS OF THERAPY

Symptoms

Headache—There was relief in three of five cases in which headache was a prominent symptom. In one instance (No 10) the recurrence of symptoms did not include headache.

Visual Disturbances—Of eleven patients complaining of impairment of vision, eight were benefited. The improvement occurred even in some of those cases in which optic atrophy, with bitemporal hemianopsia, existed. The improvement was evidenced by less marked limitation of visual fields and greater visual acuity. In some cases, the patients manifested a greater control of the oculo-motor mechanism. It may be stated that the greatest improvement occurred in those cases in which treatment was begun in the early stages of the disease.

¹This dose of 860 r units (including back scattering from the patient) represents an erythema dose. The r unit refers to the International Roentgen Unit as recently adopted by the Bureau of Standards Washington D. C.

Polydipsia and Polyuria—Three of the six patients with a diabetes insipidus syndrome showed a definite diminution in symptoms

Dyspituitarism—Berven (6) and others have expressed doubt that regression in skeletal overgrowth may occur. In Cases No 1 and No 3 regression was definitely shown by the fact that, after radiotherapy, these patients wore smaller shoes and gloves. Another patient (Case No 5) was told by her family and friends after the third course of treatment that her features did not look "so big."

Menstrual Disorder—Following treatment, there was a return of menses in three cases. In Case No 3 the return of menses persists regularly, although scantily. In Case No 2, there was a menstrual flow on two occasions, each time following a course of treatment. In Case No 6, for a time the regularity of menstrual flow approximated a return to normal but later again became irregular. In other cases of amenorrhea, the patients were either in the normal menopause years or the cessation of menses had existed for a long time.

Somnolence—In four cases there was a definitely more alert attitude noted following treatment.

VALUE OF SUCCESSIVE SERIES

It has been stated that no improvement is noted after the third series of treatments (Berven, 6). While it is true that the greatest improvement may be expected after the first or second course of deep X-ray therapy, we have been able to observe definite improvement after the third course of treatment (Cases Nos 1, 4, and 5).

DURATION OF OBSERVATION

These cases were followed over varying periods of time, from nine months (Case No 10) to six years (Cases Nos 1 and 2).

Case No 13 moved away and could not be traced.

COMMENT

Variation in technic has been stated by Béclère (2) to be the chief reason for the unsuccessful results obtained in the treatment of pituitary tumors with the roentgen ray. This may be applicable to a limited extent only, for, in our experience, variation in technic has failed in some cases to alter the unfavorable course and progressive advance of the disease (Cases Nos 9, 11, and 13). The variation in the response to treatment, we believe, is due, rather, to the type of neoplastic tissue, i.e., radiosensitivity of the tumor. Cyst formation, macroscopically evident, is the most likely reason for failure of radiotherapy in certain cases. This point is strikingly exemplified in Case No 10, in which autopsy showed a cranio-pharyngeal pouch cystic tumor, and in Case No 9, in which a similar tumor was partially removed at operation. Of interest is the fact that Case No 10 showed definite, though temporary, improvement after deep X-ray therapy.

The cardinal value of deep X-ray therapy as compared to surgical intervention lies in the beneficial results obtained in the majority of cases, with the absence of immediate mortality. This is in accordance with a critical analysis of the literature. It is not assumed that radiotherapy can entirely replace surgical interference. It is recognized that under certain conditions urgent surgical intervention is indicated, i.e., marked intracranial pressure with increasing loss of vision. In view of the foregoing, it may be stated that the patient presenting signs and symptoms of pituitary tumor should first have the benefit of a therapeutic trial with radiotherapy. Surgery may be resorted to in those cases in which this form of therapy has failed to influence the course of the disease. It may be added that radiotherapy subsequent to the operation has been found

to be a valuable therapeutic adjuvant and has been adopted as a routine procedure

CONCLUSIONS

1 Thirteen cases of pituitary tumor were subjected to roentgen-ray therapy and observed at trimonthly intervals for varying lengths of time

2 Ten of the thirteen cases were females, three were males

3 Endocrine dysfunction consisted of manifestations of hypopituitarism in eight cases and of hyperpituitarism in four cases

4 Seven of the thirteen cases were distinctly benefited by the treatment and one showed temporary improvement Amelioration of headache and improvement in vision were most frequently noted In no case was there a complete disappearance of symptoms

5 Failure to respond to treatment is highly suggestive of a cystic tumor (cranio-pharyngeal pouch cyst)

6 Patients in whom diagnosis of pituitary tumor has been made should receive therapeutic trial with roentgen therapy before proceeding to surgical intervention

New Process of Photography by Ultra-violet Light—Photographic plates sensitive to ultra-violet light will shortly be made commercially by a new process, Dr C E K Mees has reported to the Optical Society of America

"Schumann" plates used for this purpose till now were difficult to make and had to be prepared by hand They had a coating either entirely free from gelatine or containing only a small trace of gelatine to bind the silver bromide together

In order to avoid the use of Schumann plates, two Frenchmen, Duclaux and Jeantet, suggested the treatment of ordinary plates

with a fluorescent substance which glows when exposed to ultra-violet light, and they employed petroleum oils to paint it on the plates Satisfactory results have been obtained by many workers with petroleum, but it is difficult to apply the oil uniformly and to remove it before development

R E Burroughs tested a large number of organic substances and found the most suitable to be ethyl dihydrocolhdine dicarboxylate, which fluoresces strongly in the ultra-violet This substance can be applied in organic solvents, from which it crystallizes in microscopic crystals over the surface of the plate, these crystals being easily removed before or during development of the plate—*Science Service*

AN X-RAY STUDY OF THE PASSAGE OF DIFFERENT FOOD-STUFFS THROUGH THE SMALL INTESTINE OF MAN¹

By LEON J MENVILLE, M.D., F.A.C.R., and J N ANÉ, M.D., Department of Medicine,
Tulane University of Louisiana, NEW ORLEANS, LOUISIANA

THE study of the passage of various foodstuffs through the stomach and intestines had been undertaken by many investigators previous to the discovery of the roentgen ray. It was impossible at that time to visualize the viscera of experimental animals except by operation, and this was undesirable as the process of digestion was thereby interfered with. These investigators could make observations only on animals having artificial fistulas, with variable results. Cannon (1), a few years after the discovery of the roentgen ray, was the first to report observations of the passage of various foodstuffs through the gastro-intestinal tracts of healthy animals.

In recent years, marked advancement has occurred in the study of the gastro-intestinal tract, due to improved roentgen-ray technic and the use of modern powerful apparatus. For this reason, we undertook the study of the passage of carbohydrate, protein, and fatty foodstuffs through the gastro-intestinal tracts of rats and human beings, in order that the findings of the earlier investigators might be compared with the results obtained through the employment of present modern facilities.

In a recent publication (2), we reported certain X-ray observations made on the passage of carbohydrate, protein, and fat through the gastro-intestinal tracts of rats. Rats were the animals of choice for our experiments because the character of their diet is closely related to that of the human species. The rat is an animal that ideally serves this purpose, in fact, it serves better than herbivorous or graminivorous mammals.

¹Read before the Radiological Society of North America
at the Sixteenth Annual Meeting at Los Angeles Dec 1-5
1930

The results of these experiments showed that there was very little difference in the passage time of protein and carbohydrate through the small intestines of rats, although the protein moved slightly faster. Fats were much slower than either carbohydrates or proteins. The rates of emptying time of the stomach, small intestine, and colon were in accordance with the findings of other observers. The rates of passage of the different foodstuffs through the small intestine were at variance with those recorded by earlier investigators who stated that carbohydrates passed through the small intestine fastest, fats next, and proteins the slowest of all.

Experiments conducted on human beings are always desirable when practical, because the results of animal experiments, when compared to the results in man, often show marked discrepancies. In animal experiments, however, certain liberties can be taken with the use of the X-ray which would become dangerous when applied to the human, and often very valuable and important information is obtained that proves of value for subsequent experiments conducted on man.

In our reported study of the passage of different foodstuffs through the gastro-intestinal tracts of rats, certain information was obtained which would prove of great value if similar results could be procured in man. For this reason the following experiments were undertaken on humans. The observations herein reported are the results obtained from X-ray examinations of healthy normal individuals fed carbohydrates in the form of cream of wheat, protein in the form of casein, and fat in the form of pure cream. These individuals

to be a valuable therapeutic adjuvant and has been adopted as a routine procedure

CONCLUSIONS

1 Thirteen cases of pituitary tumor were subjected to roentgen-ray therapy and observed at trimonthly intervals for varying lengths of time

2 Ten of the thirteen cases were females, three were males

3 Endocrine dysfunction consisted of manifestations of hypopituitarism in eight cases and of hyperpituitarism in four cases

4 Seven of the thirteen cases were distinctly benefited by the treatment and one showed temporary improvement. Amelioration of headache and improvement in vision were most frequently noted. In no case was there a complete disappearance of symptoms

5 Failure to respond to treatment is highly suggestive of a cystic tumor (cranio-pharyngeal pouch cyst)

6 Patients in whom diagnosis of pituitary tumor has been made should receive therapeutic trial with roentgen therapy before proceeding to surgical intervention

| Carbohydrate | 5 | 162 | 5 feet, 8 inches | 30 | 176 | 2 hours, 42 minutes | 2 hours, 37 minutes |
| Fat | 6 | 164 | 5 feet, 10 inches | 30 | 170 | 3 hours, 45 minutes | 5 hours, 6 minutes |

TABLE II —AVERAGES
(Rat)

| Foodstuff | Number | Weight (Grams) | Ate (Grams) | Cecum appearing time | Stomach emptying time | Small intestine emptying time | Colon emptying time |
|--------------|--------|----------------|-------------|----------------------|-----------------------|-------------------------------|---------------------|
| Protein | 18 | 245.1 | 6.8 | 4 hours, 26 minutes | 13 hours, 9 minutes | 15 hours, 1 minute | 63.4 hours |
| Carbohydrate | 15 | 204.1 | 5.3 | 5 hours, 5 minutes | 7 hours, 5 minutes | 10 hours, 24 minutes | 53.15 hours |
| Fat | 6 | 235.8 | 5.3 | 8 hours, 35 minutes | 16 hours 44 minutes | 29 hours, 10 minutes | 61.3 hours |

tine and colon. This was considered unnecessary because our previous observations, made on the emptying time of the small intestines and colons of rats, were in accordance with those of other observers.

Table II represents our previous re-

ported results obtained in the rat experiments. In comparing the two tables we find that, in both rats and humans, the rate of passage of protein through the small intestine is fastest, carbohydrate only slightly slower, and fats decidedly slowest of all.

Fig 1 Stomach of individual fed a mixture of protein and barium sulphate in the proportion of 3 parts of protein to 1 part of barium sulphate. Film made immediately after meal³

Fig 2 Stomach of individual fed a mixture of carbohydrates and barium sulphate in the proportion of 3 parts of carbohydrates to 1 part of barium sulphate. Film made immediately after meal

Fig 3 Stomach of individual fed on fats, a mixture of cream and barium sulphate in the proportion of 3 parts of cream to 1 part of barium sulphate. Film made immediately after meal

were about of the same weight, height, and age, and were fed the same amount of food-stuffs

After being deprived of their evening and morning meals, at 9 A M we fed each group 170 gm of foodstuffs in the proportion of three parts of food to one part of barium sulphate. Immediately after feeding they were carefully fluoroscoped to ascertain if any of the food had emerged from the stomach, in every instance this had occurred. This observation is in accord with that of McClure, Reynolds and Schwartz (3). We continued our fluoroscopic observations at frequent intervals until the food column had entered the cecum.

The protein group consisted of six individuals of an average age of 30 years, average height of five feet, eight inches, and average weight of 154 pounds. They were fed a mixture of casein and barium sulphate in the proportion of three parts of casein to

one of barium sulphate. They ate 170 grams

In the carbohydrate group we had five individuals of an average age of 30 years, average height of five feet, eight inches, and an average weight of 162 pounds. This group was fed a mixture of cream of wheat and barium sulphate in the same proportion as in the protein group. They ate 176 grams.

Six individuals comprised the fat group. Their average age was 30 years, the average height five feet, ten inches, and the average weight 164 pounds. This group was given a mixture of pure cream and barium sulphate in the same proportion as in the other two groups.

Table I represents the results of observations upon the emptying time of the stomach and the cecum appearance of individuals fed different foodstuffs. As we were principally interested in the rates of passage through the small intestines of the different foodstuffs we did not continue our observation for the emptying time of the small intes-

³The observations of our experiments were obtained by fluoroscopic examination, the plates here shown (Figs 1-6) merely serving to give an idea of how the work was done.

(Rat)

| Foodstuff | Number | Weight (Grams) | Ate (Grams) | Cecum appearing time | Stomach emptying time | Small intestine emptying time | Colon emptying time |
|--------------|--------|----------------|-------------|----------------------|-----------------------|-------------------------------|---------------------|
| Protein | 18 | 245.1 | 6.8 | 4 hours, 26 minutes | 13 hours, 9 minutes | 15 hours, 1 minute | 63.4 hours |
| Carbohydrate | 15 | 204.1 | 5.3 | 5 hours, 5 minutes | 7 hours, 5 minutes | 10 hours, 24 minutes | 53.15 hours |
| Fat | 6 | 235.8 | 5.3 | 8 hours, 35 minutes | 16 hours, 44 minutes | 29 hours, 10 minutes | 61.3 hours |

tine and colon. This was considered unnecessary because our previous observations, made on the emptying time of the small intestines and colons of rats, were in accordance with those of other observers.

Table II represents our previous re-

ported results obtained in the rat experiments. In comparing the two tables we find that, in both rats and humans, the rate of passage of protein through the small intestine is fastest, carbohydrate only slightly slower, and fats decidedly slowest of all.

CONCLUSIONS

The experiments on the human subjects demonstrate that protein—in the form of casein, carbohydrate—consisting of cream of wheat, and fat—ingested as cream, all leave the stomach at approximately the same time

The passage of protein through the small intestine of the human is much faster in every instance than fat and only slightly faster than carbohydrate. These findings in humans are similar to those obtained in our experiments with rats

We believe that the passage rate of the food column of different foodstuffs through the

small intestines of human beings is probably due to the muscular response of this organ. The rate of emptying time of the stomach seems negligible as it was demonstrated that some of the meal of the different foodstuffs passed through the pylorus at about the same time

Radium Rays Live Only Fraction of Second—"A short and adventurous life of a hundred millionth of a second is enjoyed by an alpha ray from radium after being imprisoned in the nucleus of the atom for a period which may range from less than a year to one thousand million years" Lord Rutherford recently described in London the results of his long researches in radio-activity in these terms in a lecture before the Royal Institution. "Despite its hectic life after escaping," he continued, "the brief period of activity of the alpha particle has been so thoroughly studied that we are better acquainted with its character and adventures than we could ever hope to be with the character and personality of a distinguished citizen

"The alpha particle has played a great part in the development of physics," continued Lord Rutherford. "It provided the first evidence of the transmutation of elements. It first afforded the opportunity of detecting effects due to a single atom, thus furnishing, for the first time, definite proof of the truth of the atomic theory. By its aid, also, an early

estimate was made of the dimensions of the atom. It was, moreover, by studying the scattering of alpha particles that the nuclear structure of the atom had been revealed, a peculiarity which constituted the basis of all modern views on the nature of the atom. The alpha particle had also proved invaluable in investigating the forces reigning at the heart of the atom, and had been applied with great success to the artificial transmutation of the light elements

"The nucleus of an atom constituted a minute world of its own. If an atom of radium were magnified to the size of the lecture room, its nucleus would be smaller than a pin head. In some sense we might regard the nucleus as analogous to a drop of water which was held together by surface tension, but the analogy would be a very rough one. In the case of the nucleus, the surface tension of the water drop is replaced by a potential barrier of great height, through which the particles inside are unable to escape. The height of the barrier at its crest might be as much as 20,000,000 volts"—Science Service

PRESENT STATUS OF THE PROBLEM OF MEASUREMENT OF X-RAY INTENSITY AND QUALITY¹

By JESSE W M DuMOND, B S, M S, PH D, and ARCHER HOYT, PH D,
California Institute of Technology, PASADENA, CALIFORNIA

OUR purpose in this paper is especially to stress the need for physically precise methods of measurement of X-radiation so as to render all clinical results accurate and mutually comparable. In our opinions, the presence of quantitative uncertainty in the biologic domain does not excuse the introduction of still more uncertainty in the physical domain, where precision is possible. In fact, physical precision is imperative in the measurement of the quality and quantity of X-rays given the patient before any progress in biologic precision can be hoped for. We wish also to point out a few of the pitfalls to be avoided in making physical measurements on X-radiation.

The physical measurements required fall into two groups, namely, measurements of *quality* and measurements of *quantity*. We shall consider first measurements of *quality*.

It is well known that X-rays form a spectrum of wave lengths. The radiation from an X-ray tube operated at, say, 200 KV constant potential is continuously distributed over a range of wave lengths from 0.061 down to, say, about 1 Ångstrom unit. The shorter the wave length, the more penetrating the radiation. If the tube is operated at a constant potential, such as can be supplied with valve tubes and condensers—or better yet with a storage battery of many cells such as the one used by William Duane in his physical researches—it is found that the radiation emitted by the tube has a sharply defined minimum wave length called the short wave limit. The tube emits no radiation harder than this limiting wave

length. Moreover, this limiting wave length is related to the constant voltage operating the tube by a very rigid physical law which states that the minimum wave length is inversely proportional to the voltage. In addition to the continuous spectrum emitted by an X-ray tube, spectral lines characteristic of the material of the target are present at certain definite wave lengths. All this is an old, well-known story.

The quality of X-radiation can be roughly described in terms of its penetrating power, or effective wave length, or depth dose, but strictly speaking it is more than any of these. In this paper, when we speak of the *quality* of X-radiation, we mean the way in which the radiant intensity is distributed over the wave length spectrum. Needless to say, the quality, or spectral distribution of radiation, is a factor of prime importance in X-ray dosage.

It has been general practice to specify quality by measuring the voltage applied to the tube, specifying the filters used. This would give a fairly dependable description, provided the voltage were supplied from a constant potential source and were measured by an accurate method. In practice, however, the source of voltage is frequently a mechanically rectified outfit which supplies a very fluctuating voltage. If the mechanical rectifier is ill designed or in poor adjustment, oscillations or surges of rather high frequency occur incident to the sparking. The peaks of these oscillations correspond to a much higher voltage than the voltage actually effective during the bulk of the time. If the voltage is measured with a sphere gap, this latter will, of course, measure the highest peak of the highest

¹Read before the Radiological Society of North America, at the Sixteenth Annual Meeting at Los Angeles Dec. 1-5, 1930.

oscillation and will, therefore, mislead the radiologist into the belief that his radiation is much harder than it actually is.

If all radiologists had mechanically rectified equipment, and if all the mechanical rectifiers were identical and in identically the same state of adjustment, the discrepancy I have just mentioned would cause no trouble. A radiologist might measure 200 KV with his sphere gap and, even if his radiation really corresponded to only about 160 KV, all other radiologists would be able to reproduce his results.

On the contrary, many hospitals and clinics now have constant potential sources of high voltage with valve tube rectifiers and condensers. Such sources are entirely free from oscillations and supply a voltage with negligible ripple. In this case a sphere gap or other measurement of voltage will give the true voltage effective in producing X-rays and not a fictitious voltage a considerable percentage higher.

Between these two extremes the discrepancy may vary as much as 40 per cent, depending on the wave form of the voltage supply. As an example, we may cite two different hospital sets which the radiologists thought in good faith were operating comparably. One spectrogram, taken on a constant potential outfit with the Seeman spectrograph, showed radiation extending in hardness down to a sharply defined minimum wave length of 0.078 Ångstrom. The voltage was computed at 157 kilovolts. The other spectrogram, taken on a mechanically rectified outfit with the same Seeman spectrograph, had an ill defined short wave limit, and only a small fraction of the radiation was harder than 0.1 Ångstrom, equivalent to 129 kilovolts. The important point, however, is that the sphere gap on this latter set broke down at a setting corresponding to 200 kilovolts. Part of this enormous discrepancy was due to the erroneous method of setting the sphere gap and then switching

on the voltage instead of first switching on the voltage and then slowly screwing the spheres together until sparking occurs. Surges incident to switching may give excessive momentary voltages. But a great part of the discrepancy is also due to the oscillations and irregular wave form of the mechanical rectifier.

The effective wave length from the constant potential set operated at 157 KV, 0.5 mm of Cu and 1 mm Al was measured with filters and found to be about 0.16 Å, while the effective wave length from the mechanically rectified set measured in the same way was about the same although its sphere gap had indicated 200 kilovolts. The effective wave length measured with filters is thus a less misleading index of the quality of the radiation though it evidently does not tell the whole story because there is a great difference in the intensity of the radiation from the two sets in the region between 0.1 and 0.07 Ångstroms.

From these and other observations we have made we conclude that it is most unsafe and uncertain to describe the quality of X-radiation merely in terms of voltage as measured with a sphere gap.

The radiologist is interested in the quality of radiation given the patient, and direct measurements of that radiation are to be preferred to indirect measurements with a sphere gap. The Seeman spectrograph in the hands of a skilled operator gives complete information as to the spectral distribution of the radiation. Depth dose measurements with a water phantom and effective wave length measurements with filters as recommended by William Duane give results that correlate well with the spectrograph.

VOLTAGE CALIBRATION WITH SPECTROGRAPH

It is possible to calibrate the voltage of a constant potential X-ray outfit very satisfactorily with the Seeman spectrograph by

making measurements of the short wave limit, because in the constant potential outfit this limit is sharply defined. We made a voltage calibration for a local hospital in this way and the departure of the individual points from the straight line was very small.

INTENSITY MEASUREMENTS

The last International Radiological Congress at Stockholm, July, 1928, has defined the roentgen unit as that "quantity of X-radiation which when the secondary electrons are fully utilized and the wall effect of the chamber is avoided produces in 1 c.c. of atmospheric air at 0°C and 76 cm mercury pressure such a degree of conductivity that one electrostatic unit of charge is measured at saturation current."

Using the Wilson Cloud chamber method,² we photographed the tracks of the fast electrons ejected by X-rays passing through air. Three photographs were made with increasingly hard X-rays, and, the harder the radiation, the longer the tracks of the fast ejected electrons. Now small ionization chambers are used for measuring the integrated intensity of both direct and scattered radiation in the vicinity of human tissues. In such chambers an appreciable number of the electrons ejected from the air atoms in the chamber strike the walls of the chamber before they have produced their full quota of ions. This effect is greater the harder the radiation because the electron tracks are longer. The emission of fast electrons from the walls of the small chamber into the air introduces a further complication. In three of the best dosimeters now on the market which we have examined these two effects do not compensate each other for all voltages or qualities of radiation. Because of these and other facts there is good reason to believe that it is next

to impossible to build a dosimeter which will have one and the same calibration for all qualities of radiation.

We have pointed out that the quality of radiation (spectral distribution of intensity) on different types of X-ray high voltage supply is so variable that it seems infeasible for manufacturers to calibrate their dosimeters in terms precisely applicable to all sets. This means that in the present state of development of high tension generators for deep therapy the intensity measuring instrument should be calibrated at least once, and preferably periodically, against a standard ionization chamber for several voltages and filtrations *on the set with which it is actually to be used*. By the standard ionization chamber we mean a large chamber so arranged that the wall effects just mentioned are negligible. Standard chambers are suitable for calibrations of X-ray intensities only and cannot be used directly to integrate both scattered and direct radiation at a point in the vicinity of human tissues.

In the course of our work we have devised a new and simple type of dosimeter described below, which avoids many of the complications of the ionization type. With all others, however, it shares the necessity of being preferably calibrated for the set on which it is to be used.

A NEW FLUORESCENT X-RAY INTENSIMETER

About a year ago while doing some incidental work on the problem of measuring X-ray intensities we made a rather extensive analysis of the various possible methods of measurement. Searching for a simple, as well as reasonably accurate, method we set about to make use of the brilliance of the fluorescent screen as an indication of the intensity of the exciting X-ray beam. It is a matter of common experience that the brilliance of the fluorescent screen depends on the intensity of the exciting X-rays. That

²Water vapor is made to condense on the air molecules photographed.

fluorescence is a very complex physical phenomenon, having a complicated law which governs the relation of intensity to brilliance, is not necessarily a drawback to the use of this phenomenon as a means of measuring X-ray intensity, since all intensity measuring devices must be individually calibrated in terms of the international standard of intensity, roentgen units-seconds.

In using the brightness of a fluorescent screen to measure X-ray intensity, we must compare this brightness with some standard luminosity. This standard of luminosity must have about the same color as the fluorescing screen and some means must be provided to compare the standard of luminosity with the fluorescent screen excited by the X-ray beam the intensity of which is to be measured. Through the use of a device somewhat akin to the optical photometer this can be accomplished. The standard of luminosity taken is a piece of fluorescent screen (cut from the same sheet as the first screen) excited by the rays from a small quantity of radium (about 2 milligrams). It was found that the color of the fluorescent light was the same in both cases. Further, the intensity of the radiation given off by radium does not vary more than 2 per cent in 20 years, and even then varies in a known and uniform manner. Since one cannot make accurate judgments about two luminosities which differ greatly in brilliance, a neutral gray filter wedge made by the Eastman Company is used in our intensimeter to equalize the two fluorescent fields, the brilliance of the X-ray screen being cut down until it matches that of the standard, radium-excited, screen. The position of the wedge is recorded by an arbitrary scale, and calibration curves (for various voltages and filters) are made up which relate the readings on this scale to the X-ray intensity as determined initially by a standard air ionization chamber. The standard screen, which is protected by a lead

shield, is not held in the primary X-ray beam. The measuring screen is housed in a thin micarta tube which is water-proof and may be inserted into body cavities or a water phantom, if so desired. A photometric match of the two luminosities is made by viewing the two optically superimposed, concentric images of the two fluorescing screens through a Ramsden eyepiece, shifting the optical filter wedge until the central field is of the same brilliance as the outer field. This scale reading is then applied to the proper calibration curve and the intensity in r units-seconds is obtained therefrom.

This instrument possesses several special features which make it desirable in many cases. There are no electrical circuits involved with the insulation difficulties attendant upon measuring very small currents accurately. The instrument is compact, relatively inexpensive, and cannot get out of order easily. The standard of luminosity is the brilliance of a second fluorescent screen excited by radium, consequently it will not vary over a long period of time. The instrument can be used in any position and in a water phantom, further, it has no extremely delicate suspensions and fibers to be broken as do electrometers and galvanometers.

To verify the operation of our particular experimental instrument, we made a set of calibration curves for each particular filter and voltage setting used, relating the scale reading of the filter wedge to the intensity in r units-seconds. During the calibration of this instrument two independent observers agreed in the intensity measurements to within 5 per cent most of the time. This precision would be sufficient for most biologic dosage work, but by a special improvement in the optical system this precision can be somewhat improved, making the instrument quite adequate for general use.

CO-OPERATION BETWEEN PHYSICIST AND PHYSICIAN

Our experience in this locality in X-ray measurements has impressed us with the numerous pitfalls besetting the path of the roentgenologist who is anxious to be precise as to his dosage. The entire question of the physical measurements of X-ray intensity and quality is a delicate one even for a highly trained physicist. For these reasons, we feel that much could be gained by a more extensive co-operation between the physicist and the physician and we cannot too highly commend the practice of a few roentgenologists who employ the part-time services of a trained physicist to insure at all times an accurate knowledge of the radiation

given their patients. We physicists are ready to help you if physicians will call on us.

DISCUSSION

DR DUMOND (closing remarks) The instrument we have devised is not yet on the market and it is still under observation, but we feel that it has reached a sufficient stage of development to be of interest to radiologists. We have reason to believe that this instrument is not subject to the objection of deterioration of screens. However, except when the instrument is in use, we do take the precaution of removing the source of radium used as a standard from behind the screen on which it is supposed to act. We are continuing our tests on this particular feature.

Cosmic Riddle Solution Seen in Electricity on Earth and Sun—Hope that “the solution for the great cosmic riddles of the world” will be found by continued careful study of such seemingly unrelated phenomena as spots on the sun, electrified atmosphere miles above the earth, radio echoes, and electricity and magnetism in and around the earth has been expressed by Dr Arthur E Kennelly, Professor Emeritus of Electrical Engineering of Harvard University and Massachusetts Institute of Technology. His name is linked with that of the English physicist, Oliver Heaviside, in the discovery of one of the phenomena in which he thinks the solution to the great riddles lies. It is the Kennelly-Heaviside layer of ionized, or electrified, atmosphere.

“It is found from numerous records,” Dr Kennelly said, “that the apparent height of the ionized layer is related to the strength of

long-distance radio signals, such as those coming over the Atlantic ocean. Also the strength of received radio signals is found to be related to the earth’s magnetic activity, as recorded photographically in a number of terrestrial magnetic observatories. This magnetic activity, in turn, is related to the conditions at the surface of the sun as revealed by sunspots. Thus, radio reception, ionized layer height, terrestrial magnetic activity, and the 11-year sunspot cycle are all correlated. Changes in one accompany changes in the others. The spots on the surface of the sun are found to be associated with outpouring of ultra-violet light, and this may change the depth and density of the ionized layer in the atmosphere. This can affect radio signals, and somehow affects the earth’s magnetism”—*Science Service*

ROENTGEN EVIDENCE OF OSSEOUS MANIFESTATIONS IN SICKLE-CELL (DREPANOCYTIC) ANEMIA AND IN MEDITERRANEAN (ERYTHROBLASTIC) ANEMIA¹

By LEON THEODORE LEWALD, M.D., Professor of Roentgenology, New York University and Bellevue Hospital Medical College, Attending Roentgenologist Willard Parker Hospital, NEW YORK CITY

MEDITERRANEAN anemia would appear to be of unusual interest to roentgenologists because of the fact that bone changes are characteristic of the disease. There are two types which have come under my personal observation first,

Case 1 J R, male, aged 6 years, colored, presented a case of sickle-cell anemia. *The diagnosis in this case is based entirely upon the X-ray appearances of the skull.* This patient was referred to the X-ray Department at St. Luke's Hospital from the Out-

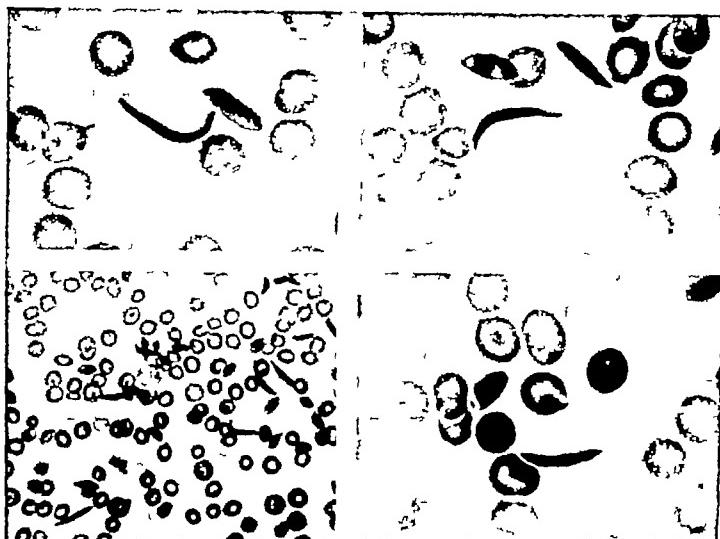

Fig 1 Blood from a case of sickle-cell anemia (Herrick)

one in which the lesion is found in the negro race (16), being commonly associated with sickle cells (5) in the blood (Fig 1), and second, the type commonly known as erythroblastic anemia (9), which occurs in races bordering on the Mediterranean, more particularly among the Italians and Greeks (2, 10). One case of the first type and two cases of the second type will be described, and comparison with similar cases reported by other authors is noted.²

patient Department for examination because of a lesion in the lower jaw

X-ray Examination—A most unusual and remarkable condition, due to the thickening of the middle and outer tables of the skull associated with peculiar radiating lines passing almost at right angles with the inner table of the skull, was revealed. The skull was approximately from one to two inches in thickness at the vertex, this thickening giving it a peculiar shape resembling that of tower skull (Figs 2 and 3). In fact, the case was regarded as belonging to this category until a paper by Rose (10), of

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting, at Los Angeles, Dec. 1-5, 1930.

²An additional case of Dr W. Edward Chamberlain's will be reported in a subsequent issue of RADIOLoGY.

Chicago, brought to my attention the fact that this type of skull was associated with sickle-cell anemia Dr Rose and several

Fig 2 Case 1 Colored male, age 6 years (for X-ray appearance, see Figure 3) This case is regarded as one of sickle-cell anemia from the X-ray appearance of the skull

others, who have examined skulls of this type in which the blood findings have been studied, have agreed with me that this case represents one of sickle-cell anemia, although the findings have not as yet been confirmed by blood examination, and the patient has passed out of observation I am still making efforts to trace him

Fig 3 Case 1 Since the skull shows enormous thickening, this is regarded as a case of sickle-cell anemia (See Figure 2)

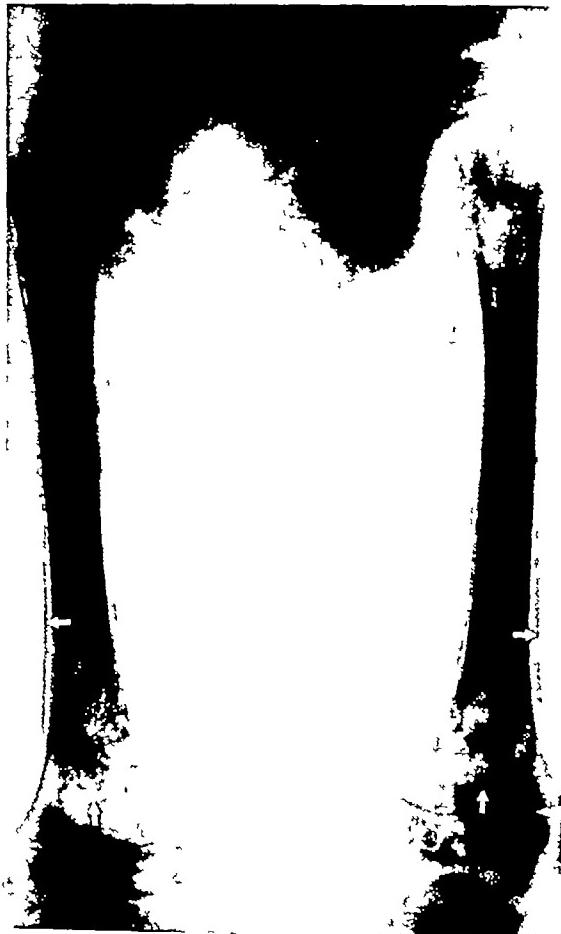

Fig 4 Chloroma in a male child, three and a half years of age Note the elevation of the periosteum in addition to the reticulated appearance of the medulla

Comment—This type of lesion has been studied particularly by Cooley, Hahn, Mandeville, Rose, Sosman, Vogt, and Wollstein In addition to the changes in the cranium, Mandeville describes irregular trabeculations in the pelvis, vertebræ, ribs, clavicles, and scapulæ He also describes thinning of the cortex of the long bones, stating that this is an important rather constant finding, and rarefaction of the shafts of the long bones, sometimes referred to as "transparent medulla"

In distinction to the bone changes observed in chloroma, I would call attention to the fact that there are no periosteal changes in sickle-cell anemia, while, in chloroma (3),

periosteal changes, in addition to medullary changes, constitute an important radiologic appearance (Fig. 4) In chloroma there is also a characteristic separation of the suture lines of the skull along with productive

female (reported as Case 3) are said to have anemia

Blood Examination (April 30, 1930)—Hemoglobin, 36 per cent, erythrocytes, 3,670,000, leukocytes, 13,000 The cor-

Fig 5 Same case as shown in Figure 4 Note the separation of the sutures

changes in other portions, such as about the orbits and temporal regions rather than the vertex (Fig. 5) The changes are easily distinguished from those seen in rickets, scurvy, and syphilis

Case 2 N D, male, aged 14 years was born in New York of Italian parents, the mother coming from southern Italy This case (Fig. 6) is one of Mediterranean anemia of the congenital type associated with enlargement of the spleen (erythroblastic anemia) The patient had been under observation six years previously on account of enlarged spleen He had been given X-ray treatment which resulted in marked reduction of the size of the spleen and apparent improvement in his general condition Three cousins, two males and one

puscles showed marked anisocytosis and poikilocytosis with a few sickle-shaped forms, many normoblasts, and an occasional megaloblast There were pronounced central pallor, basophilic stippling, and polychromatophilia. The differential leukocyte count showed polymorphonuclear neutrophils, 48 per cent, small lymphocytes, 45 per cent, large mononuclear leukocytes, 3 per cent, eosinophils 3 per cent, and basophils, 1 per cent

After treatment, the blood examination showed hemoglobin, 48 per cent, erythrocytes 4,180,000, leukocytes, 8,000 Characteristics of erythrocytes the corpuscles showed anisocytosis and poikilocytosis with marked central pallor some polychromatophilia and basophilic stippling An oc-

casional normoblast was seen. The differential leukocyte count showed polymorphonuclear neutrophils, 49 per cent, small

striations and thinning of the cortex of the long bones reported by other observers in this type of anemia (Fig. 7) were seen

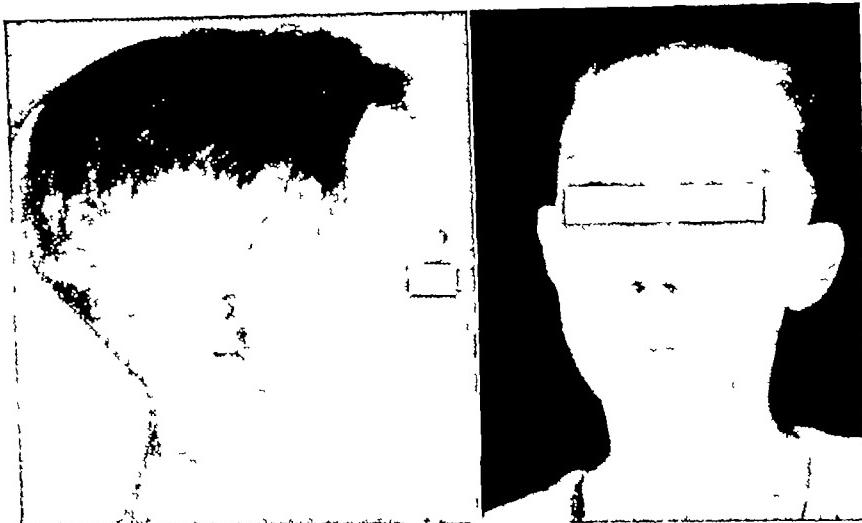

Fig. 6 Case 2 Mediterranean anemia (erythroblastic type). Note the mongoloid features

Fig. 7 Case 2 (A) Note the striated appearance of the medulla and thinning of the cortex (B) Normal shown for comparison

lymphocytes, 42 per cent, large mononuclear leukocytes, 4 per cent, eosinophils, 5 per cent, basophils, none

X-ray Examination—The characteristic

The skull showed a peculiar thickening in the frontal and in the occipital region (Fig. 8). In the frontal region the bone was about one-half inch in thickness, in the oc-

Fig. 8. Case 2. Note the thickening of the skull with radiating lines over the vertex. The sphenoid sinuses are undeveloped.

cipital, the skull was about three-quarters of an inch thick. The sella turcica was rather small. The sphenoid and left frontal sinuses were undeveloped, and the maxillary sinuses were very small.

Comment.—This case is of particular interest in view of the fact that, whereas splenectomy has been advised in this type of anemia, the same result seems to have been accomplished by means of X-ray therapy. The patient's spleen has remained reduced

in size after an interval of several years after X-ray treatment ceased.

The changes in the skull in this type of anemia offer considerable contrast to the changes found in sickle-cell anemia. The thickening of the skull is more uniform and appears to be localized to the frontal and occipitoparietal regions, rather than to the vertex. There is less evidence of striations than in sickle-cell anemia. The changes in the medulla of the long bones are particularly evident, especially when contrasted with the normal subject on the same film.

Case 3. I.D., female, aged 11 years, born in New York of parents from Southern Italy, is a cousin of Case 2 (Fig. 9). The diagnosis was Mediterranean anemia, congenital in nature (erythroblastic anemia).

X-ray Examination.—The skull showed the typical thickening characteristic of erythroblastic anemia. The thickening was particularly evident in the middle and outer tables in the frontal region where the skull measures three-quarters of an inch in thickness. The parietal region also showed thickening amounting to about one-half inch.

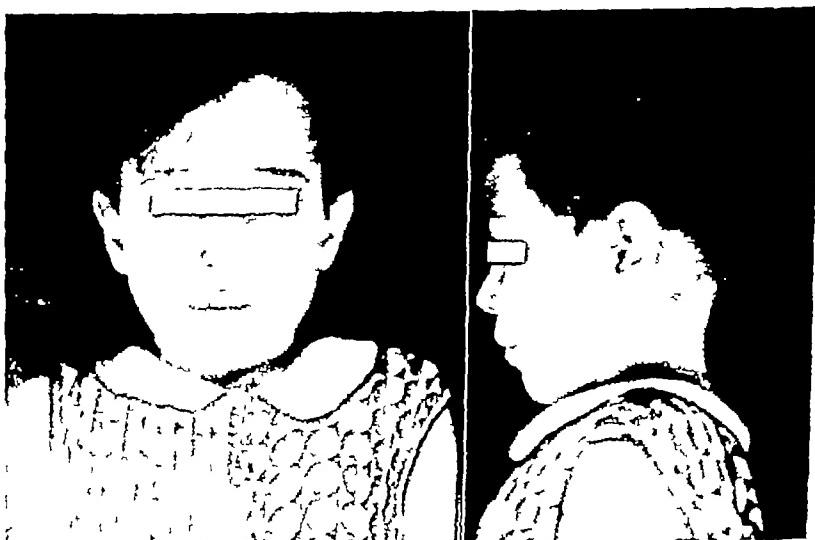

Fig. 9. Case 3. Mediterranean anemia (erythroblastic type). This child is a cousin of the patient known as Case 2.

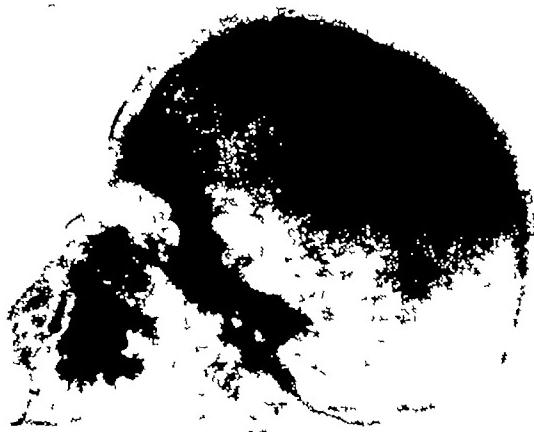

Fig 10 Case 3 Note the thickening of the skull, with radiating lines over the vertex

(Fig 10) There was fairly well marked striation at right-angles to the inner table of the skull in the thickened area in the frontal region. The sphenoid sinuses were undeveloped. The sella turcica was of average size. In the long bones examined, the cortex was thinned and the medulla striated. Similar changes were noted in the small bones of the hand, being particularly evident in the metacarpal bones of the thumb (Fig 11)

Comment—This case is of particular interest in view of its familial type, showing its congenital nature

CONCLUSIONS

1 Mediterranean anemia shows characteristic changes in the bones of the skull and other portions of the skeleton

2 In the negro, the disease manifests itself as sickle-cell anemia, being characterized by involvement of the vertex of the skull, which shows at times enormous thickening in the form of radiating lines at right-angles to the inner table of the skull

3 Erythroblastic anemia occurs in white children of Mediterranean parentage, especially in Italians and Greeks. The roentgen findings show characteristic changes in the skull consisting of thicken-

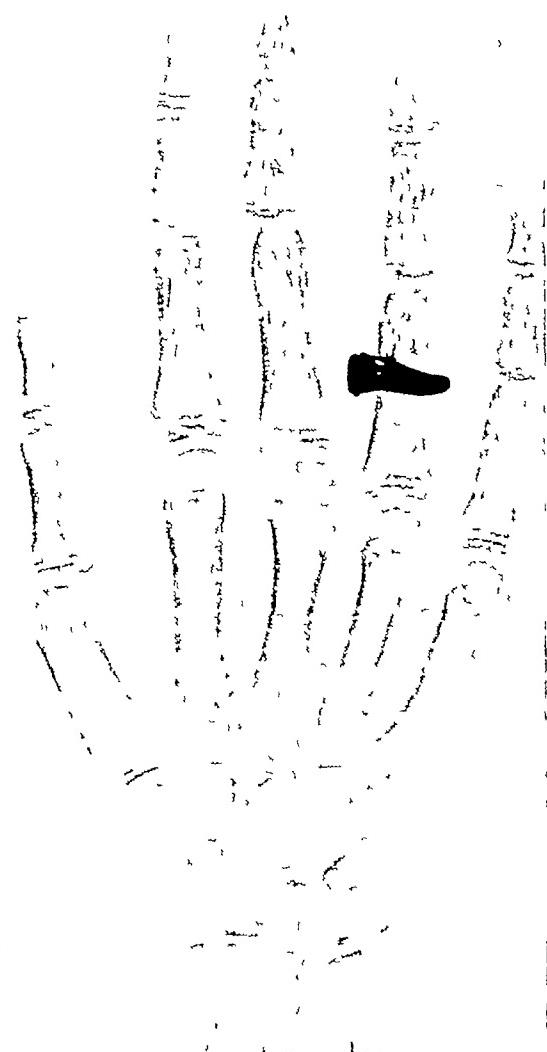

Fig 11 Case 3 Note the striated appearance of the medulla and thinning of the cortex

ing, especially in the frontal and occipitoparietal regions

4 In erythroblastic anemia associated with enlargement of the spleen and liver, roentgenotherapy is an exceedingly valuable method of treatment and may give as satisfactory and permanent a result as splenectomy

Lists Eight Forerunners of Cancer of Digestive Tract—Eight conditions of injury or degeneration which occur in the digestive tract before the development of cancer have been listed by Prof Matthew J Stewart, of the University of Leeds, in a series of lectures delivered before the Royal College of Physicians

"At the present time it is probably true to say that the most hopeful side of cancer research is that concerned with the demonstration of local causative factors, and the recognition and prevention of precancerous lesions of one kind or another," Prof Stewart declared at the beginning of his first lecture

"Unfortunately it is to the more superficial forms of malignant disease, a very small fraction of the whole, that this principally applies"

Conditions of the digestive tract that may develop into cancer are not so definitely known as precancerous conditions elsewhere in the

body, Prof Stewart pointed out, nor are the opportunities so good for preventing cancer of the digestive tract

In one year there were 56,896 deaths from cancer in England and Wales, according to the official figures he quoted. Of these, over half in men and nearly half in women were referable to the digestive tract

Prof Stewart divided the chief precancerous conditions into three groups. The first consisted of chronic inflammatory conditions, such as sores due to burns and chemical caustics, cirrhosis of the liver, certain diseased conditions of the gall bladder, chronic stomach ulcer, chronic inflammation of the stomach, chronic duodenal ulcer, and three conditions less well-known to the layman, diverticulitis hemochromatosis, and leukoplakia. The second group consisted of simple tumors which may be forerunners of cancer. The third group consisted of sores or injuries due to animal parasites.—*Science Service*

THE PRESENT STATUS OF APPENDICEAL DIAGNOSIS¹

By ROY A PAYNE, M.D., PORTLAND, OREGON

THE papers on appendiceal pathology, in 1886, and the reports of the first operation for the removal of the appendix, in 1887, had far-reaching effects. The spectacular results in a certain percentage of the cases led to operations for acute or chronic appendix for a wide range of abdominal symptomatology, either real or imagined. The inevitable reaction followed and the pendulum swung far back until operation for any except acute appendices was condemned. The diagnosis of chronic appendicitis was disputed by many surgeons. There must be a calm or a cyclone—no gentle breeze was tolerated.

My work in diagnosis began at a time when, of patients entering the clinic in which I worked, nearly 50 per cent had previously had their appendices removed. At least one-half of these had received no admitted benefit from the operation. Routine X-ray examinations of 6-hour and immediate meal, 24-hour, 48-hour and enema, revealed few appendices outlining. Naturally we accepted the prevalent view and in those early years I remember only two diagnoses of appendicitis being made.

Yet from time to time reports filtered back of patients who had suffered removal of ruptured appendices at later dates. Re-checking of our records revealed no sure criterion for a diagnosis. Upon seeking the opinions of others on this subject which was of tremendous interest to us, we found a wide variation of opinion among roentgenologists. I well remember a discussion in which I was interested to hear one roentgenologist maintain that all appendices which did not outline were pathologic and should come out. His opponent was equally

certain that any appendix that did outline was pathologic and should come out. We decided that more work was necessary before the subject could be closed.

Our efforts to obtain evidence redoubled. More careful and more frequent screenings of the emptying cecum revealed filling in the majority of appendices. Careful palpation discovered tenderness often appearing at a screening although it had been absent on previous exposure. In some cases this pain was referred to the region of the solar plexus and the patient compared it to digestive discomforts that had been complained of in his history. At about this time A. L. Gray, M.D., of Richmond, Virginia, reading in Washington, D.C., on "Cyclic Vomiting in Children," traced the etiology to the appendix. He stated his belief that children showing an appendix with an emptying time of over 100 hours had a pathologic appendix. In cases in which the appendix was removed, the patients were relieved of the vomiting.

Rejoicing that this work in children coincided with our studies of adults, we continued our investigation. In checking the literature we found a gradually increasing number of articles on this subject. The reason for this is well set forth by Gatewood (3), who states:

Despite the enormous literature on appendicitis, the recent statistical reports show an increasing mortality. The reasons for this are not at once apparent but, in looking over new cases, we have been struck by the fact that mortality occurs chiefly at the two extremes of life. The seriousness of appendicitis in children has been well recognized, but there has not been so much observed about appendicitis in the aged. Moes, discussing the subject at the Louisiana Medical Society, gave a mor-

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting, at Los Angeles, California, Dec. 1-5, 1930.

tality of 29 per cent in patients over 50 years of age E M Fitch, in 1928, reported the results of a questionnaire covering 6,548 cases The average mortality rates in institutions replying to his queries averaged from 19 to 9 per cent In patients over 50 years of age, the death rate averaged from 19 to 50 per cent

In his series at the Claremont, North Hampshire, Hospital the mortality was 21 6 per cent in patients between 50 and 60 and 54 per cent in patients between 60 and 70 Part of the high mortality is attributed to the lowered resistance of the patients Much more however, can be explained upon the basis of errors in diagnosis and upon pathology peculiar to these older individuals Lehman reported six cases from the Virsorginshien, in Lains, calling attention to this atypical picture, and Erdheim, in his pathologic conferences at the same institution, has frequently demonstrated autopsy specimens of old persons dying of unrecognized appendicitis with resultant peritonitis

I wish to present an analysis of findings in 256 cases, taken from a series of 4,500 case records in private practice, in which appendiceal pathology has been demonstrated Our observations of the appendix are listed under (1) Abnormality in position, (2) Tenderness, (3) Stasis, (4) Non-filling, (5) Abnormal outlines and adhesions While this research has been developed independently, we make no claim to originality in this matter Bird (1), 1928, stated and illustrated beautifully the majority of these points He says

In following up a number of cases in which I had reported what I believed to be a pathologic appendix, and in which the surgeon had agreed with the diagnosis and performed an appendectomy, a correlation of the findings has led me to consider that an appendix having any of the following characteristics is probably pathologic

(1) Retrocecal and bound down by adhesions

- (2) Adhesions holding the tip in a fixed position
- (3) The presence of sharp kinks or loops that are constant and cannot be smoothed out under the fluoroscope
- (4) A constriction of the lumen at the base, with a bulbous tip
- (5) Pressure tenderness over the appendix, changing with change in position of the cecum
- (6) Retention of barium in the appendix after the cecum is empty

It is to amplify this and to study further relationships that we undertook our inquiry

Let us review the causes of the first of these conditions Accidents to the cecum naturally affect the appendix and, conversely, accidents to the appendix may affect not only the appendix but the position and the function of the cecum Whether the pathology present in these instances is the result of early inflammations or mere accidents of growth is open to question Certainly the demonstration of the altered position is most important to the patient, as, knowing it, any physician who sees the patient during an acute attack may much more easily obtain a diagnosis in the presence of atypical symptomatology, and the surgeon at operation may incise to fit the altered anatomy Relationships to other organs are much altered Altered positions must result in changed lymphatic drainage In our experience gallbladder and duodenal pathology seem much more frequent in these cases

Again, in the matter of stasis, anatomic conditions are involved Andresen (2) states

Several anatomic facts in regard to the appendix must be borne in mind to understand its physiologic and pathologic behavior In the normal appendix, the mucosa is ciliated, with the action of the cilia directed towards its outlet, its muscular coat is fashioned for contraction in the same direction and the valve of Gerlach at its outlet acts to prevent regurgitation of cecal contents into the appendix It is,

therefore, evident that the appendix is supposed to empty itself of its contents, but is not supposed to be invaded by the contents of the cecum. It also seems reasonable to suppose that contractions of the cecum, induced by the entrance of material from the ileum, play a part in stimulating the appendicular contractions.

A considerable ileal residue twenty-four hours after a barium meal, when not due to a prolonged gastric retention, is indicative of some pathology in the ileocecal region and further study of the ileum at one-hour intervals following the barium meal may show that this pathology is a narrowing, dilatation, or deformity of the ileum due to kinks or inflammations so frequently associated with appendix adhesions.

In attempting to get some reasonable basis upon which to interpret this factor of stasis in the appendix, we have followed the cases in some instances for as long as 32 days and have observed the relationship of stasis to pathologic findings at the time of operation. We are inclined to think that if Gray had continued his observations he would at present possibly lower somewhat his 100-hour limit for normal appendices in children. From our observations we would feel that, in the adult, an appendix which remains filled over this time should be considered as pathologic. When we think of the absorption factors in this narrow-lumened organ, it is evident that any fecal material remaining in here for that period must necessarily bring about the possibility of an inflammatory reaction. Particularly is this true when we consider that the cecum is probably the site of the most virulent bacteria growth of any part of the bowel.

Of the cases 197, or 77 per cent, show tenderness, 136, or 53 per cent, show stasis of from 100 to 700 hours. Next to tenderness this is the most frequent finding. In all, 65 cases, or 25 per cent of the total, were found in an abnormal position. This is enough to indicate the opportunities for not

visualizing except by most persistent and painstaking study.

We were ourselves somewhat startled to find no cases in this list which we were able to diagnose as appendiceal pathology when there was absence of filling. To us this emphasizes the fact that a very great percentage of appendices will fill at some time if closely watched.

The grouping together of adherent appendices and abnormal outlines seems fitting to us. This group will include enteroliths, narrowed lumen, sharp, fixed angulations, and dilatations. The appearance of these in 35 cases, or 13 per cent, is rather understating the frequency of these findings.

We have records of operative procedure in 30 cases, or 11 per cent. Doubtless numbers of others have undergone surgery. Even if double this number, it would but emphasize that these findings are essentially medical in the majority of cases.

Of related diagnostic points many are briefly discussed. The most important of these is the presence of 157 cases of colon stasis. The relationship of constipation to appendiceal tenderness is so clearly evident that in those cases in which tenderness is present without colon stasis we are much more inclined to advise immediate surgery.

Gall-bladder pathology was present in 61, or 24 per cent of the cases, duodenal pathology (ulcer, persistent spasm, banding), in 52, or 20 per cent, and stomach pathology in 9, or 3 per cent. The frequently related pathology in the old triumvirate of appendix, gall bladder, and duodenum seems well borne out.

Though we find many appendices without gall-bladder or duodenal pathology, it is indeed seldom that we find the latter two present without evidences in the appendix of old, if not present, trouble. We believe it is in this right lower quadrant that the majority of the trouble with the gall bladder, at least, has its start.

Colitis diagnosed in 10 cases, or 4 per cent, is perhaps leaning backward. So strong is our impression that these irritations of the colon mucosa are frequently secondary to periodic passing of irritating bacteria from the gall bladder or appendix that we diagnose colitis only when anatomic changes show the walls and mucosa so altered that pathology is self-sustaining there, independent of the original source of infection.

Dental sepsis was present in 44 cases, or 17 per cent. Tonsil (nose and throat) sepsis was present in 105, or 41 per cent. This last seems of particular moment to us. The resemblance between the adenoid tissue in the tonsil and that of the appendix has been frequently marked. The frequency with which appendiceal flare-up, often of most serious character, follows a cold and tonsillitis, is striking.

Pelvic pathology was diagnosed in 38, or 15 per cent. Not only does trouble in this quarter cause conflicting diagnoses but frequently the varying blood supply in pelvic pathology actually incites appendiceal irritations.

We note nervous and mental complications in 8 cases, or 3 per cent, thyroid abnormality in 32, or 13 per cent, and lung pathology of varying degrees in 73, or 29 per cent. Of more direct interest here is the appearance of ileac regurgitation in 26, or 10 per cent. In a considerable percentage of cases this is due to distortion of the ileocecal valve by inflammatory adhesions. Evidence of bands about the cecum or ileum is present in 76 cases, or 30 per cent.

Pathology of the urinary tract appeared in 34 cases, or 13 per cent. We are convinced that more careful study over large numbers of cases will demonstrate relationship between appendiceal pathology and pus conditions in the kidney pelvis. We have seen one case, which required frequent irrigations of the kidney pelvis, while carrying an appendix with a 300-hour stasis, live

for two years without serious kidney trouble after an appendectomy.

Blood changes occurred in 20 cases, cardiospasm in 1, arthritis in 11, and cardiovascular affections in 14 cases.

Changes in blood sugar occurred in 12 cases. This is of interest in the light of the discussion by surgeons and clinicians of the value of removal of the gall bladder in diabetic cases. Our impression is that the gall bladder should be removed, when possible, in the presence of definite sepsis, as is the tonsil. But we do feel that before this is done the appendix should be evaluated roentgenologically and removed at operation if the X-ray examination shows pathology, no matter what its appearance is to the surgeon.

Skin complications in 2 per cent of the cases are small numerically, but the relationship between appendiceal stasis and acne vulgaris should have widespread study. In some cases the factor causing skin sensitivity to low-grade infection may be, as in at least two of my cases, related to prolonged appendiceal stasis.

We agree fully that tenderness is the most important sign to be elicited in a study of an appendix. But when Lahey (4) says, "X-ray evidence as to the possible presence of chronic or recurrent appendicitis is limited in our opinion to tenderness directly over the appendix by fluoroscopy," he is speaking for the surgical appendix.

It is full time for surgeons and internists to realize that there is appendiceal pathology which is subject to medical treatment. Bowel regulation alone will help many. Often as we study these cases we wonder how much relief in the colon stasis cases has been from coincident relief of appendiceal symptoms. Relief from associated sepsis will aid and in a considerable percentage of cases, avoid acute inflammatory reactions.

The evidence obtainable can be of greatest value in determining expediency of opera-

ANALYSIS OF 256 CASES WITH DIAGNOSIS OF APPENDICEAL PATHOLOGY

1—Appendiceal Findings

| Number of cases | Abnormal position | Tender-ness | Stasis | Non-filling | Adhesions and abnormal outlines | Surgery |
|-----------------|-----------------------|------------------------|------------------------|-------------|---------------------------------|---|
| 256 | 65, or 25 per cent | 197, or 77 per cent | 136, or 53 per cent | 0 | 35, or 13 per cent | 30 and 2 post-operative, or 11 per cent |

2—Associated Diagnosis

| Colon stasis | Gall bladder | Pathology involving duodenum | Pathology involving stomach | Colitis | Septic teeth | Nose and throat sepsis | Pelvic pathology |
|------------------------|-----------------------|------------------------------|-----------------------------|-----------------------|-----------------------------|------------------------|-------------------------|
| 157, or 61 per cent | 61, or 24 per cent | 52, or 20 per cent | 9, or 3 per cent | 10, or 4 per cent | 44, or 17 per cent | 105, or 41 per cent | 38, or 15 per cent |
| Nervous and mental | | Thyroid pathology | Lung | Ileac regurgitation | Bands about cecum and ileum | | Urinary tract pathology |
| 8, or 3 per cent | | 32, or 13 per cent | 73, or 29 per cent | 26, or 10 per cent | 76, or 30 per cent | | 34, or 13 per cent |
| Neuritis | Blood | Diverticulum | Cardio-vascular | Arthritis | Blood sugar abnormalities | Skin | |
| 0 | 20, or 7 per cent | 4, or 1 per cent | 14, or 6 per cent | 11, or 4 per cent | 12, or 3 per cent | 7, or 2 per cent | |

tion when other factors are present. For instance, the question of surgery or medical treatment, and the best method of approach in surgery, may well be affected in a tubal infection when appendiceal pathology is present roentgenologically. Double surgery may often be avoided if this study is made. Listed abnormalities in the position of the appendix clarify questionable symptomatology and alter the optimum site for surgical approach. Careful study and record of pathologic appendices will be of tremendous value in determining the etiology of some obscure disease complications.

Frankly, appendiceal pathology is too important to be buried under the opprobrium attached to the term "chronic appendicitis." Roentgenologists alone can evaluate the condition of the organ. Let them select the term to apply to the finding so that the internist will understand there is need of care in the line of his efforts. Let it be a term that the surgeon can hear without reaching for his surgical kit.

DISCUSSION

DR. LEWALD (New York). There are two things in particular I wish to speak of. One is the length of time that opaque material may be observed in the appendix. Dr. Payne called attention to one case of 300 hours—I have one case of about 3,000 hours. The second point bears directly on retention and if that long-retaining appendix would necessarily have had to be removed. That appendix I cite has not been removed. The patient has given more attention to the bowels, and the attacks she had had previously have not recurred, so far as I can find out, in over two years.

There are two extreme displacements of the

appendix that were not mentioned by Dr Payne, but they are very pertinent

A very short time ago, a surgeon operated in the usual way on a child of about 10 years of age for supposed appendicitis. No X-ray examination had been made and it was found on operation that there was no appendix in the usual location. The surgeon naturally surmised that there was an appendix somewhere in the abdomen, enlarged his incision, and brought it out from the *left* side. I made an X-ray examination of the child afterwards and found a complete *transposition of the viscera*. But the little girl who did not need to have her appendix out at all now has a scar.

I asked her about her symptoms when I saw her later. So far as I could figure out, she had what we ordinarily speak of as "congestion of the spleen" or a "stitch in the side," in her case her spleen being on the *right* side. I asked her if she had this trouble any more and she said, "Yes, when I run, I feel the same old pain on my right side." So I presume this bears out the fact that it was her spleen and not the appendix.

The other type of lesion is the *non-rotation of the colon* which brings the appendix to the left side. I saw one case operated on for a supposed duodenal ulcer or adhesions to the gall bladder in which a series of films were made of the upper right side of the abdomen alone, but in that particular case the appendix was on the left side and very low down. The surgeon, after exploring thought he would

reach down and see if he could find the appendix, but he could not, and so he had to close up *without* removing the appendix. There were no adhesions about the duodenum. I mention this because, there being no transverse colon and no complete U-shaped duodenum, the duodenum runs a peculiar course—it does not loop down, but shoots straight out to the right, looking as if it were fixed by adhesions to the gall bladder.

DR PAYNE (closing) During the meal, we sometimes find that an appendix which has not filled before will fill when the opaque enema is taken. We usually screen those cases 48 hours after the enema. As a rule I find it is better, when we have been working with an appendix of this kind, to terminate the work with a plate. Oftentimes the image is so faint that one is unable to pick it up with the fluorescent screen, and so I think it is safer to plate the right lower quadrant and check up for the position of the appendix in this way.

We list segmentation simply under the abnormal appearance and barium stasis, being prone to judge the importance of this finding by its associated symptomatology.

Dr LeWald has surpassed us on the length of his emptying time. As I stated, we watched one boy's appendix for thirty days and his appendix was still filled at the end of that time. We advised operation, but the patient put it off. A month or so later, the condition flared up in the middle of the night, demanding emergency surgery.

HEREDITY OF CANCER¹

By MME. N DOBROVOLSKAYA-ZAVADSKAYA, M.D., PARIS

IT is rather difficult to speak on the heredity of cancer in this country, where such a great deal of work concerning this subject has been done. But the problem is so complex and so important that, I believe, any new material is of interest.

Our research on cancer heredity was started in 1927, by establishing a few isolated strains of mice, descending each from a cancerous mother. We are endeavoring, of course, to eliminate all possible causes of cancer, except heredity, to keep the mice as clean as possible, and to create for them conditions as hygienic as can be attained with animals.

Professor Borrel, in France, insists, as you know, on cancer in mice being produced by a small worm (*filaria*) *Muspicea borreli*, which he found in his stock and which he supposes to be a conveyer of an invisible virus, a real cancerogenic agent.

In order to find out whether or not our cancerous mice carry this filaria, we examined 40 of our cancerous stock (among them were two normals taken for control), following exactly the method of cleavage of Professor Borrel, and found this worm in only five cases, that is, in 13.2 per cent of all cancerous animals examined. It means that about 87 per cent of our stock develop their tumors without any influence of that parasite, whereas Professor Borrel reports them to be present in his stock in from 80 to 90 per cent of all cancerous mice. The difference between our results and those of Professor Borrel is probably to be explained by the greater attention we pay to the hygienic conditions of our stock.

Small nodules in the mammary glands, supposed by Professor Borrel to be due to ir-

ritation produced by *Muspicea*, are rather characteristic of adenocarcinomatous condition in general. In the cases of sarcomas, nodules were not found in the mammary glands, even in the presence of *Muspicea*.

Our breeding experiments are far from being concluded, but two strains of mice presenting a striking difference are nearly ready and their preliminary results may be reported now.

Strain No 5 (Chart II) was originated by a female having an ordinary adenocarcinoma of the breast and was continued by inbreeding until the third generation. The general result of this strain may be summed up as follows: out of 125 males, six developed epithelial tumors of a glandular type, and five developed sarcomas. Out of 114 females, 66 developed epitheliomas—in which there were 64 adenocarcinomas of the breast—and six developed sarcomas.

Strain No 4 (Chart I) was originated by a female having a very rare tumor, reproducing in the most typical points the structure of hair follicles and known under the name of Borrel-Haaland's tumor. This female, fecundated by an unknown male, gave birth to a litter of three females which developed cancer, and two males, one of which developed a sarcoma. The whole second generation was produced by three cancerous sisters mated to one sarcomatous brother, the reproduction being stopped with the third generation.

On the whole, this strain consisted of 242 animals. Out of 125 males, five developed sarcomas, and two, epitheliomas. Out of 117 females, 16 developed sarcomas, and eight, epitheliomas, among which were only three mammary adenocarcinomas.

If all kinds of cancers were controlled by

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting at Los Angeles Dec. 1-5, 1930.

appendix that were not mentioned by Dr Payne, but they are very pertinent

A very short time ago, a surgeon operated in the usual way on a child of about 10 years of age for supposed appendicitis. No X-ray examination had been made and it was found on operation that there was no appendix in the usual location. The surgeon naturally surmised that there was an appendix somewhere in the abdomen, enlarged his incision, and brought it out from the *left* side. I made an X-ray examination of the child afterwards and found a complete *transposition of the viscera*. But the little girl who did not need to have her appendix out at all now has a scar.

I asked her about her symptoms when I saw her later. So far as I could figure out, she had what we ordinarily speak of as "congestion of the spleen" or a "stitch in the side," in her case her spleen being on the *right* side. I asked her if she had this trouble any more and she said, "Yes, when I run, I feel the same old pain on my right side." So I presume this bears out the fact that it was her spleen and not the appendix.

The other type of lesion is the *non-rotation of the colon* which brings the appendix to the left side. I saw one case operated on for a supposed duodenal ulcer or adhesions to the gall bladder in which a series of films were made of the upper right side of the abdomen alone, but in that particular case the appendix was on the left side and very low down. The surgeon, after exploring thought he would

reach down and see if he could find the appendix, but he could not, and so he had to close up *without* removing the appendix. There were no adhesions about the duodenum. I mention this because, there being no transverse colon and no complete U-shaped duodenum, the duodenum runs a peculiar course—it does not loop down, but shoots straight out to the right, looking as if it were fixed by adhesions to the gall bladder.

DR PAYNE (closing). During the meal, we sometimes find that an appendix which has not filled before will fill when the opaque enema is taken. We usually screen those cases 48 hours after the enema. As a rule I find it is better, when we have been working with an appendix of this kind, to terminate the work with a plate. Oftentimes the image is so faint that one is unable to pick it up with the fluorescent screen, and so I think it is safer to plate the right lower quadrant and check up for the position of the appendix in this way.

We list segmentation simply under the abnormal appearance and barium stasis, being prone to judge the importance of this finding by its associated symptomatology.

Dr LeWald has surpassed us on the length of his emptying time. As I stated, we watched one boy's appendix for thirty days and his appendix was still filled at the end of that time. We advised operation, but the patient put it off. A month or so later, the condition flared up in the middle of the night, demanding emergency surgery.

There seems to be in the human body some antagonism of one for the other. We know that the average age of a case of carcinoma is about 48 years and that of sarcoma is about 28 years, and that most of the cases of sarcoma, about 34 per cent, occur between the ages of 11 and twenty.

I would like to know if, in any of these animals, the two diseases occurred in the same animal?

DR. J. E. GENDREAU (Montreal) I would like to ask Dr. Zavadskaja if the conditions under which she bred mice were the same as those used by Maud Slye, if the presence or absence of secondary factors in producing the cancers could explain a difference in the results, and if these secondary factors were very important in the production of cancer?

DR. LEON MENVILLE (New Orleans) The question of cancer heredity is a subject of great importance. Dr. Zavadskaja has exemplified the possibilities of heredity in the production of cancer. The work of Dr. Smith, of the Department of Agriculture in Washington, is also quite interesting. By the use of certain bacilli, Dr. Smith has produced tumors in the vegetable kingdom, particularly in the beet and castor plant, analogous to cancer tumors. The injection of this bacilli will produce the parent tumor with metastasis in other parts of the plant. The microscopic section of these tumors is similar to the malignant tumors in the human. Therefore, it would seem somewhat convincing that the micro-organism theory could play a part in the production of cancer. The heredity theory is also convincing, especially after listening to such an eminent authority as Dr. Zavadskaja.

DR. H. J. ULLMANN (Santa Barbara, Calif.) After reading it, one will have to think this paper over for some time to appreciate the problems involved and the possibilities of the findings.

In evaluating any such reaction as has been described, one must compare the evidence and the data presented with a formula or equation which must be integrated in which all the fac-

tors are variables. Doctor Zavadskaja had demonstrated the selective action, and one can, therefore, say that the type of cell is one of the factors that is a variable. Let me suggest another variable—the metabolism as a whole, and perhaps, also, the metabolism or type of cells surrounding the tumor being treated. We must, also, take into consideration the time intensity of the irradiation, another variable, and perhaps, in addition, the wave length of the irradiation. I have felt for some time that the wave length might be a factor to be considered in spite of Arndt-Schulz's well accepted law.

Regaud has shown that, the shorter the wave length, the more selective the action of the irradiation. Moffatt, in the *Medical Journal of Australia*, April 11, 1930, presented a very interesting piece of work. He showed the varying effects of different wave lengths on the egg membrane of eight-day chick embryos. He found complete atrophy at 0.11 Ångstrom, 0.53 and 0.79. The effect was sharply restricted to these wave lengths, the greatest atrophy being found at 0.11 and the least at 0.79. An extensive myxomatous change occurred at 0.16 Ångstrom, apparently it was a characteristic response to that wave length. Hypertrophic nodules occurred, this effect being most pronounced at 0.63 Ångstrom. A leukocytosis had its chief effect at 0.32 and again at 0.34 Ångstrom. Epithelial stimulation was most definite in this reaction. Some stimulation in all was found, but the peak was at 0.16 Ångstrom and again at 0.89, where it was enormous. At this point it was almost like a carcinomatous growth. At 0.84 Ångstrom, the epithelium was invaded by leukocytes. The atrophy was so sharply confined to certain wave lengths that Moffatt feels that other effects than the electron effect must occur. As 0.11 Ångstrom was so much shorter than the characteristic radiation of any element present, he suggests that the effect is on an inner electron and relatively close to the nucleus.

Of course, in most of the tests so far made, portions of the spectrum relatively close together have been used, and, in looking for

the same gene as a simple mendelian character, recessive to normal condition, such a combination as given in this strain (three cancerous sisters mated to a sarcomatous brother) should produce only cancerous descendants. In reality, the numbers obtained are too small for cancer, being of a simple mendelian character, either dominant or recessive. A premature mortality cannot explain this deficit because there were many animals which lived sufficiently long and died without cancer. The only assumption which can account for the results of Strain No 4 is that there are different genes for sarcoma and for epithelioma, both recessive to normal condition.

Some other peculiar conditions as angiomas, angiomatous cysts of the ovaries, a kind of rodent ulcer, cystic kidneys, etc., were observed in the same strain.

Since the majority of these conditions are generally not considered as malignant tumors, and as their relation to cancer, especially from a genetic standpoint, is not yet quite clear, the full interpretation of the results of this strain is not yet possible. But there is a point which is quite evident, that is, a profound difference exists between the two strains (Charts I, II). This difference becomes apparent if we consider the most common tumor in mice, *i.e.*, cancer of the breast. There are 64 mammary adenocarcinomas in 114 females of Strain No 5, and only three such tumors in the 117 females of Strain No 4. This difference cannot be explained by any external conditions, because these were exactly the same for both strains and in some instances the animals even lived together in common cages. The causes of this difference may be sought only in intrinsic conditions most probably hereditary and primarily, in the histologic structure of two initial tumors one was an ordinary mammary adenocarcinoma, and the other a very rare tumor of a special structure, reminding one of the hair follicles.

The observations just reported, incomplete as they are, seem to allow the following preliminary conclusions:

1. There is evidence in favor of a hereditary factor in the origin of cancer and, perhaps, neoplastic diseases in general.

2. The different histologic types of tumors are probably dependent on different genes in germ plasm.

3. All kinds of irritations, chronic inflammation, etc., contribute to the development of cancer in predisposed organisms and determine its localization.

CHART I—STRAIN NO 4, TUMOR BORREL-HAALAND

| | Normal | Sarcoma | Epithelioma | Totals and tumors (per cent) |
|---------|--------|---------|-------------|------------------------------|
| Males | 118 | 5 | 2 | 125 = 5.6% |
| Females | 93 | 16 | 5 + 3 | 117 = 20.5% |
| Totals | 211 | 21 | 10 | 242 = 12.8% |

CHART II—STRAIN NO 5, ADENOCARCINOMA OF THE BREAST

| | Normal | Sarcoma | Epithelioma | Totals and tumors (per cent) |
|---------|--------|---------|-------------|------------------------------|
| Males | 114 | 5 | 6 | 125 = 9.6% |
| Females | 42 | 6 | 2 + 64 | 114 = 63.2% |
| Totals | 156 | 11 | 72 | 239 = 34.7% |

DISCUSSION

DR. EMIL G BECK (Berkeley, Calif.) Has the Doctor ever observed that carcinoma and sarcoma co-existed in the same animal? In the human being this is very rare, there are only a few cases reported in the literature. I have never seen a case myself, and I have asked a good many of my confreres but they cannot remember that such a case has occurred in their practice.

We know that sarcoma affects principally the young and carcinoma the elder people.

UNNECESSARY ROENTGENOSCOPY NOT REQUIRED

(United States Fidelity & Guaranty Co
et al vs Wickline (Neb.),
170 N W R 193)

The Supreme Court of Nebraska holds that a claimant for compensation under the employers' liability act pursuant to Section 3675 of the Revised Statutes of Nebraska of 1913, cannot be denied a recovery because of a refusal to submit to a roentgen-ray examination or to have a roentgenogram taken of the person, where the uncontradicted evidence shows that neither was necessary. Section 3675 provides that, after an employee has given notice of an injury he shall, if so requested by the employer or the insurance company carrying such risk, submit himself to an examination by a physician or surgeon furnished and paid for by the employer or the insurance company, and refusal of the employee to submit to such examination shall deprive him of the right to compensation during the continuance of such refusal. The court says that under the statute the request for an examination must be reasonable, and it did not appear to have been in this case. The testimony before the court showed affirmatively that neither a roentgen-ray examination nor a roentgenogram was necessary. No physician nor other person testified that either was necessary, nor did it appear that a request was made to the court to require the employee to submit to either. In the present advanced state of the science of roentgen-ray examinations and the taking of roentgenograms of the person there appears to be no reason why such examination or roentgenogram should not be permitted by a claimant for compensation under the employers' liability

act, on request by the employer or insurer, unless the request is shown to be unreasonable.

BARS TESTIMONY AS TO WHAT ROENTGEN- GRAMS SHOW

(Lang *vs Marshalltown Light, Power & Railway Co (Iowa)*, 170 N W R 463)

The Supreme Court of Iowa holds that there was no error in a ruling in this personal injury case sustaining objection to questions such as one asking a physician to state whether or not a certain roentgenogram did, or did not, show a curvature of the spine, as appeared in the negative. The Court says that the defendant cited a number of cases to the proposition that roentgen-ray negatives and photographs, properly verified, are admissible in evidence, and this proposition was not disputed by the plaintiff. Cases were also cited by the defendant, holding that it is proper for experts to interpret and explain roentgen-ray plates to the jury. Among these was the case of *State vs Matheson*, 142 Iowa, 414, 120 N W 1036. It was claimed, too, that some of the cases hold that a witness may testify as to what the photograph shows. But the court thinks that the questions asked in this case, and the ruling thereon, were within the ruling of *Elzig vs Bales*, 135 Iowa, 208, 112 N W 540, wherein it was said, in effect, that, as demonstrative evidence, roentgenograms serve to explain or illustrate and apply the testimony, and are aids to the jury in comprehending the questions in dispute. When taken for either purpose they are the best evidence of what appears on them. The rule exacting the best evidence applies to the testimony of experts, as well as to that of other witnesses, and it was error to permit a physician to testify to what appeared in a roentgenogram.

the selective effects of different wave lengths, we must compare very short and very long wave portions of the spectrum I believe that the wave length effect must be taken into consideration in at least certain parts of our work

DR. ZAVADSKAIA (closing) In replying to Dr Beck's question, if there is coincidence of both tumors, sarcoma and epithelioma, I might say there is, but very rarely in mice

Sarcoma in humans is a malignancy of the young, in mice it is rather a tumor of old age, even older than adenocarcinoma of the breast, because adenocarcinoma was generally developed between six and eighteen months, and sarcoma was mostly developed at two years of age and even later (once, at two years and eight months) Therefore, you see, the tumor age is different in different species If we admit that there are two different genes for sarcoma and epithelioma, the coincidence of both of them in one animal is probably very rare

To reply to Dr Gendreau's question about the rôle of external conditions Miss Maud Slye and I try to put our animals in the best possible conditions to eliminate all causes of cancer but heredity But there may be some kind of parasite which escapes us, and this is one of our next problems to study It is very probable that other causes, an irritation, for instance, may develop cancer only in predis-

posed animals The demodec, very common on the skin of man, is very rarely the real cause of cancer All this calls for further research

I know Dr Smith's experiments, but I know, also, other facts, for instance, the experiments in plants, of Dr Kostoff He obtained real tumors in the Nicotiana hybrids by crossing different species which, as pure lines, never developed a tumor He examined these tumors and did not find any microbe there It is probable that microbes play a part in certain plant cancers But you cannot easily transfer the results obtained in plants to animals, even in mice, sarcoma and epithelioma behaved differently, as you have seen it, and probably we have to deal with many different kinds of cancer

Tumors in hybrids are now being studied by Dr Reed and Dr Gordin in the Zoological Department of Cornell University They have found tumors in hybrids of small Mexican fish I do not remember the name of this fish, but when I visited them they showed me these animals Hybrids developed a very malignant pigmented tumor, a kind of nevo-sarcoma which kills the animals

So you see how complex is the problem and there are different approaches to the study of it Perhaps these tumors in hybrids are also indications that the hereditary factor plays an important part in the development of cancer

Urge X-ray Diagnosis of Children's Teeth
—Full X-ray examination of the mouths and teeth of young children has been urged by Dr Leo J Schoeny, of New Orleans before the American Dental Association

"Recent developments in X-ray apparatus render it possible to make such examinations even upon very small and nervous children," he said "Such examination will enable the

dentist to discover dental defects and disorders at an early age and to prevent their further development and more serious consequences, such as malocclusion, pyorrhea, and dental caries By means of the X-ray diagnosis on small children, the dentist shall be in a position to contribute his full share toward preventive dentistry and medicine"—*Science Service*

So you see how complex is the problem and there are different approaches to the study of it. Perhaps these tumors in hybrids are also indications that the hereditary factor plays an important part in the development of cancer.

Urges X-ray Diagnosis of Children's Teeth
—Full X-ray examination of the mouths and teeth of young children has been urged by Dr Leo J. Schoeny, of New Orleans, before the American Dental Association.

"Recent developments in X-ray apparatus render it possible to make such examinations even upon very small and nervous children," he said. "Such examination will enable the

dentist to discover dental defects and disorders at an early age and to prevent their further development and more serious consequences, such as malocclusion, pyorrhea, and dental caries. By means of the X-ray diagnosis on small children, the dentist shall be in a position to contribute his full share toward preventive dentistry and medicine."—*Science Service*

based on the information divulged by these plates. The expert who made the plates did not testify, nor did any one who was present at the time the plates were made. The Court said that the plates were not admissible in evidence, nor could they be, until they were properly identified or shown to have been made by trustworthy instruments properly used by a person skilled in making, reading, and interpreting such plates, and further shown to be correct representations of the bony structure of the plaintiff's head. The admission of roentgenographic plates in evidence rests fundamentally on the theory that they are the pictorial communication of a qualified witness who uses this method of conveying to the jury a reproduction of the object of which he is testifying, this being true, the roentgenographic plates must be made a part of the testimony of some qualified witness, and the witness should qualify himself by showing that the process is known to himself to give correct representations, and that it is a true representation of such object.

RULE AS TO PRIVILEGED COMMUNICATIONS
IS APPLIED TO ROENTGENOLOGIST

(Shaw *vs* City of Nampa (Idaho), 171
Pac R 1132)

The Supreme Court of Idaho applies the

rule as to privileged communications to a roentgenologist, in this personal injury case, under the following circumstances, as stated by the Court. When the plaintiff was injured, she employed a physician who immediately took her to another town, where he employed a physician to take a roentgen-ray picture of her broken arm. After the picture was taken and developed, the second physician or roentgenologist consulted with the first or plaintiff's regular physician relative to the interpretation of the picture and the treatment to be administered. Counsel for the plaintiff objected to the roentgenologist's testifying as to any facts learned while he was thus employed, which objection the Supreme Court holds was properly sustained. It appeared from the evidence, the Court goes on to say, that the roentgenologist did more than perform mere mechanical work as a photographer, and that he used his knowledge and experience as a physician in interpreting the meaning of the picture, and advised with the plaintiff's regular physician as to what treatment should be given, the plaintiff paying the roentgenologist for his services. The trial court was justified in excluding such evidence as privileged communication, under the Revised Codes of Idaho, Section 5958, Paragraph 4.

PHYSICIAN PREPARING TO GIVE EXPERT
TESTIMONY MAY PROPERLY STIPULATE
FOR COMPENSATION

(*Birch vs Sees (N Y)*, 165 N Y
Supp 846)

The Supreme Court of New York Appellate Division, Second Department, said that it must take it as established by the verdict for \$500 rendered in favor of the plaintiff that he, an attending physician and a life-long acquaintance of the deceased whose will had been offered for probate, having testified on a prior trial as an expert witness for the proponent of the will, at an agreed compensation of \$50 per day, was thereafter employed by a succeeding attorney for the proponent at the same terms, to go over the witness' records to prepare himself so as to give expert testimony on the issue of the deceased's mental soundness, which he did on two trials, there having been three trials. It was, however, objected that as the plaintiff had been the attending physician his testimony was not that of an expert, and that such agreement for compensation should not be enforced. But it seems settled that if a medical witness, or other witness with technical qualifications, goes beyond mere testimony to facts, observed by the senses, and is asked to draw a technical inference or conclusion, he may properly stipulate for compensation. The facts in this case were therefore within the permissive rule, and the judgment on the verdict for the plaintiff, should be affirmed with costs.

PURPOSE FOR WHICH ROENTGENOGRAMS
MAY BE USED

(*Russell vs Borden's Condensed Milk Co of Utah (Utah)*, 174 Pac R. 633)

The Supreme Court of Utah says that in this personal injury case it was contended that the trial court erred in admitting in evidence certain roentgenograms showing the condition of the plaintiff's hip and hip joint.

It was insisted that the roentgenograms had a tendency to mislead the jurors, who were merely laymen and thus possessed no knowledge respecting the injuries to the bone or to the hip or hip joint. If the roentgenograms had been introduced for the purpose indicated by counsel, there would be much force to their contention. A jury of laymen possessing no knowledge or experience respecting the bones and injuries thereto might easily be misled by a mere roentgenogram, by which at the best merely the outline of the bone can be shown. The roentgenograms, however, were not introduced for the purpose indicated by counsel. They were used by the physicians in illustrating their evidence, and were fully explained, and were introduced in evidence only as affording a fuller and clearer understanding by the jury of the physicians' testimony respecting the condition of the plaintiff's injured hip and hip joint. The court committed no error in receiving the roentgenograms for the purpose for which they were received and used.

UNIDENTIFIED ROENTGENOGRAMS NOT

ADMISSIBLE AS EVIDENCE

(*Bartlesville Zinc Co vs Fisher (Okla.)*,
159 Pac R 476)

The Supreme Court of Oklahoma reverses a judgment obtained by Plaintiff Fisher, for personal injuries, on account of error in the admission in evidence of certain roentgenographic plates tending to prove the existence of certain physical defects in and about the bony structure of his head. The evidence afforded to identify the plates was given by a physician who testified that from an examination of the plaintiff, based on symptoms related to him, he was unable to find the cause of the plaintiff's trouble, and sent him to another physician to have a roentgenographic plate made, and that he was not present when the plates were made. The witness further testified that his evidence, relative to the plaintiff's injuries was

Valve V_1 , a magnetic valve which closes the passage from A to B , consists simply of a small cylindrical piece of soft iron loosely sealed in a glass plunger which is ground with fine emery to make a good joint at one end. The solenoid furnishes a magnetic field

vents any air from accidentally entering A which would cause the loss of the collected emanation. D is a regulator which automatically increases the amount of heat supplied to H when the pressure in E and H is increased.

for lifting the plunger when an electric switch is closed. B and E are traps used to collect vapors when they are submersed in a mixture of solid CO_2 and acetone.[†] Y is the tube which connects the duplicate sides of the apparatus. The apparatus is made in duplicate in case one side becomes broken or out of order. V_2 is an emergency valve to prevent any possibility of mercury getting into or beyond B . G is a mercury reservoir into which the mercury is drawn to open the passage from B to E . The mercury is always kept at a height of about 40 cm in C except when the passage is being opened, so that, in case any part of the apparatus becomes accidentally broken, the mercury will rise to a difference in height of approximately 76 cm and stop. This pre-

V_3 is a magnetically operated, mercury-sealed valve which when closed prevents vapors from migrating from E into F or H . The opening in V_3 must be fairly large to allow a free circulation of gases and vapors from E to F and H . This valve is shown in detail in Figure 3 in which B' is a glass plunger which is ground to form a tight joint at A' . The joint is surrounded with mercury to form a mercury seal when B' is lowered into the mercury. D' is a glass plunger containing a small cylinder of soft iron. When it is desired to open the valve for a long period of time, B' is raised and the plunger D' is moved under it with a permanent magnet. The valve will withstand atmospheric pressure in the direction of the arrows E' to F' . In the opposite direction it will withstand only a low pressure.

F is a small tube containing a few crystals

[†]The freezing point of acetone is below that of CO_2 which permits a better thermal contact with the glass trap than of the trap.

CASE REPORTS AND NEW DEVICES

AN APPARATUS FOR COLLECTING RADIUM EMANATION

By ALEXANDER J ALLEN and
RACHEL G FRANKLIN

Cancer Research Laboratories, University of
Pennsylvania Graduate School of Medicine,
PHILADELPHIA

INTRODUCTION

Radium emanation has a definite place in the treatment of cancer. Its chief advantage over the radium element is that it can be put into small enough containers and is of such nature that, once inserted into a tumor, it need never be removed. A second advantage is that while radon can be used for every treatment for which the radium element can be used, radon implants contain no radium. If they are mislaid, carried away on a patient, or lost in any other way, the loss is negligible. However, good radium emanation plants are of necessity sufficiently complicated to make them costly to install and to maintain. By the adoption of modern scientific methods it was hoped to develop a plant of low initial and maintenance costs which would be practical for both small and large amounts of radium.

The requisites of a good emanation plant are

1 The apparatus must be efficient, that is, as much as possible of the emanation formed must be collected in the container in which it is to be used, and it must be well purified, as it is usually desirable to use the emanation in as small a container as possible.

2 The apparatus must be reliable and as fool-proof as possible, that is, it must be sturdy and practically free from breakdown.

3 It is desirable to have it as simple as possible to maintain and operate.

4 The problem of safety to the operator must be considered.

5 Any saving in cost is always desirable.

With the above points in mind, a constant effort has been made to simplify and improve the apparatus described in the article published last year(1). The necessity of using P_2O_5 has been eliminated by the use of solid CO_2^* and the plant is of such design that any water which is taken from the radium solution is again returned. Once the plant is installed it is not necessary to renew or replace any parts, except the gold and glass implant tubing.

The apparatus is made entirely of Pyrex glass, which makes it more sturdy and less liable to break down than if it were made of soft glass. Mercury diffusion pumps simplify the usual pumping procedure and produce excellent vacua with a minimum amount of labor. Magnetic valves simplify the design and operation of the apparatus. The time that an attendant must be in the vicinity of the apparatus is small, which reduces the danger of over-exposure to gamma rays.

DESCRIPTION OF PARTS

In the diagram of this plant (Fig 1), *A* indicates a glass bulb which is enclosed in a safe and contains the radium solution. This is surrounded by a copper coil, *W*, through which water is circulated to keep the temperature of the radium solution below that of the outside room temperature.

*Through the courtesy of the Sharpless Ice Cream Company we have been furnished free of charge with all the solid carbon dioxide necessary to develop and operate our plant.

Valve V_1 , a magnetic valve which closes the passage from A to B , consists simply of a small cylindrical piece of soft iron loosely sealed in a glass plunger which is ground with fine emery to make a good joint at one end. The solenoid furnishes a magnetic field

AN APPARATUS FOR COLLECTING RADIUM EMANATION

By ALEXANDER J ALLEN and
RACHEL G FRANKLIN

Cancer Research Laboratories, University of
Pennsylvania Graduate School of Medicine,
PHILADELPHIA

INTRODUCTION

Radium emanation has a definite place in the treatment of cancer. Its chief advantage over the radium element is that it can be put into small enough containers and is of such nature that, once inserted into a tumor, it need never be removed. A second advantage is that while radon can be used for every treatment for which the radium element can be used, radon implants contain no radium. If they are mislaid, carried away on a patient, or lost in any other way, the loss is negligible. However, good radium emanation plants are of necessity sufficiently complicated to make them costly to install and to maintain. By the adoption of modern scientific methods it was hoped to develop a plant of low initial and maintenance costs which would be practical for both small and large amounts of radium.

The requisites of a good emanation plant are:

1 The apparatus must be efficient, that is, as much as possible of the emanation formed must be collected in the container in which it is to be used, and it must be well purified, as it is usually desirable to use the emanation in as small a container as possible.

2 The apparatus must be reliable and as fool-proof as possible, that is, it must be sturdy and practically free from breakdown.

3 It is desirable to have it as simple as possible to maintain and operate.

4 The problem of safety to the operator must be considered.

5 Any saving in cost is always desirable.

With the above points in mind, a constant effort has been made to simplify and improve the apparatus described in the article published last year(1). The necessity of using P_2O_5 has been eliminated by the use of solid CO_2^* and the plant is of such design that any water which is taken from the radium solution is again returned. Once the plant is installed it is not necessary to renew or replace any parts, except the gold and glass implant tubing.

The apparatus is made entirely of Pyrex glass, which makes it more sturdy and less liable to break down than if it were made of soft glass. Mercury diffusion pumps simplify the usual pumping procedure and produce excellent vacua with a minimum amount of labor. Magnetic valves simplify the design and operation of the apparatus. The time that an attendant must be in the vicinity of the apparatus is small, which reduces the danger of over-exposure to gamma rays.

DESCRIPTION OF PARTS

In the diagram of this plant (Fig 1), *A* indicates a glass bulb which is enclosed in a safe and contains the radium solution. This is surrounded by a copper coil, *W*, through which water is circulated to keep the temperature of the radium solution below that of the outside room temperature.

*Through the courtesy of the Sharpless Ice Cream Company we have been furnished free of charge with all the cold carbon dioxide necessary to develop and operate our plant.

radon is forced when glass implants are wanted. The radon is transferred into the small gold tube, L , which is waxed on to the glass when gold implants are wanted.

V_6 , V_7 , and V_8 are magnetic valves sim-

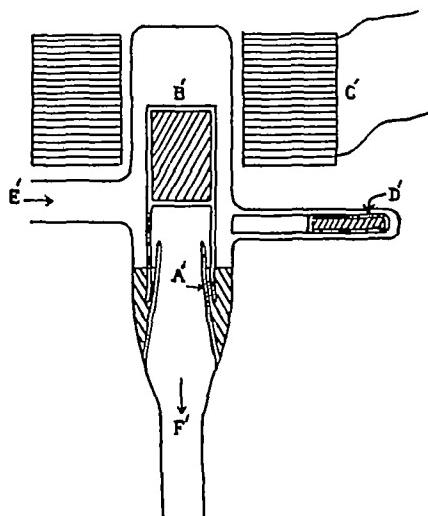

Fig. 3 Detailed diagram of special magnetic valve

ilar to V_1 . T is a trap which when filled with mercury prevents radon from entering O and prevents air from entering N . V_9 is similar to V_5 and V_2 and prevents mercury from flowing into O . O is an ordinary glass mercury vapor diffusion pump which aids in quickly and easily obtaining an excellent vacuum throughout the system. P is a Mega Vac oil pump which produces sufficient vacuum for the operation of O and also for the withdrawal of the mercury from C , J , and N . S_4 , S_5 , S_6 , and S_7 are ordinary glass stop-cocks which control the inlet or exit of air to the various parts of the system. S_1 , S_2 , and S_3 are mercury-sealed stop-cocks (2) which control the flow of mercury in and out of C , J , and N , respectively. V_{10} is the same as V_2 , acting as an emergency check valve which prevents the mercury from flowing past it in case of accident. X is a trap which prevents mercury or foreign material from entering the oil pump P . Q is a CaCl_2 dryer and glass wool air filter.

A photograph of this plant is shown as Figure 2.

PROCESS OF WITHDRAWING RADON

Assuming the apparatus to be completely evacuated and the mercury and valves in positions as indicated in Figure 1, the procedure for withdrawing, purifying, and collecting the radon into the gold or glass tubes is as follows: immerse trap E into a Dewar flask containing solid carbon dioxide and acetone. Valve V_4 remaining closed, open valve V_8 . Lower the mercury in C for about 20 seconds or longer, depending on the total amount of gases collected in A , by applying a vacuum to G , thus opening a passage from A to E . The fact that E is nearly -40°C will cause a rush of water vapor from A which condenses in E and carries with it most of the radon, hydrogen, oxygen, carbon dioxide, helium, etc. \ddagger . The water vapor is thus trapped in E , and the hydrogen and oxygen pass on to the hot copper screen in H and are reduced to water vapor. The CO_2 is taken up in F . After standing three or four minutes C is again opened for a few seconds and practically all the remaining radon is drawn into the purification chambers. The apparatus is then allowed to stand about 25 minutes, during which time the radon becomes well purified. Before V_4 is opened, it is necessary to close the trap T and the passage from J to N . This is done by admitting air pressure to M and opening cock S_3 , thus allowing the mercury to rise in N .

V_4 is then opened and the mercury diffusion pump I quickly (approximately one minute) forces the purified radon from the purification chambers into J . S_2 is then opened, which allows the mercury to rise in

\ddagger At -40°C the vapor pressures of the enclosed vapors are water, 0.096 mm., radon, 200 cm., hydrogen, very high, oxygen, very high, CO_2 , 76 cm., approximately. Since the vapor pressure of water is very low, it condenses and remains in the trap while the other gases or vapors present are free to migrate about the purification chambers.

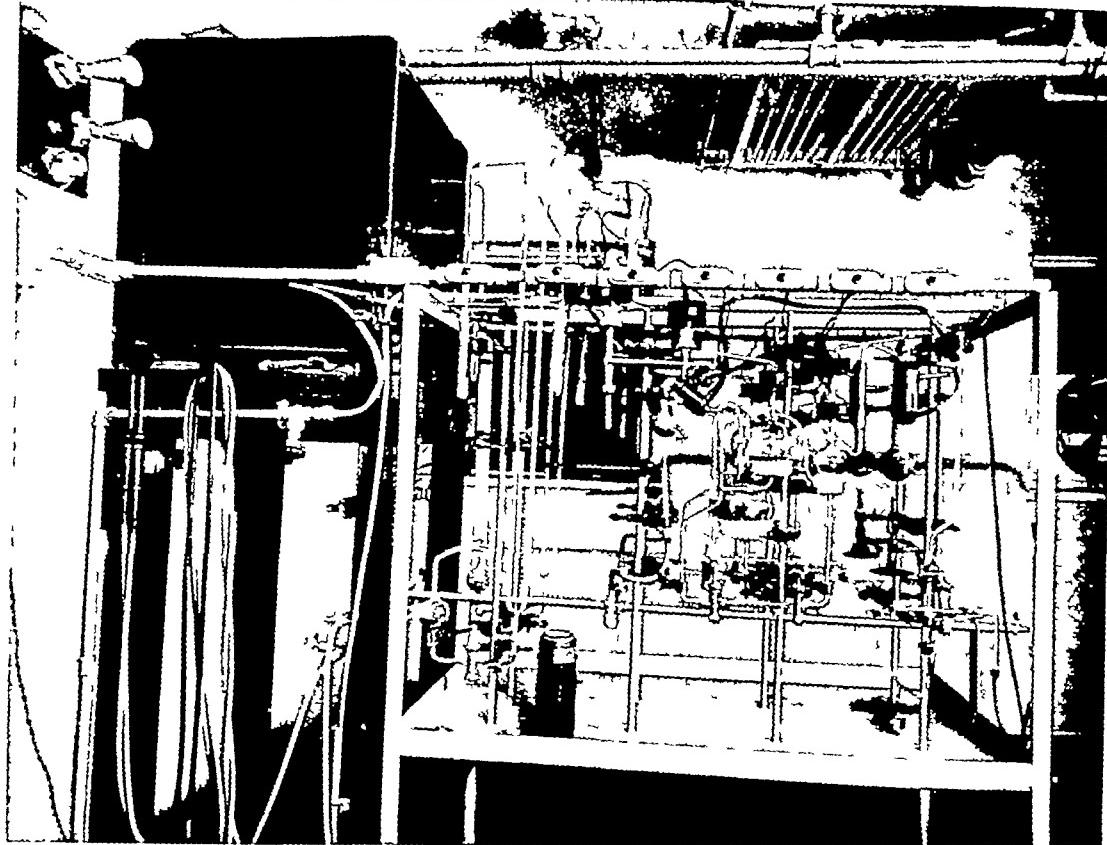

Fig 2. Photograph of emanation plant. Such an apparatus has been placed by the Cancer Research Fund in the Oncologic Hospital in Philadelphia, where it is in regular and successful use with 200 mg of radium.

of potassium hydroxide. This removes small traces of CO_2 , which is apparently generated by the disintegration of small amounts of organic matter which could not be removed from the apparatus. This seems necessary, to obtain radon of high concentration, especially when the apparatus is first put into operation. If it were not for the presence of the CO_2 , valve V_3 and tube F could be eliminated. H is a platinum wire which is placed in or around a quartz tube and heated with an electric current. This supplies heat to an oxidized copper gauze surrounding the quartz tube which causes hydrogen and oxygen to recombine to form water vapor. Hydrogen and oxygen are produced by the disintegration of water in A by the presence

of the α , β , and γ radiations from the radium and its disintegration products.

V_4 is a valve similar to V_3 , except that it can be much smaller. Its use is to prevent the radon from entering I until it has become well purified. I is a small mercury diffusion pump which is used to force the purified radon from D , E , F , and H into J . This pump works very satisfactorily and very quickly. V_5 is a glass check valve which automatically prevents mercury from flowing from M into I . J , N , and M are simple Toppler pumps used to force the radon into K or L . For convenience in making the diagram, reservoir M is shown lower than it is in reality. Actually, c and f are at the same level. K is the small glass capillary into which the

radon is forced when glass implants are wanted. The radon is transferred into the small gold tube, L , which is waxed on to the glass when gold implants are wanted.

V_6 , V_7 , and V_8 are magnetic valves sim-

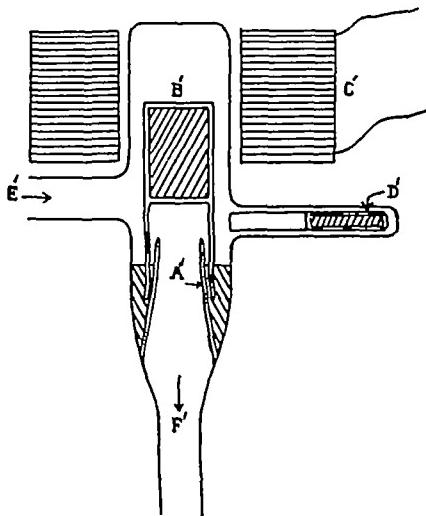

Fig. 3 Detailed diagram of special magnetic valve

ilar to V_1 . T is a trap which when filled with mercury prevents radon from entering O and prevents air from entering N . V_9 is similar to V_5 and V_2 and prevents mercury from flowing into O . O is an ordinary glass mercury vapor diffusion pump which aids in quickly and easily obtaining an excellent vacuum throughout the system. P is a Mega Vac oil pump which produces sufficient vacuum for the operation of O and also for the withdrawal of the mercury from C , J , and N . S_4 , S_5 , S_6 , and S_7 are ordinary glass stop-cocks which control the inlet or exit of air to the various parts of the system. S_1 , S_2 , and S_3 are mercury-sealed stop-cocks (2) which control the flow of mercury in and out of C , J , and N , respectively. V_{10} is the same as V_2 , acting as an emergency check valve which prevents the mercury from flowing past it in case of accident. X is a trap which prevents mercury or foreign material from entering the oil pump P . Q is a CaCl_2 dryer and glass wool air filter.

A photograph of this plant is shown as Figure 2

PROCESS OF WITHDRAWING RADON

Assuming the apparatus to be completely evacuated and the mercury and valves in positions as indicated in Figure 1, the procedure for withdrawing, purifying, and collecting the radon into the gold or glass tubes is as follows: immerse trap E into a Dewar flask containing solid carbon dioxide and acetone. Valve V_4 remaining closed, open valve V_3 . Lower the mercury in C for about 20 seconds or longer, depending on the total amount of gases collected in A , by applying a vacuum to G , thus opening a passage from A to E . The fact that E is nearly -40°C will cause a rush of water vapor from A which condenses in E and carries with it most of the radon, hydrogen, oxygen, carbon dioxide, helium, etc.‡ The water vapor is thus trapped in E , and the hydrogen and oxygen pass on to the hot copper screen in H and are reduced to water vapor. The CO_2 is taken up in F . After standing three or four minutes C is again opened for a few seconds and practically all the remaining radon is drawn into the purification chambers. The apparatus is then allowed to stand about 25 minutes, during which time the radon becomes well purified. Before V_4 is opened, it is necessary to close the trap T and the passage from J to N . This is done by admitting air pressure to M and opening cock S_3 , thus allowing the mercury to rise in N .

V_4 is then opened and the mercury diffusion pump I quickly (approximately one minute) forces the purified radon from the purification chambers into J . S_2 is then opened, which allows the mercury to rise in

‡At -40°C the vapor pressures of the enclosed vapors are water 0.096 mm., radon, 200 cm., hydrogen, very high, oxygen, very high, CO_2 , 76 cm., approximately. Since the vapor pressure of water is very low, it condenses and remains in the trap while the other gases or vapors present are free to migrate about the purification chambers.

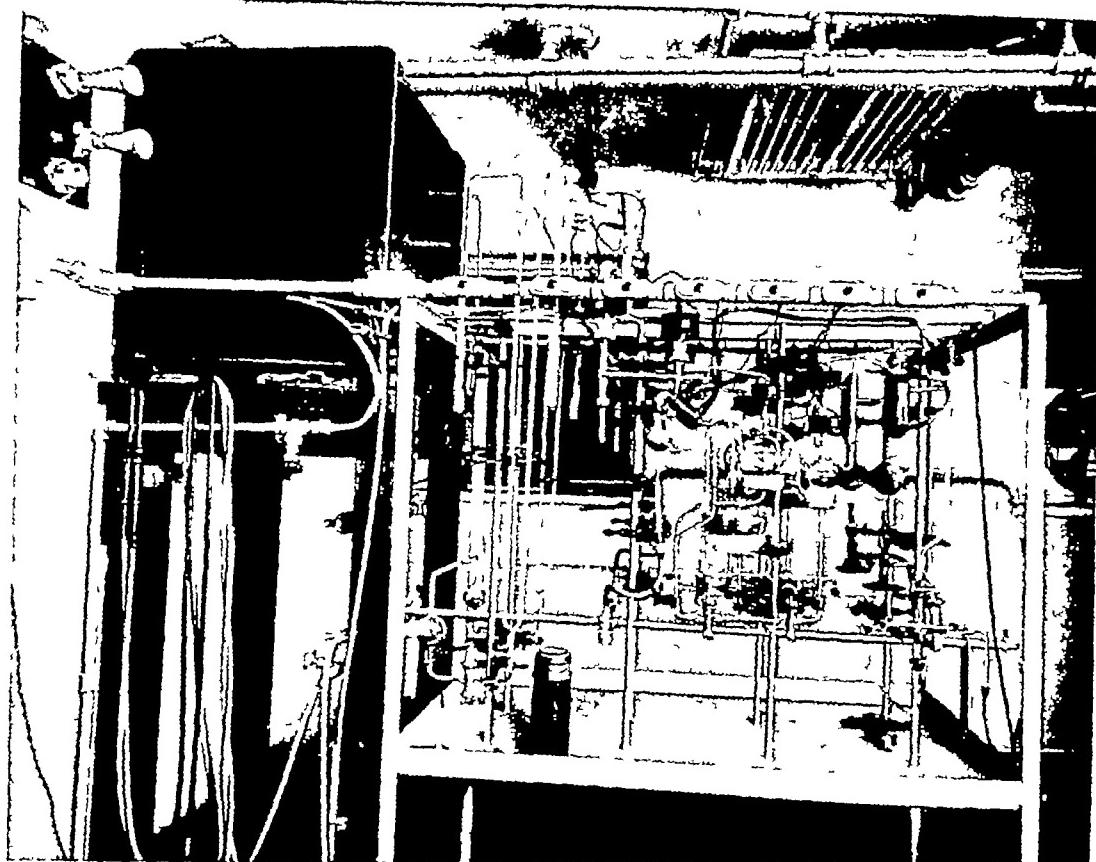

Fig 2. Photograph of emanation plant. Such an apparatus has been placed by the Cancer Research Fund in the Oncologic Hospital in Philadelphia, where it is in regular and successful use with 200 mg of radium.

of potassium hydroxide. This removes small traces of CO_2 , which is apparently generated by the disintegration of small amounts of organic matter which could not be removed from the apparatus. This seems necessary to obtain radon of high concentration, especially when the apparatus is first put into operation. If it were not for the presence of the CO_2 , valve V_5 , and tube F could be eliminated. H is a platinum wire which is placed in or around a quartz tube and heated with an electric current. This supplies heat to an oxidized copper gauze surrounding the quartz tube which causes hydrogen and oxygen to recombine to form water vapor. Hydrogen and oxygen are produced by the disintegration of water in A by the presence

of the α , β , and γ radiations from the radium and its disintegration products.

V_4 is a valve similar to V_5 , except that it can be much smaller. Its use is to prevent the radon from entering I until it has become well purified. I is a small mercury diffusion pump which is used to force the purified radon from D , E , F , and H into J . This pump works very satisfactorily and very quickly. V_6 is a glass check valve which automatically prevents mercury from flowing from M into I . J , N , and M are simple Töpler pumps used to force the radon into K or L . For convenience in making the diagram, reservoir M is shown lower than it is in reality. Actually, c and f are at the same level. K is the small glass capillary into which the

done if the water is allowed to remain in *E* for several pumpings

With as small an amount of radium as 200 mg in the plant, it is quite easy to supply gold implants 4 mm long, 0.15 mm internal diameter, containing 4 mc of radon

SUMMARY

The outstanding qualities of this apparatus are

1 Once installed, no parts or chemicals need be renewed or replaced, except the implant tubing

2 Heavy Pyrex glass is used throughout, which makes the apparatus stronger and less apt to become broken

3 Radon can be easily, efficiently, and quickly purified and forced into gold or glass tubes with little danger of over-exposure of the attendant to gamma rays

DESCENDING INTRAVENOUS PYELOGRAPHY

By CARLOS HEUSER, M.D., BUENOS AIRES,
ARGENTINA

Translation by JOSEPH MALDONADO, M.D.,
NEW ORLEANS, LA

It has been observed that, in pregnant women, intravenous pyelography is more successful than in non-pregnant women and this has proved true in cases in which the two iodine compounds, uroselectan and abrodil, have been used. The success of this method of visualization in pregnant women has been explained by the fact that the fetus makes pressure either on the iliopsoas muscle or on the ureters as they cross the brim of the pelvis, or just before they enter the bladder.

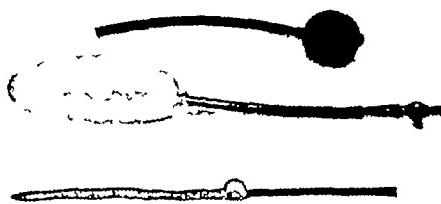

Fig. 1 I, The collapsed balloon, II, Air bulb, III, Distended balloon

This observation incited us to try to imitate fetal pressure. To produce the necessary effect we have to apply pressure either on the bladder or the ureters, as the fetus applies its pressure. In the German literature on this subject, we read that pressure is applied over the abdomen to compress the ureters. This, obviously, is difficult and at times impossible of accomplishment, especially in obese individuals.

When we realized the faults of the abdominal pressure method, we began to work out a method of imitating fetal pressure in the most physiologic manner possible. This, we thought, could be accomplished by filling the large intestine and also the bladder with air, thus producing the desired pressure on the ureters as they enter the bladder. In this manner we could bring out

- (1) The outline of the bladder,
- (2) The kidney outline, which stands out better because the pressure on the ureters keeps the urine from flowing too rapidly into the bladder, allowing the radiologist to study the flow of opaque substances from the kidney.

The procedure, which we term "artificial pregnancy," is as follows. The bladder is filled with 100 c.c. of air. Now if the large intestine is also distended, all the air goes to the transverse portion, causing blurring of the shadows sought, i.e., kidneys and ureters so that air in the intestine is a dis-

J, forcing the radon ahead of it past V_6 into *K*. The mercury is then lowered in *J* but the radon remains behind, trapped beyond valve V_6 in *K*. V_6 automatically forms a mercury-sealed stopper as the mercury level is lowered into *J*. In practice, less than 1 or 2 per cent of the radon remains behind after the first stroke of this Toppler pump. If on the second stroke 1 per cent of the remainder is left, there is little use for the third stroke §.

If no gold implants are wanted, the radon is compressed to the desired volume into the end of *K* and sealed off with a tiny gas flame, being later separated into implants of the desired size. The volume is regulated in the following manner: if stop-cocks S_5 and S_6 are opened, there will be a pressure of 1 atmosphere on the surface of the mercury in *M* and, since the difference in height between the surface and *K* or *L* is approximately 38 cm, the radon will be compressed to approximately $\frac{1}{2}$ atmosphere. This is a desirable pressure for sealing glass radon implants. However, the radon can be further compressed by closing stop-cocks S_2 and S_3 and applying a pressure on the mercury surface in valve V_6 by opening cock S_4 . After taking off the radon the vacuum should immediately be re-established above V_6 before opening S_2 or S_3 .

In case it is desired to put all the radon into gold implants, cocks S_2 and S_3 are opened and the mercury lowered in *J* to about *c* and in *N* to below *c*. Valve V_6 is opened and practically all the radon diffuses into *J* and *N*. V_6 is closed and the mercury is caused to rise in *J*, forcing the radon into *N*. The mercury is then caused to rise in *N*. Valve V_6 has acted automatically to prevent the mercury from entering the gold tube *L*. Its action is stopped by applying a magnetic field which holds it down against the buoyant

force of the mercury. *V* then acts as did V_6 , and *N*, S_3 , and *M* becomes a Toppler pump, which after one or two strokes transfers practically all the radon from *K* into *L*. The radon is again compressed to the desired volume, sealed off with a special pair of pliers, and later cut into implants of the desired length. If all the radon was not forced into *L*, it can be returned to *K* by reversing the process.

In case, for instance, it is desired to put only one-third of the radon into gold seeds (the volume of *N* is equal to one-fourth that of *J*), open stop-cock S_2 and allow the mercury to lower until *J* is one-half emptied. Close S_2 . Lower mercury in *N* below *c* and open V_6 . Shortly the radon will come to equilibrium and one-third will be in *N* and two-thirds in *J*. Allow the mercury to rise in *N*, then in *J*, forcing the one-third into *L* and the two-thirds into *K*. By adjusting the mercury level in *J*, the radon can be divided roughly into any amounts between *L* and *K*. To open *T* for re-evacuation purposes, lower the mercury in *N* below *c*, leaving *J* filled. Open stop-cocks S_6 and then S_4 , allowing air pressure to force the mercury from *T* into *N*.

At this stage there will be a certain amount of condensed water vapor in *E* and it is desired to transport this back into *A*. Close valve V_1 , which prevents water from passing from *A* to *B*. Move the Dewar flask containing the solid CO_2 and acetone from *E* to *B*, having first closed valve V_5 to prevent the KOH in *F* from absorbing the freed water vapor. Enough heat will soon be supplied from the room to melt the ice in *E*. *C* is then opened and the water soon migrates to *B*. Again close *C*, remove the Dewar flask, and allow the ice to melt and the water to become warm. Open V_1 and the water will slowly migrate back to *A*, it being the cooler place. The migration is accelerated if the heat from an electric heater is allowed to fall on *B*. No harm is

§ The volume of the tubing between *J* and *J* (*ab*) is very small compared to the volume of *J*; hence the amount of radon left in *ab* after the second stroke is negligible, providing, of course, that the pump *J* had in the beginning drawn all the radon from the purification chambers.

This shadow, which was somewhat oval in shape, did not conform to the haustral markings of the colon, which could be seen below it. The finding seemed indicative of free air in the abdomen. For verification, a chest

film (Fig. 2) was made with the patient erect, and a small amount of air was seen under each diaphragm.

At operation, a perforated duodenal ulcer was found.

First X-ray Examination of Lungs of Students—For the first time in the educational history of this country, a policy of subjecting the lungs of all members of the entering classes in all departments of a university to X-ray examination has been adopted. This measure was put into practice by Yale University as a further means of safeguarding the health of its students, an annual report of the Department of University Health states:

The X-ray films are made with a view to determining the presence of tuberculosis in any of its manifestations. All students whose

chest films show indications of trouble are to be carefully followed during their college courses and examination of their chests will be made at least once a year.

"A certain number of them should thus be saved from a breakdown, and a single one so saved would justify the expense," the report stated.

Stereoscopic X-ray films were made last year of 1,602 new students. A total of 283 students, or 17.7 per cent of those examined, gave evidence of an amount of infection potentially dangerous but, in most cases, not destined to cause trouble.—*Science Service*

advantage rather than an aid To meet this obstacle the author devised a rubber balloon attached to a tube with a key, which controls the air passage at the end A rubber bulb is used to inject the air With a forceps, the collapsed balloon (I) is inserted into the rectum When one feels that the balloon is on the level with the base of the bladder, the air is injected gradually, using the bulb (II) When the balloon is dilated, the key is closed, stopping the flow of air The balloon then remains distended (III), pressing against the bladder base

While the method described above is quite effective, still we have found it advantageous to use at the same time abdominal pressure by means of a binder which prevents the balloon from passing up the rectum past the base of the bladder, where the pressure is desired The pressure at the

base of the bladder should be continuous for from four to five minutes before the X-ray plates are made

SUBHEPATIC PNEUMOPERITONEUM DEMONSTRATED IN GALL-BLADDER FILMS

By ARTHUR BETTS, M.D.,
SPOKANE, WASHINGTON

Pneumoperitoneum is a well-established sign of perforation of the gastro-intestinal tract The following case is reported because of the characteristic gas shadow obtained in the films of the gall-bladder region

B H, male, was admitted to St. Luke's Hospital on May 29, 1931, and immediately referred to the X-ray Department for cholecystography On the preliminary roentgenograms (Fig 1) of the gall-bladder region, there was a dark shadow lying beneath the liver and above the kidney

Fig 1 Air shadow between eleventh and twelfth

Fig 2 Free air under diaphragm with patient erect

should be paid to their durability and ease of operation than their beauty

Accuracy—The energy put into the X-ray tube must be measured by a milliammeter and a kilovoltmeter which has been calibrated under working conditions with a sphere gap. The daily use of a sphere gap is not necessary, as a kilovoltmeter can be depended upon to furnish a constant index of voltage, although it may not indicate the actual voltage.

The output of radiation from the tube cannot be determined by formulæ. It can be roughly estimated from the effect of experimental exposures on the untanned skin. A far more reliable procedure is to have the output measured at regular intervals by an instrument calibrated in absolute units. The time is fast approaching, if it is not here now, when the ownership and regular use of a measuring instrument will be considered essential to accurate roentgenotherapy.

Finally, the amount of apparatus to be purchased and its capacity depends upon the number of patients to be treated. The articles enumerated in the foregoing paragraph are the bare essentials. As patients become more numerous, other pieces of equipment may be added, such as transformers and tubes of greater capacity, water-cooled tubes, sphere gaps, stabilizers and electroscopes, water phantoms, and spectrographs for experimental study and research.

THE SELECTION OF THERAPY APPARATUS¹

The development of modern roentgenotherapy has brought into common use a great deal of expensive and delicate apparatus. It is not surprising that the young roentgenologist, trained in a great university which is equipped regardless of expense so that a large number of patients can be treated rapidly and efficiently, may assume that a similar expenditure is essential on his part. He may wonder how the income from the few patients he can expect to have will justify what seems to be a large, but necessary, investment. In this time of economic adjustment it is prudent to try to separate necessities from luxuries.

The minimum requirements for modern roentgenotherapy apparatus are that it will permit any required dose of rays to be delivered to any part of the body safely and accurately.

Capacity — Increasing the capacity of transformers and tubes enables us to produce X-rays of increased intensity and hardness. Great intensity, from the use of 200 KV transformers and deep therapy or water-cooled tubes, has one, and only one, distinct advantage. While very hard X-rays save time and allow us to treat many patients rapidly, they have not yet been shown to

possess any peculiar therapeutic virtue. They do have greater penetrative power, permitting a closer approach to homogeneous distribution. This has the practical advantage of proportionately decreasing the amount of radiation absorbed by the healthy tissues surrounding a deep lesion, and, theoretically at least, lessening the danger of severe constitutional reactions. Transformers and tubes capable of operation at from 130 to 140 KV meet the minimum requirement, that is, they will deliver any required dose to any part of the body. If the economical limit of a 40 cm anode-skin-distance and 0.25 mm copper filters are used with 140 K.V., the depth-dose-percentage at 10 cm is 30 as compared to 39.3 with a 50 cm anode-skin-distance and 0.5 mm copper with 200 kilovolts. The time for each area is about one and one-half times as long, and more areas are necessary. If the anode-skin-distance is increased to 70 cm and the filter thickness to 0.5 mm copper, the depth-dose-percentage is 38.6, the distribution comparing well enough with that obtained by a high voltage technic. We may conclude, therefore, that a well-trained roentgenologist who is willing to spend his time need not hesitate to accept patients for treatment because the capacity of his transformer and tube is only 140 kilovolts.

Safety — Danger to the patient from electrical shock, and from stray radiation as well, can be entirely eliminated by completely surrounding the tube with lead and by guarding with grounded metal all wires that can possibly be touched by the patient. This means that tube-stands of the open-bowl type should be abandoned and replaced by the cylinder, the couch, or the slanting wall. These need not be ornate, more attention

BOOK REVIEWS

A RADILOGICAL STUDY OF THE PARA-NASAL SINUSES AND MASTOIDS By AMEDÉE GRANGER, K.C.B., K.C.I., M.D., F.A.C.R., Professor of Radiology, Louisiana State University Medical Center, Director of the Department of Radiology, Louisiana State Charity Hospital, New Orleans, Gold Medal of the Radiological Society of North America in 1926, Gold Academic Palms of France in 1929. Contains 186 pages and 113 engravings. Published by Lea & Febiger, Philadelphia, 1932. Price, \$5.50.

This work, as stated by the author, is a compilation of a number of articles which have appeared from time to time in the current literature. The section devoted to the para-nasal sinuses deals largely with the posterior ethmoids and sphenoids, as it is Granger's belief that the other sinuses can usually be examined satisfactorily by the rhinologist. His observation that a small amount of pus in the maxillary sinus usually collects along the nasal wall is particularly interesting to the reviewer.

Granger makes the observation that in infants under about three years of age, the mastoid cells are so undeveloped that the anterior wall of the lateral sinus cannot be seen, since there is no pneumatization in front of it to act as a contrasting medium. In these infants if the mastoid becomes infected and the bone destroyed over this area, the anterior wall of the sinus becomes distinctly visible. In many cases this new sign of mastoid disease has been the means of diagnosing mastoid abscess when it was not possible to do so by other means.

Granger believes that treatment with very mild doses of X-rays in infantile mastoiditis before the stage of pus formation may result in resolution of the process.

There are also many beautiful illustrations in this section of the book which includes demonstrations of the technic of his positions as well as many examples of mastoiditis in all stages, cholesteatomas, acoustic tumors, and infantile mastoiditis, recognized by the unusually clear visualization of the anterior sinus wall.

Altogether this little book is a very valuable addition to the literature of roentgenology of the sinuses and mastoids.

G W GRIER, M D

STUDIES IN THE PHOTO-ACTIVITY AND THERAPY OF THE TUNGSTEN-TITANIUM ARC By J. BURDON-COOPER, M D, B S, B Sc (Duch), F R C S E, D O (Oxon), F C S, and A ROBERTS, T D, F R C S E, M R C S Eng (Bath) Pages 85, with 21 plates Published by William Wood & Co, New York, 1931 Price \$3 50

This monograph has been written in order to supply information gained by the authors during the last three years with a therapeutic lamp using a composite electrode of tungsten and titanium. In the first

part the emission of the tungsten-titanium arc is analyzed, mostly by the spectral method, a large number of spectrograms is appended. The results can be summarized as follows. The spectrum of the arc contains about 50 per cent short erythema-producing rays, 25 per cent long non-erythema-producing rays, and 25 per cent visible rays in the photo-active part of the light spectrum. This compares very favorably with the pure tungsten arc, which, according to the authors, has, for instance, only 42 per cent of short erythema-producing rays. The times for producing identical skin reactions are 1 8 1 in favor of the tungsten-titanium arc.

In the second and clinical part of the book the clinical model of this arc, known as the Crombie lamp, is described with its accessories. Detailed instructions are then given as to the proper use of the equipment. The general effects following the exposure are also outlined, they are illustrated by excerpts from a patient's letter describing his experience after the use of this lamp. As appears from the next chapter, beneficial results will be obtained in eczema, acne, alopecia, general debility, circulatory disturbances, asthma, anemia, and rheumatic conditions. Numerous histories taken from the files of Dr Roberts are quoted. In conclusion, the authors state that this monograph is offered as the "groundwork of a sincere conviction that the tungsten-titanium arc not only has potential energy and characteristics that are in some respects unique, but also possesses a clinical value in general actinotherapy which we cannot well afford to ignore."

E A P

as is also the statement that a fluid level can seldom be observed, confirming my own belief

Likewise, his experience with iodized oil would seem to be that of many other radiologists, namely, that this method serves only to demonstrate more vividly lesions which may be observed on properly made films without the use of oil

In the examination of the sphenoids, Granger has evolved a position which throws the roof of these sinuses in clear relief, and, even if not accepted as a substitute for all other positions, is undoubtedly a valuable addition to the study of these cavities. The author stresses at considerable length the necessity of following his technic rigidly if his own results are to be duplicated. Briefly, his technic is as follows:

1. The patient must lie prone with the head tilted beyond the horizontal. The object of this position is to cause any pus in the sphenoids to run forward against the anterior wall, as it is this portion of the sinuses which is demonstrated by his position.

2. An angle block tilted 17 degrees beyond the horizontal must be used to support the patient's face.

3. This angle block must have a false top with a hole in it through which the nose projects, the film cassette being beneath.

4. With the patient in position, the face must rest firmly against the forehead and alveolar process in the upper incisor region.

5. The central ray is projected directly downward through the tragus of the ear.

6. If all factors are correct the shadow of the petrous portion of the temporal bone will fall entirely within the orbit, and the roof of the sphenoids will be represented by a convex line at the base of the frontal sinuses.

If pus is present in the sphenoids the lower border of this line will be obliterated because the pus will be lying right up against it. The area below the line will be opaque for the same reason. Polypi produce a similar appearance, although the shadow is usually more dense. Hyperplastic sinusitis produces a rarefaction of the sinus walls, and the line is less distinct and broadened, with the lower border difficult to recognize.

The author believes that the greatest use of the lateral view is to measure the distance between the anterior nasal spine and the anterior wall of the sphenoid, so that the surgeon may know definitely when he is in the sphenoid sinus. For this reason, he always makes his lateral views at a distance of six feet so as to minimize the magnification of this measurement. The numerous beautiful illustrations of specimen skulls with the sinuses filled with opaque material and the great variety of cases demonstrating actual pathology serve to convince one of the value of the author's methods.

In the section on mastoids, Granger describes his modification of Arcelin's position, first reported by him in 1926. This position gives an approximate anteroposterior view of the mastoid and is especially valuable to demonstrate the tip cells. In the reviewer's opinion, this view is an indispensable part of the X-ray examination of the mastoid. Granger's method of making this view is superior to the original Arcelin position in that the patient lies on his back instead of on his face, certainly an easier position for the patient. The head rests on an angle block of 17 degrees, inclined toward the feet. The head is rotated laterally away from the side to be examined, the inclination being 40 degrees beyond the vertical. The central ray is focused directly downward through the mastoid, giving an approximate anteroposterior view.

Granger uses a special head rest with a support for the side of the face which makes it easy to measure the desired angle. In this view the cells in the tip and those directly above are brought into relief in a way which is impossible in any other view. By this view, not only opacity of the cells, but destruction of cell partitions and even erosion of the cortex (Bezold mastoid) can be recognized.

In some cases of furunculosis of the auditory canal, with swelling of the external ear, the mastoid area may appear opaque in the usual Law position, but in Granger's position it will be seen that the pathology is not actually in the mastoid cells. The same observation applies to periostitis of the mastoid tip. Tumors of the acoustic nerve are also well demonstrated by this position.

MUNICIPAL INSTITUTE OF RADI-
OLOGY AND ELECTROLOGY,
BUENOS AIRES

By CARLOS HEUSER, M.D.,
BUENOS AIRES, ARGENTINA

Translation by JOSEPH MALDONADO, M.D.,
New Orleans, La

Last year a new Institute was opened, its object being to give patients sent by attending physicians of the various municipal

treatment, electrotherapy, radium therapy, and kinesitherapy

Besides, the Institute has access to 80 beds where patients can be placed while they are being treated. There is a chemical laboratory, rooms for roentgenography, and rooms for electrocardiography and X-ray diagnosis of the respiratory, digestive, and genitourinary tracts, fractures and dental lesions. There is a department for X-ray therapy

Municipal Institute of Radiology and Electrology, Buenos Aires

hospitals in the city the necessary radiologic treatment. It is a central laboratory as well as a therapy center. Any patient who needs either radiologic or electric treatment and who is in good enough condition to be moved from his hospital is brought here. The necessary tests are made on the patient and a report is sent to the physician in charge.

The Institute, which is under the direction of Dr. Umberto Caselli, is subdivided into departments for X-ray, both diagnosis and

(both deep and superficial) as well as divisions for radium therapy, diathermy, electrotherapy, and electrodiagnosis. The department for local and general ultra-violet radiation is under the direction of Dr. Fernández. Each of these departments has its own attending chief, assistants and nurses, and equipment of apparatus.

We have been informed that this Institute is the most complete and best equipped in the world.

six to eighteen hours. After the bleeding is controlled, fulguration may be done and X-radiation given. In the author's opinion, cystotomy should be avoided, if possible, and resorted to only as a life-saving measure.

The author reports several cases of tumors of the urinary bladder and discusses the methods of treatment employed in these cases. Favorable results were obtained in this series following the instillation of a 2 per cent solution of urea and quinine hydrochloride. The author believes that this chemical is not greatly different from fulguration and radiation in its action upon the tissues, for these agents all sclerose the blood vessels and are anesthetic in their action.

BONE (DIAGNOSIS)

Lines of Arrested Growth in the Long Bones in Childhood the Correlation of Histologic and Radiographic Appearances in Clinical and Experimental Conditions H A Harris British Jour Radiol, November, 1931, IV, 561-588

The author studied intensively the development, appearance, and disappearance of the transverse lines of increased density seen not infrequently in the ends of long bones a little distance proximal to the epiphyses. These lines are similar to the lines of epiphyseal union in that both groups obey certain laws of nature. First, the density of the line is proportionate to the severity of the illness; second, the arrest of growth is manifested at the more rapidly growing ends of the long bones, that is, at the knee, ankle, and wrist. The extent to and rate at which these lines tend to disappear bear some relation to the stresses and strains in the neighborhood of the joint and to the degree of functional usage of the part following the illness which produced the line. Hence, the lines are more apt to persist in moribund joints, such as the ankle and knee, but the more active the individual following the development of the lines of arrested growth, the more remodelling of bone and absorption of the lines is apt to occur. Finally, with increasing age of all individuals, whether they are leading active or sedentary lives, there is greater probability of eventual disappearance of the lines as a part of the process of absorption and deposition which is continually going on in living bone.

As a result of this study the writer believes that there may be a practical medico-legal application for identification of individuals, also that studies of the long bones, such as the knee or ankle regions, might prove of value to insurance companies. Absence of lines of arrested growth would indicate either absence of severe illness during the growth

period or active life thereafter, with subsequent removal of all evidence from the bones of the periods of disturbance in growth.

J E HABBE, M D

Halisteresis of the Epiphyses on the Basis of Endocrine Disturbances Friedrich Tebrügge Röntgenpraxis, Nov 1, 1931, III, 988-990

It is known that rickets, osteomalacia, and osteitis fibrosa are not local diseases of the bones, but are caused by severe disturbances in the calcium metabolism. Many authors believe that an hyperparathyreosis is responsible for osteitis fibrosa generalisata (Recklinghausen).

In an 18-year-old boy who complained of rheumatic pains, especially in the shoulders, roentgenograms revealed relatively wide epiphyseal lines and quite marked osteoporosis of the epiphyses themselves, especially in the shoulders and hips. Chemical tests showed a pathologic amount of calcium excretion and a high calcium level in the blood (from 25 to 30 mg per cent). The clinical and roentgenologic picture points to a hyperfunction of the parathyroids.

H W HEPKE, M D

Total Luxation of the Talus P Pfahler Schweiz med Wchnschr, Aug 8, 1931, LXI, 768, 769

Complete luxation of the talus without fracture is an unusual occurrence. Kronlein found no dislocations in 400 cases of luxation, the author having observed no cases previously. Bohler had never seen a dislocation similar to the one the author describes and illustrates (a medial and anterior dislocation).

A 33-year-old man fell from a height of 35 meters, striking the inner surface of his foot, in plantar flexion, against a circular object. The force was the opposite to that usually described as being responsible for this type of injury.

H C OCHSNER M D

The Use of Roentgen Rays in Fractures (Technic and Organization) Lorenz Böhler München med Wchnschr, Sept 18, 1931, LXXVIII, 1609-1613

The diagnosis of a fracture can usually be made by an experienced physician without the aid of the X-ray, but X-rays are absolutely essential for treatment and in the event of industrial compensation cases. It is especially unwise if the physician ad-

APPARATUS

Gastric Endophotography M G Spehl Arch d mal de l'app digestif, October, 1931, XXI, 968, 969

The author gives a technical description of the apparatus, which consists essentially of a photographic tube and a condenser-transformer. It is best to use a current of 220 volts and 6 amperes. The instrument can be easily inserted if it is introduced obliquely.

Before taking plates it is important to obtain sufficient inflation, so that the instrument is from about 5 to 6 cm away from the gastric wall.

The greatest source of error lies in the fact that folds of mucosa resemble lesions at times. Some of the findings have been the recognition of hypertrophied and atrophied mucosa, various types of small and large ulcers, including plaques of small bullæ in a case of pulmonary tuberculosis, suggestive of gastric tuberculosis. The absence of large folds on the smaller curvature was also noticed.

Colored photography has been tried, but it is very difficult to perform.

Photo-electric Tube. Archie J McMaster and Charles E. Parson (to G M Laboratories, Inc.) U S Patent 1,831,314, Nov 10, 1931

A light-sensitive surface is provided on a cathode of a photo-electric tube by depositing an alkali metal, such as Cs, on the cathode and subsequently admitting O to the tube to oxidize the metal, and expelling the excess of the metal.

CHEMICAL ABSTRACTS

THE APPENDIX

Reflex Phenomena in Chronic Appendicitis George Coote Field British Jour Radiol, October, 1931, IV, 504-506

The writer considers the three following signs or symptoms to constitute an important triad in the diagnosis of "chronic appendicular lesion." Onset of gastric discomfort within from three to four hours after eating, no gastric or duodenal lesion radiologically demonstrable, and reflex pyloric spasm seen roentgenoscopically, with associated increase in gastric peristalsis following pressure in the right iliac fossa. These roentgenologic findings were more often seen associated with non-visualization of the appendix, the appendix at operation often being found to be retrocecal in position. With the

appendix lying free of the cecum and with no associated cecal inflammation, the reflex could not be elicited.

J E HABBE, M D

THE BLADDER

Tumors of the Urinary Bladder Henry A Brady Med Bull Veterans' Administration, December, 1931, VII, 1165-1169

The author attempts to explain the development of bladder tumors as an exaggeration of a physiologic process. Continual irritation and the promotion of hyperemia serve to give unnatural impetus to the inherent power of cells to proliferate and create new tissue in the process of repair. In the end, "super cells" are thus created which are so powerful that these crowd out and break through and invade other tissues. In this manner physiologic phenomena are converted into a pathologic process.

In the bladder we have the ideal field for the inception and development of tumors. Long-continued irritation from unrecognized infection, together with the excessive acidity or alkalinity which accompanies it, furnishes the necessary stimulus until the tumor has reached the proportions of a malignancy.

Papilloma is the most frequent newgrowth found in the bladder, and carcinoma, which is thought to be an evolution of the papilloma, is the next tumor of importance in order of frequency. The adenoma is usually an invasion from the prostate gland. Histologically these tumors are composed of a fine framework of connective tissue in which there is a network of small blood vessels, covered at first with epithelium and later with the tissues which they have invaded. These tumors are usually pedunculated.

The symptomatology of bladder tumors varies with the size, location, character, and tissue involvement. Hematuria has long been considered the cardinal symptom of vesical tumors. Cystoscopic examination is considered of great value in the diagnosis as well as in the determination of the size, location, and character of the tumor and the type of therapy to be instituted.

The author is of the opinion that early fulguration through the cystoscope offers the most favorable results. The patient should be carefully examined every three months for at least two years after the tumor has completely disappeared. Radiation should be combined with fulguration in the treatment of tumors which have attained considerable size, even though they fail to show any malignant change. Radium is found valuable in many cases, especially when used to control hemorrhage. From 50 to 100 milligrams may be applied for a period of from

nose. It is especially difficult to differentiate it from syphilis, osteomyelitis, and tumors of the long bones. The following clinical and roentgenologic points are presented in assisting one in making an accurate diagnosis.

(1) The bone lesions are multiple, (2) the bones of the forearms are most often affected, (3) the sclerotic changes are mild, (4) sequestra are frequently present, (5) the lesion is usually confined to the middle of the shaft, (6) the soft tissues are swollen, (7) the temperature is elevated, (8) suppuration is abundant, (9) youthfulness of the patient, and (10) negative Wassermann reaction.

A series of roentgenograms accompanies the paper, illustrating the gradual improvement of the bone lesions under the treatment.

SAMUEL BROWN, M.D.

Acute Suppurative Conditions of the Hip Joint
Guy A Caldwell Jour Am Med Assn, Jan 2,
1932, XCVIII, 37-40

The author includes all infectious processes that produce pus within the capsule of the hip joint, previously described acute infectious arthritis, acute suppurative arthritis, acute epiphysitis, acute pyogenic arthritis, and septic joints. Penetrating wounds of the hip, with infection and gonorrhreal arthritis, have purposely been omitted, because they are rarely seen in children.

A summary of the records of seventeen patients with eighteen acutely involved hip joints is presented to show pus found in these joints resultant from a hematogenous infection of the synovial lining, femoral neck (intra-articular portion), capital epiphysis of the femur, and pelvic bones forming the acetabulum.

The anatomy and pathology are reviewed with a brief summary of the symptoms and diagnosis. Treatment involves early emptying of the joint and prevention of reaccumulation of pus.

A review of the end-results indicates that ankylosis or pathologic dislocation is the usual sequel when the primary site of infection is in the intra-articular bony structures, whereas an excellent functional result is the rule when the process begins in the synovial membrane.

Röntgenograms should be made after drainage to determine whether or not there is bone involvement; if bone destruction is apparent, drainage must be provided by some other route than through the hip joint.

C G SUTHERLAND, M.D.

CANCER (DIAGNOSIS)

The Dilatation of the Duodenum in the Case of a Circumferential Lesion of the Upper Portions of the Jejunum

A M Rybak Röntgenpraxis, Oct 15, 1931, III,
932-934

Malignant tumors of the jejunum are very rare. A case is described in which a marked dilatation of the entire duodenum, with retention in the duodenum for twenty-four hours, was found on roentgenologic examination. It is impossible, in the author's opinion, to differentiate roentgenologically a malignant tumor leading to obstruction from an obstruction produced by other causes (adhesions, tuberculous glands, etc.). The clinical history (marked loss of weight) and other clinical findings (tumor, blood in the feces) must help to determine the etiology.

H W HEIKE, M.D.

CANCER (THERAPY)

Pre- and Post-operative Treatment of Cancer of the Breast by Radiation (Metastasis Excluded)
J E A Lynham British Jour Radiol, November,
1931, IV, 534-560

Search of the literature by the author reveals the fact that from 75 to 95 per cent of all cases of cancer of the breast are in the stage of skin involvement, adhesions to the muscles, glandular invasion, or wide-spread metastases when first submitted to medical care. Many of these cases are obviously beyond any hope of actual benefit by surgery.

The complex processes involved, whereby irradiation can effect such changes in the tissues as to inhibit malignant growth, bring about its disappearance, or prevent its occurrence, have been widely studied experimentally, but they are not yet well understood. Certain facts of interest from experiments dealing with tumor implantation in animals have been obtained, however, which may have some practical application to the problems of pre- and post-operative irradiation of breast cancers. It has been shown that by giving a certain dose of X-rays to a localized area in animals, the number of tumor implantation "takes" in such irradiated areas is much smaller than the number of "takes" in non-irradiated areas in the same animals. Also, doses of irradiation given to tumor tissue *in vitro* before implantation, which have no inhibiting effect on subsequent growth *in vivo*, will, if given to the tissues after tumor implantation, often cause a disappearance of the tumor. Such experimental results suggest some tumor immunizing effect on the cells of the host by the radiation. In this connection it has been observed that too heavy a dose will fail to inhibit the subsequent tumor growth. There is considerable conformity of opinion derived from experimental work to the effect that cells in a latent state show complete cumulation of several radiations, while cells in an active state show incomplete cumulation. Hence, in practical

tient suggests one A fluoroscopic examination alone often leads the inexperienced to wrong diagnosis, by failure to see a very thin fracture line, as, for instance, in a fracture of the navicular bone of the hand, which sometimes on the radiograph can be seen only by means of a magnifying glass. Films must be taken in two views, frontal and lateral. The central ray must pass through the fracture and the film must be large enough to include the next joint. It is also essential to place the necessary markers on the cassette for identification. A fracture should be radiographed before and after adjustment, and in difficult cases every one or two weeks thereafter, also, after removal of the cast and before the patient is to be discharged.

E A MAY, MD

Avulsion Fracture of the Tibial Tuberosity O Winterstein Schweiz med Wchnschr, Aug 8, 1931, LXI, 761-763

The possibility of confusing Osgood-Schlatter's disease with fracture of the tibial tuberosity has been suggested by Schlatter. The author reports an avulsion fracture somewhat similar to Schlatter's seventh case. A 17-year-old boy, who had previously complained of pain in the knee, met with an injury which caused a detachment of the tuberosity of the right tibia.

H C OCHSNER, MD

Isolated Fracture of the Pisiform W Jaeger Schweiz med Wchnschr, Aug 8, 1931, LXI, 766, 767

Before the advent of the roentgen rays, only one case of fracture of the pisiform bone was reported—that of Guihot, in 1848. Since that time eleven case reports have appeared in the literature. To these the author adds another, with illustrations of the roentgen findings. The occurrence of the rare pisiform secundarium must be excluded by roentgenographs of the opposite hand. Treatment should be conservative, but if pain continues for longer than three months the bone should be removed.

H C OCHSNER, MD

A Case of Isolated Fracture of the Lesser Trochanter Yngve Kewenter Acta Orthopaedica Scandinavica, 1931, II, 160-165

Isolated rupture of the lesser trochanter is to be classed among the fractures of rare occurrence. The author reports a case of this nature in a boy, 12 years of age, who suffered the injury during gymnastic exercises. During the double quick march with long steps the order to halt was given,

when suddenly the hip became "locked." The roentgenogram showed a fracture of the lesser trochanter, with the minor fragment dislocated upwards and medially. The patient's hip was bandaged with plaster of Paris, with the injured leg somewhat flexed, slightly adducted, and rotated outwards.

At the end of two weeks, the patient was discharged, with a slight limp, but otherwise free from symptoms. Three months later, roentgen examination revealed good callus formation between the trochanter and the epiphysis of the femur.

This fracture nearly always occurs between the ages of 12 and 16, and almost exclusively in boys. Diagnosis is not easy to establish, but may be facilitated by the anamnesis and by the presence of Ludloff's symptom, i.e., inability to raise the leg in a sitting position. This symptom, however, may be negative if the fracture is incomplete. But roentgen examination confirms the diagnosis and generally reveals the displaced trochanter, luxated medially and proximally. Prognosis in the case of young patients seems to be invariably favorable.

W W WHITELOCK, Ph D

BONE DISEASES (DIAGNOSIS)

A Rare Picture of a Symmetrical Disease Seen in the Skeletons of the Extremities H U Billig Röntgenpraxis, Nov 1, 1931, III, 984-988.

A case is described which presented bilateral symmetrical areas of density in the upper thirds of both tibias. The distal thirds of both bones of the leg showed less extensive areas of density. The same changes were noted in the distal thirds of the bones of the forearm. All of these bones showed osteitic, specifically osteosclerotic, densities in symmetrical form, more marked near the joints. These findings remained stationary for 18 months. The Wassermann reaction was negative.

The author considers this condition to be indicative of a bone lesion, with features both of melorheostosis (Leri) and osteitis condensans (Sicard).

H W HEPKE, MD

Tuberculous Infection of the Diaphysis of the Long Bones B K Popoff Vestnic Röntgenologii i Radiologii, IV, Nos 2 and 3, p 173

The author reports a case of a child, of the age of one year and seven months, who presented multiple lesions involving the shafts of the long bones. He received a series of ultra-violet and heliotherapy exposures with very good results, although his general condition was very poor at the start.

The author presents a full discussion of tuberculosis of the diaphysis which he states is very rare as a primary affection and is very difficult to diag-

ing to that technic were followed up. One patient died after the operation, due to hemorrhage, two remained well for ten and seven years, respectively, one died seven and one-half years after the operation.

Since 1924, pre-operative irradiation has been given up. Since 1921, radium screens have been used in the axillary region, inserted through drains. In the supraclavicular area 2×66 mg screens are applied, in the infraclavicular area 3×66 mg screens are used, the screens being placed along the blood vessels. Perpendicular to those in the infraclavicular region, 3×66 mg screens are placed in the posterior angle of the wound, for from 50 to 60 hours. This corresponds to from 20 to 24 millicurie doses. After the wound has closed, deep therapy is given spark gap from 35 to 38 cm, 0.5 mm Zn + 1.0 mm Al, 30 cm FSD, 11×16 sq cm field. At least five ports of entry are used, sometimes as many as seven or eight. Each field receives from 3,000 to 4,000 Solomon R units distributed over from 6 to 7 days. Fifty-one cases treated according to this method show the following results. During 1921, five patients were treated, two of whom are still alive, during 1922, ten were treated, none surviving, during 1923, seven were treated, none surviving, during 1924, 26 were treated and seven survived, early in 1925, three were treated and one survived. This means that 7 out of 26, or 27 per cent, are alive seven years following operation and irradiation.

During the period from 1919 to 1924, 13 cases were treated after operation by X-rays only. Four of these are still alive and are in perfect health. One patient died nine years after treatment at the age of 71, and another patient, six years after treatment, from advanced carcinoma of the other breast. Another patient died three years after the operation. In this series, therefore, 30 per cent of the cases were still alive seven years following operation and irradiation.

Since 1925, radium has been applied immediately after operation. A mold of Columbian paste 1.5 cm thick holds from six to eight screens, 10 mg each, filtered through gold equivalent to 20 mm. Pt, and so arranged as to permit homogeneous irradiation. The treatment takes from seventeen to twenty days over an area of from 300 to 400 square centimeters. The total dose amounts to from 250 to 300 millicurie doses, or approximately 40,000 milligram-hours. The exact time of application depends on the condition of the wound. Treatment is given sometimes from 10 to 14 days after operation and sometimes from four to six weeks later. Great care is taken that all radium screens are so arranged that they cover the lymphatics in the infraclavicular region and the area drained by the mammary system. The scar itself, its immediate surroundings as well as the axilla are treated later, usually from two to three months after operation by X-ray deep

therapy. During the first year from eight to ten treatments are given, during the second year five or six, and during the third three or four. In each single sitting about 50 per cent HED are applied. During 1925 and 1926, seven cases were treated this way, and three are still alive. During 1927, nine cases were treated, and three are still living. Five of the six patients treated during 1928 are still alive. During 1929, of fifteen who were treated, ten are alive. Two patients of the latter group have developed metastases.

The author concludes his analysis as follows. During 1925, 51 cases were treated by implantation of radium tubes, after six years, ten, or 20 per cent, are still well. One must consider, however, that many advanced cases were in this group because too many inoperable cases were subjected to operation. Of 21 cases which had received X-rays only, either before or after operation, six, or 28.5 per cent, are still alive eight years after operation. Three of those patients who died had remained well for six years.

Of 20 cases which were treated by radium more than three years previously, in addition to moderate roentgenotherapy, ten, or 50 per cent, are still alive. (In comparing the percentages of results, one must not forget that the last group is based on three years' observation, while the first and second groups are based on six and eight years', respectively.) It is concluded that although the therapeutic results obtained by roentgen and radium therapy alone are not sufficiently good to warrant one in giving up operation, post-operative irradiation is undoubtedly valuable.

ERNST A. POHLE, M.D., Ph.D.

The Treatment of Cancer of the Lip by Electro-coagulation and Irradiation. George E. Pfahler and Jacob H. Vastine. Jour Am Med Assn, Jan 2, 1932, XCIVIII, 32-36.

The great majority of patients give a history of smoking excessively, many having an associated dry, scaly, or atrophic condition otherwise on the lip. As an additional source of irritation, many of these patients have been exposed much to the sun and wind, being farmers and sea-faring men. These atrophic areas are now destroyed at the beginning, healthy granulation and a well-nourished scar following.

During the last five years biopsies have been done in all cases. When there is any doubt, the lesion is treated as malignant until the microscopic report comes. The general methods of treatment and technic are given in detail.

There has been a recovery of 95.5 per cent in all primary cases, even when there were palpable lymph glands, but only 71 per cent of recoveries in the recurrent cases. Of all types of cases that were treated

radiation therapy two objectives should be sought extinction of actively dividing cells and ultimate inhibition of activity of latent ones

With the above facts in mind, the author believes that pre-operative radiation should be relatively intense, should be delivered in a short period of time, and should include the entire breast and the related lymphatic areas, but should not be of such a character as to damage tissues or interfere with healing of the operative wounds (From ten to thirty days should elapse between cessation of radiation and operation)

Post-operative radiation may ordinarily be commenced three weeks post-operative, the first series of treatments following the principles of pre-operative irradiation, with, however, the intensity of dosage being gradually reduced and the time interval lengthened. This would be given with the thought of destruction of actively dividing cells (which must always be presumed to exist), while the latent tumor cells could be most effectively controlled by divided doses extending over a prolonged period, irradiation being administered widely over various areas of the body

J E HABBE, M D

The Influence of Radio-active Energy upon the Carbohydrate Exchange in Cancerous Disease. A P Kostigova. *Vestnic Röntgenologu i Radiologu*, IX, Nos 2 and 3, p 122

Fifty-one female patients, thirty-three of whom had cancer of the sexual organs, were subjected to radium or roentgen-ray treatment, or both. Before radiation was instituted, the sugar content in the blood was determined and was found to be below normal in most of the cases. After the radiation treatment, the sugar content in the blood was again determined and was found to have declined in those patients who showed improvement in their condition, while in those who showed no improvement the sugar content in the blood was found to be raised

SAMUEL BROWN, M D

A Study of Cancer in Ex-service Men Philip B Matz. *Med. Bull. Veterans Administration*, December, 1931, VII, 1128-1149

The author found in his study of 319 cases of cancer, occurring in ex-service men, that syphilis was associated in only 21 per cent, arthritis in 69 per cent, and diabetes in 19 per cent. It is of interest also that of the 319 cases of malignancy there were 41 patients with co-existing active pulmonary tuberculosis and one with tuberculosis of the dorsal vertebrae.

Among 89 ex-service men who died from cancer, the minimum known duration of the disease was two months, the maximum known duration was 156 months, and the mean known duration was 256 months. Of a group of 203 living ex-service men affected with malignancy, the mean known duration was 45.5 months. The activity of patients with cancer is dependent to a considerable extent upon the site as well as upon the stage of the disease. While, as a general rule, constitutional symptoms of cancer develop in the later stages, it is of common occurrence that in tumors of the digestive tract and of the lymphatic system the activity of the patient is greatly limited in the incipient stages.

A study of the results of treatment correlated with the various regimens used showed that the most effective therapeutic procedures in the order named were Radium, surgery and irradiation, X-ray, surgery, X-ray and radium. Of 315 patients with cancer undergoing hospitalization, 42.8 per cent were considered improved upon the termination of the hospitalization, 20 per cent were unimproved, 5.1 per cent were worse, and 32.1 per cent died during the period of hospitalization. At death the mean age of patients with carcinoma was 47.6 years, and with sarcoma, 42.5 years.

J N ANÉ, M D

Alkaline Reserve in Cases of Uterine Carcinoma after Radiotherapy G de Candia. *L'Actinoter.*, June, 1930, IX, 75-94 (Reprinted from "Cancer Review" by permission.)

From blood examinations made on women with uterine carcinoma, the author finds that, following treatment by radium or X-rays, there is diminution of alkali content. This diminution is progressive from the first to the fifth or sixth day, then it passes off and after about fourteen days the alkali content returns to normal. Apparently, the strength of the dose given bears no relation to the degree of this acidosis.

F CAVERS, D Sc

Clinical Data Concerning the Pre-operative and Post-operative Irradiation of Cancer of the Breast Paul de Backer. *Strahlentherapie*, Nov 14, 1931, XLII, 744-752

During the period from 1919 to 1929, the author observed 109 cases of carcinoma of the breast, which received pre- and post-operative irradiation. In the beginning treatment was given for from fifteen to twenty days before operation and post-operatively as soon as the wound had closed. One or two fields were applied over the tumor area and one or two fields over the anterior and posterior axilla and the suprACLAVICULAR region. Eight cases treated accord-

nence of linear markings of varying degree, which so often are without pathologic significance. A number of sketches are used to illustrate the article, and these serve to make the paper easy to understand by one not yet versed in roentgen pathology of the chest.

I E HABBE, MD

Localization of Pleural Adhesions J V Sparks and Franklin G Wood British Jour Radiol, November, 1931, IV, 592-598

Cases of pulmonary tuberculosis undergoing artificial pneumothorax treatment not infrequently require accurate localization of pleural adhesions which are interfering with the collapse therapy. This can be done in some cases with satisfactory accuracy by routine stereoscopic postero-anterior views (taken by the writers oftentimes, with the patient lying prone and with the tube in a fixed position, while the table is shifted the usual 10 cm distance between exposures of the first and second films). Many times, however, this procedure is not sufficient for certain localizations of the site of attachment of the adhesion on the parietal pleura. In such cases the authors use fluoroscopy to determine the optimum angle for visualization of the adhesion in the right and left oblique positions and then make films in these positions. The nearer the adhesion to the apex the more difficult it is to localize because of the relative shallowness of the thoracic cavity in this region.

CHEST (THERAPY)

Pneumolysis in Pneumothorax with Adhesions, Report of Five Cases S T Taylor Med Bull Veterans' Administration, December, 1931, VII, 1160, 1161

As a general rule, pneumothorax is successful in direct proportion to the degree of collapse of the diseased area that is obtained. However, in some cases of partial pneumothorax the splinting effect of the thin layer of air and the resulting reduction of mobility act as favorable influences in promoting healing. Practically all unsatisfactory pneumothorax inductions are due to unyielding adhesions which prevent adequate collapse of diseased structures. Extensive surgical procedures would be necessary to convert these chests into satisfactory pneumothorax cases.

The author has adopted the method of cutting these adhesions by means of a thoracoscope and an electric cautery. In his opinion, this procedure is applicable to those cases in which sufficient space exists between the surfaces of the two pleurae, and the adhesions are suitably thinned out.

Five cases with reproductions of roentgenograms are reported. All of these patients had been receiving pneumothorax therapy for six months or more before the pneumolysis operation. The cavities were unclosed and the diseased areas were not immobile. Clinically, the progress of these patients was considered unfavorable. Eight months subsequent to the cutting of the adhesions by means of the thoracoscope and the electric cautery, all the cases in the author's series showed marked improvement, as determined from clinical and roentgenologic examinations.

J N ANÉ, MD

Roentgenographic Appearance of Thorax after Rib Resection for Pulmonary Abscess John T Farrell, Jr Jour Am Med Assn, Dec 26, 1931, XCVII, 1939-1943

This study is based on the post-operative roentgen observations of twenty-three patients. In thirteen, the abscess followed operation, twelve, tonsillectomy, and one hemorrhoidectomy. In nine, it followed an acute respiratory infection, in six, non-specific respiratory infection, and in one, it developed as a sequel to fracture of the mandible. Information is furnished as to the number and portion of ribs resected, the character of the pleural changes, and the post-operative course of the disease. Two types of alteration are seen roentgenographically after rib resection structural and positional. Pleural abnormalities are due either to edematous swelling or to the formation of fluid. The pulmonary changes depend on the site and size of the abscess, on the condition of the pleura, and on the time elapsing after operation.

Abscess associated with pleural disease requires a longer time for complete disappearance of the roentgenographic shadows than uncomplicated abscess. The positional change of the diaphragm after rib resection is directly proportional to the extent of the accompanying pleural changes.

CHEST (DIAGNOSIS)

The Subsequent Course of Forty Patients with Acute "Dry" Pleurisy Marshall N Fulton and Richard G Hahn Jour Am Med Assn, Dec. 26, 1931, XCVII, 1959-1961

Pleurisy, with effusion, occurring as a primary illness without demonstrable cause is looked on as tuberculous. That a dry pleurisy is a frequent precursor of pulmonary tuberculosis is well appreciated. The study was undertaken to secure additional information regarding the subsequent course of patients with acute dry pleurisy. Figures in the literature indicate that from 30 to 40 per cent of patients with dry pleurisy eventually manifest pulmonary tuberculosis.

The authors found that tuberculosis had developed in only four of forty patients with acute dry pleurisy in whom no primary cause could be shown and who have been followed from one to sixteen years—on an average of seven years.

While this group is not large, it points strongly to a favorable prognosis in acute dry pleurisy of unknown cause

C G SUTHERLAND, M D

The Radiographic Demonstration of the Vena Azygos W J Mowat British Jour Radiol, December, 1931, IV, 690-692

During a study of the esophagus, with the patient in the right postero-anterior oblique position, the writer accidentally observed a small oval shadow about one-half inch in its longest diameter and of the same density as the aortic shadow. It lay in contact with the right postero-lateral aspect of the esophagus at the level of the fourth or fifth thoracic vertebra. After some study it was decided that this shadow was not due to any pathologic process, but represented the horizontal portion of the vena azygos (the most important collateral channel between the superior and inferior vena cavae), seen on end. This vessel may produce sufficient pressure upon the esophagus to lead to the erroneous diagnosis of spasm of the esophagus, impacted foreign body, or peri-esophageal abscess. Of course, in the presence of thoracic neoplasm, causing pressure on the superior or inferior vena cava, one might hope to demonstrate a dilatation of the vena azygos, hence this anatomic landmark may at times, if abnormal in appearance, yield contributory evidence of pathology elsewhere.

J E HARBE, M D

Silent Pneumonia in Infants G Mouriquand and J Savoye Jour Med de Lyon, Nov 5, 1931, VII, 631-637

This is a discussion of the silent type of pneumonia in infants, including the history, etiology, and clinical and diagnostic study as well as prognosis and evolution. Of the radiologic findings the following is said: "Radioscopy shows a triangular image if the involvement is at the apex, or the right middle lobe. Most frequently, if the base is involved, it cannot be geometrically traced. The diagnosis cannot be completely made without radiological views. The radiological triangle remains the capital symptom. This silent form demonstrates the importance of the X-ray in the examination of infants with pneumonia. Incontestably, radiology alone permits of absolute precision in the study of pneumonia in the infant."

B J DELAUREAL, M D

Unusual Development of the Lower Lobes of the Lung Following Selective Artificial Pneumothorax G Rossel Schweiz med Wochenschr, Aug 22, 1931, LXI, 793-795

A case of tuberculosis of the right upper lobe was treated by selective pneumothorax, producing collapse of the upper lobe. This procedure is based upon the tendency of normal lung tissue to expand and of the areas of infiltration to collapse. In this case a series of roentgenographs demonstrated a gradual expansion of the lower lobes until they occupied almost all of the right side of the chest, the upper lobe remained collapsed.

H C OCHSNER, M D

CHEST (GENERAL)

Radiology of the Chest. An Introduction to the Study of Radiograms of the Chest. E. W Twinning British Jour Radiol, December, 1931, IV, 658-679

This article represents a reprint from the *Manchester University Medical School Gazette* in which journal it was originally published for undergraduate reading. It might well be recommended for reading by any practitioner who doubts the necessity for "special views," for, after describing the more important anatomic landmarks, the author describes some of the special positions necessary in the differentiation of pathologic conditions, particular attention being given to interlobar pleural pathology.

The second part of the article consists of a brief discussion on interpretation of pathologic changes in the lungs and pleura. Particular warning is sounded against over-emphasis of generalized promi-

demonstrated that when the systemic temperature is elevated by radiotherapy, an increased local temperature may be produced and maintained simultaneously in the vagina by applying additional electrical energy in that area. They have employed this mechanism therapeutically in the treatment of pelvic inflammation.

For the systemic elevation of temperature the subject is placed between the plates of a large condenser which forms part of an oscillating circuit. The condenser plates are 50 X 80 cm in dimensions, and are separated from one another by a distance of approximately one meter. The patient rests upon a stretcher between these plates but not in contact with them and is kept covered during the treatment to prevent excessive loss of heat. The frequency commonly used is approximately ten million cycles per second, corresponding to a wave length of 30 meters. With a total D C plate current of 0.5 amperes using radio tubes of appropriate construction, it is possible to produce an elevation of body temperature of about 4 degrees Centigrade in the course of one hour and one-half. With the patient in place between the condenser plates an electrode is placed in the vagina. This electrode is connected, through an ammeter, to a small auxiliary metal plate suspended near one of the large condenser plates of the radiotherm. The electric field produced in the region between the electrode and the condenser plate, opposite the one near which the auxiliary plate is suspended, is considerably higher than it is at any other part of the body. The pick-up plate is usually placed near the condenser plate opposite the affected side. With a pick-up plate of 300 sq cm area, the distance between the pick-up plate and the condenser plate varies from 10 to 30 centimeters. The readings on the radio-frequency ammeter usually vary from one to two amperes.

In a series of fifty cases, it was demonstrated that in the average case the temperature in the vagina was elevated to 42.5°C during a period of fifty-three minutes. At the same time the average rectal temperature rose to 40.5°C, while the average temperature in the mouth rose to 39°C. All temperature readings were made while the current flow was discontinued.

EXPERIMENTAL STUDIES

Post-operative Atelectasis and Collateral Respiration C. M. Van Allen and T. S. Jung *Jour Thoracic Surg.*, October, 1931, I, 3-14

The pulmonary function of collateral respiration is described as it is seen in dogs. The interlobular septa are incomplete and the alveoli at point of fusion communicate with each other by small openings. The pathogenesis of post-operative atelectasis, as it is

now understood, is explained and experiments are offered to show why collateral respiration and factors reducing its efficiency must be included in the pathogenesis. It was pointed out that the diaphragm is little used by patients who have abdominal operations. This in turn creates deficient aeration in the lung bases, leading to retention of inflammatory secretions and to lobular, bronchial obstruction.

Following animal experimentation, the authors found that, despite marked bronchial obstruction, collateral respiration was surprisingly efficient. A very small section of lung lobe alone proved sufficient to aerate the entire lobe. Blocking by secretions or pneumonic processes in the smaller divisions of the lobe, however, will cause atelectasis, due to blocking of collateral respiration. This is readily applicable to the human lung in cases following abdominal operation.

M M COPELAND, M.D.

Experimental Investigation of the Effect of Roentgen Rays upon the Vegetative Nerve. Part III—Effect upon the Vascular Nerve (the Irrigating Examination on the Auricle of the Rabbit) S. Suzuki *Japanese Jour Obst and Gynec.*, October, 1931, XIV, 405-409

Following his study of the effects of irradiation on the vegetative nerves, the author studied the effects of X-rays upon the peripheral nerves. One auricle of each of twenty-six rabbits was irradiated and the blood circulatory conditions in the irradiated and control auricles were studied at intervals of one day, two weeks, and four weeks after irradiation. Congestion and dilatation of the capillaries were noted in the irradiated auricles at intervals of from one day to two weeks after irradiation. It was also observed that four weeks after irradiation congestion was still present in the irradiated auricles, although in some cases the irradiated auricles appeared anemic at this time.

The extirpated auricles were studied after the application of adrenalin, pilocarpine, barium, and caffeine. An acceleration of the reaction of the blood vessels to drugs producing vascular dilatation and contraction was observed in the irradiated auricles. It is believed that the early results were due to the changes produced in the vegetative nerves of the blood vessels by irradiation. Later on, as a result of irradiation, changes occurred also in the smooth muscles of the blood vessels.

J N ANÉ, M.D.

Experimental Investigation of the Effect of Roentgen Rays upon the Vegetative Nerve. Part IV—Histologic Investigation of the Effect of the Irradiation of the Inferior Mesenteric Ganglion on

central ray is directed toward the first molar at an angle of 45 degrees

The advantages of this method are as follows
(1) The film can be held even in the absence of teeth, (2) the avoidance of introducing the finger into the mouth, (3) the possibility of holding a film in the mouth which cannot be opened widely, and, (4) the use of larger films enables one to obtain a larger area of the alveolar process and a larger number of teeth at one sitting

SAMUEL BROWN, M.D.

DIAPHRAGMATIC HERNIA

The Diagnosis and Treatment of Diaphragmatic Hernia Stuart W Harrington Jour Thoracic Surg, October, 1931, I, 24-40

The author points out the difficulty in diagnosing diaphragmatic hernia, which often simulates the symptoms associated with cholecystitis, gastric ulcer, cardiospasm, intestinal obstruction, and angina pectoris. The symptoms depend on the following: (1) Mechanical interference with the function of the herniated abdominal viscera, (2) interference with the function of the diaphragm, (3) amount of increased pressure within the thorax. The embryology of the diaphragm is discussed because its rôle in occasionally failing to completely fuse allows herniation.

Diaphragmatic hernia has been classified as follows: (1) Congenital, (2) acquired, and (3) traumatic. The author suggests the following classification: (1) Congenital, and (2) acquired after birth. The most common sites are through the hiatus pleuroperitonealis, through the dome of the diaphragm, through the esophageal opening, through the foramen Morgagni, and through the gap left by absence of the left half of the diaphragm.

Leading symptoms may at first be mild epigastric distress with belching. The pain may gradually become more severe, dyspnea with nausea and vomiting supervening with relief. Recurrent attacks are frequent.

Roentgenologic examination of the stomach is important in establishing a definite diagnosis. The clinical and operative observations are based on 45 cases of diaphragmatic hernia on which the author has operated in the past five years. Operative replacement of the herniated viscera into the abdomen and repair of the abdominal opening in the diaphragm is the only treatment which insures complete relief of symptoms. Palliative phrenicotomy has been used in selected cases in which operation was contra-indicated. Phrenicotomy as a preliminary procedure is often of value in repair of the hernial openings. Radical operation was performed in 38 cases. There were five operative deaths and no recurrences.

M. M. COPELAND, M.D.

Hernia or Eventration of the Diaphragm Report of a Case Carl Eggers Jour Thoracic Surg, October, 1931, I, 41-49

A case is presented to illustrate the difficulties of correct diagnosis. The patient was a female infant, four weeks old. At birth the child seemed normal, but with each feeding (breast) she became cyanotic and dyspneic. Examination revealed lack of movement of the left chest. The heart was displaced to the right, breath sounds being absent over the left lower chest.

A fluoroscopic examination was made and X-ray films were made. They showed the heart in the right thorax, the esophagus angulated at the cardia, and the stomach in the left thorax. Other X-ray plates made later showed that a portion of the colon was situated in the hernia.

W. H. Stewart felt that the case was one of eventration, basing his diagnosis on the presence of what he thought to be a high diaphragm, which was seen in the X-ray plates. Surgical consultation expressed itself in favor of hernia, for the reason that only hernia produces such severe symptoms and causes retention of bismuth for more than six hours. Operation was decided upon. At exploration the mass was thought to be a diaphragmatic hernia. All of its contents were reduced save for the liver, however, the patient died after fourteen hours.

A whitish structure, which was pulled into view during operation and thought to be the esophagus, was found to be a stretched-out central tendon of the diaphragm when a postmortem abdominal examination was done. The diagnosis of eventration of the diaphragm was then established.

A short discussion follows the report of the case. Eventration of the diaphragm is considered comparatively rare. The congenital form is said to be due to failure of development of the muscle elements of the phrenic nerve. The acquired type is occasionally seen as a complication of an acute infectious disease (toxic action on the nerve). The treatment of a similar case would be surgical repair.

M. M. COPELAND, M.D.

DIATHERMY

General Hyperthermia with Heat Localization by Radiotherapy William Bierman and Myron Schwarzschild Proc Soc Exp Biol and Med January, 1932 XXIX, 439-441

When heat is applied locally to any region of the body, it is rapidly dispersed, rendering it difficult to secure any substantial elevation of temperature in that region. In the live, anesthetized dog placed in the field of a high frequency current, the different organs heat up at approximately the same rate, the blood serving as a very efficient distributing mechanism of the generated heat. The authors

demonstrated that when the systemic temperature is elevated by radiotherapy, an increased local temperature may be produced and maintained simultaneously in the vagina by applying additional electrical energy in that area. They have employed this mechanism therapeutically in the treatment of pelvic inflammation.

For the systemic elevation of temperature the subject is placed between the plates of a large condenser which forms part of an oscillating circuit. The condenser plates are 50 X 80 cm. in dimensions, and are separated from one another by a distance of approximately one meter. The patient rests upon a stretcher between these plates but not in contact with them and is kept covered during the treatment to prevent excessive loss of heat. The frequency commonly used is approximately ten million cycles per second, corresponding to a wave length of 30 meters. With a total D C plate current of 0.5 amperes using radio tubes of appropriate construction, it is possible to produce an elevation of body temperature of about 4 degrees Centigrade in the course of one hour and one-half. With the patient in place between the condenser plates an electrode is placed in the vagina. This electrode is connected, through an ammeter, to a small auxiliary metal plate suspended near one of the large condenser plates of the radiotherm. The electric field produced in the region between the electrode and the condenser plate, opposite the one near which the auxiliary plate is suspended, is considerably higher than it is at any other part of the body. The pick-up plate is usually placed near the condenser plate opposite the affected side. With a pick-up plate of 300 sq cm area, the distance between the pick-up plate and the condenser plate varies from 10 to 30 centimeters. The readings on the radio-frequency ammeter usually vary from one to two amperes.

In a series of fifty cases, it was demonstrated that in the average case the temperature in the vagina was elevated to 42.5°C during a period of fifty-three minutes. At the same time the average rectal temperature rose to 40.5°C, while the average temperature in the mouth rose to 39°C. All temperature readings were made while the current flow was discontinued.

Experimental Investigation of the Effect of Roentgen Rays upon the Vegetative Nerve Part III—Effect upon the Vascular Nerve (the Irrigating Examination on the Auricle of the Rabbit). S Suzuki. *Japanese Jour Obst and Gynec*, October, 1931, XIV, 405-409.

Following his study of the effects of irradiation on the vegetative nerves, the author studied the effects of X-rays upon the peripheral nerves. One auricle of each of twenty-six rabbits was irradiated and the blood circulatory conditions in the irradiated and control auricles were studied at intervals of one day, two weeks, and four weeks after irradiation. Congestion and dilatation of the capillaries were noted in the irradiated auricles at intervals of from one day to two weeks after irradiation. It was also observed that four weeks after irradiation congestion was still present in the irradiated auricles, although in some cases the irradiated auricles appeared anemic at this time.

The extirpated auricles were studied after the application of adrenalin, pilocarpine, barium, and caffeine. An acceleration of the reaction of the blood vessels to drugs producing vascular dilatation and contraction was observed in the irradiated auricles. It is believed that the early results were due to the changes produced in the vegetative nerves of the blood vessels by irradiation. Later on, as a result of irradiation, changes occurred also in the smooth muscles of the blood vessels.

J N ANE, M D

Experimental Investigation of the Effect of Roentgen Rays upon the Vegetative Nerve. Part IV—Histologic Investigation of the Effect of the Irradiation of the Inferior Mesenteric Ganglion on

the Female Genitals S Suzuki Japanese Jour Obst and Gynec, October, 1931, XIV, 410-415

The author studied the histologic changes produced in the inferior mesenteric ganglion as a result of roentgen irradiation and also observed the secondary changes which occurred in the female genital organs. Female mature rabbits were employed as experimental animals and at intervals of from one to thirty days after irradiation the inferior mesenteric ganglion and the genital organs were extirpated, the specimens being stained with hematoxylin and eosin.

Thirty days following irradiation, examination of the stained specimen revealed atrophy of the cells of the ganglion. The cells of the ganglion were irregular and the nuclei were darkly stained and atrophied, showing no evidence of the nucleoli. Some of the cells contained small or large vacuoles, with a disappearance of the granules. The changes noted in the blood vessels and lymphatics were very slight. When the ganglion was examined from nine to twenty-one days after irradiation, the changes observed were considered very slight when compared to those observed after thirty days.

The author observed in those cases examined from four weeks to fifty days after irradiation that there occurred an acceleration in development in the female genital organs, these changes being noted to be somewhat marked in the ovaries in particular. The author is of the opinion that irradiation of the inferior mesenteric ganglion produces atrophy and degeneration of the cells of the ganglion, resulting in loss of control of the sympathetic nerves which act as vasomotor nerves in the blood vessels of the peripheral organs. This is in agreement with the previous work of the author, in which it was demonstrated that any disturbance in the ganglion produces a hyperfunction in the peripheral organs supplied by the ganglionic nerves.

J N AVE, MD

Experimental Investigation of the Effect of Roentgen Rays upon the Vegetative Nerve Part V—Clinical Observation S Suzuki Japanese Jour Obst and Gynec., October, 1931, XIV, 416-420

In previous experimental work the author demonstrated that the X-ray produces a hypertonia of the parasympathetic nervous system, as shown by the blood-pressure curves of rabbits following irradiation. In this experiment, cases of inoperable uterine cancer were selected for the study. Blood-pressure determinations were made after the patient became quiet following irradiation and again after the subcutaneous injection of 0.7 c.c. of 1-1000 solution of adrenalin chloride. The blood pressure, pulsation, respiration, and other effects were

fully studied, at approximately five-minute intervals, for a period of sixty minutes following the injection.

It was observed that a definite fall in both the systolic and diastolic blood pressure readings occurred immediately following irradiation. In the majority of cases this fall was below 4 mm Hg, and in the next largest group the fall was from 5 to 9 mm Hg. However, it is of interest to note that after the sixth treatment some of the cases showed a rise in blood pressure. Subsequent to irradiation the usual rise in blood pressure following the injection of adrenalin was decreased. The palpitation, cyanosis, and other effects of adrenalin were slight or not evident in the irradiated cases. The author concludes that these changes resulted from the parasympathicotonia caused by radiation.

J N AVE, MD

GASTRO-INTESTINAL TRACT (DIAGNOSIS)

Radiologic Diagnosis of Diverticulosis of the Colon. H Béclère and P Porcher Jour d Radiol et de l'Electrol, July, 1930, XIV, 380-390

A means of making a differential diagnosis between various types of diverticulosis of the colon is presented with radiographic evidence. Three types are distinguished as follows: False diverticula, formed only by folds of the mucosa; true diverticula, and those formed by a septum, due to perivisceral conditions.

True diverticula occur most frequently in the sigmoid or left colon, are seldom single, and never exceed the apparent volume of a large pea; they are usually asymmetrical, best seen by opaque enemas, and persist after evacuation of the segment. No modification of peristalsis occurs, but occasionally spasm is seen when they are the seat of inflammation.

False diverticula of the mucosa are seen in all parts of the colon, except the sigmoid, and are variable in number. The volume varies with the peristaltic rhythm (large in the ascending colon, in which long, strong contractions occur, smaller in the left transverse part, in which contractions are more rapid); they are never seen by an opaque enema but always following an opaque meal. After evacuation of the segment they disappear and cause no modification of the peristaltic waves.

Diverticula formed by a septum are seen especially at the level of the hepatic angle and the external border of the right and the superior border of the right transverse colon. The number is very variable and the volume can be enormous, depending on the adhesions. They can be visualized by either

method, the general contour is not preserved after evacuation, and the peristalsis is modified on the face involved

The most common error is to mistake a normal fold of the colon for a diverticulum. Although after complete evacuation of the colon the true diverticulum can be identified, it is usually very difficult, with a barium meal, to differentiate between a false and a true one. Recourse to a barium enema, preceded or not by an antispasmodic, is indicated whenever possible. The distention created by the enema permits individualization of these diverticula with much less chance of error. When infected, diverticula are seen, spasm occurs, which resists the action of belladonna and enema. The contour of the colon can become plaited (accordion-like), as in colitis, the peristaltic contractions are less deep, but closer. The segment is comparatively empty and non-expansile.

B J DELAUREAL, M D

Roentgenography of the Normal Relief of the Mucous Membrane of the Stomach and the Technic of Its Investigation V A. Fanardjev *Vestnic Röntgenol i Radiol*, 1931, IX, 270

The relief of the mucous membrane of the stomach is studied after the introduction of a small amount of thick barium mixture. Roentgenograms are taken with the patient in the erect and recumbent positions, at various degrees of pressure. In normal cases the internal relief of the body of the stomach is characterized by four longitudinal folds which are parallel to each other. In the pyloric region the course of the folds varies considerably. They may be longitudinal, oblique, or even transverse. The width of the folds and their intervals vary from 0.5 to 0.6 cm under normal conditions. The paper is illustrated by a number of figures.

SAMUEL BROWN, M D

Radiologic Examination of Non-surgical Conservative Disinvagination of Acute Invagination in Children Jacob Nordentoft *Tour Rad et d'électrol*, July, 1930, XIV, 369-379

Most surgeons are skeptical of this method chiefly because of the uncertainty of the return of the intestine to its normal position, until the first spontaneous stool occurs. The Swedish doctors, Yngve Olson and Gustav Pöllin, and, later, Arntzen and the author proposed this maneuver under X-ray guidance, following a barium lavage. This was done in 108 cases. Fifty-six gave perfect results, and four cases were unsuccessful. Three of these had ileocecal invaginations, another a colo-cecal affair. Of the

54 cases operated on, only one died, the rest were cured. Practically all had repeated lavages under increasing pressures. Eleven case histories are presented with accompanying radiologic illustrations.

The author has found the same radiologic evidence presented by Brocq and Guellette, that is, arrest of a column of barium following a regular concave line, moulding with a clear convex zone, and carrying at times in its axis an obscure defile, more or less sinuous—the effects of abnormal shortening of a colonic segment.

He believes that if the X-ray study does not show the typical form of colocolic or ileo-cecal colic invagination with concave limitation of the barium column in some part of the colon, but bizarre forms, the attempt at non-surgical relief should be abandoned. Again, in ileo-cecal invaginations surgical intervention should be done without delay. X-ray studies are easy and rapid and prevent loss of time in attempts at reduction when operations are indicated.

He concludes that radiologic examination will become an aid of certain importance in the diagnosis and therapy of this disease. When non-surgical reduction is done, the success and progress can be observed and the hours of doubt and suspense relieved while waiting for the appearance of normal stools three days later.

B J DELAUREAL, M D

Interposition of the Large Bowel between the Liver and the Diaphragm M Z Rotenfeld *Vestnic Röntgenologu i Radiologu*, IX, Nos 2 and 3, p 153

The diagnosis of interposition of the large bowel between the liver and diaphragm depends upon roentgenologic investigation of the gastro-intestinal tract. There is no symptom-complex which would lead the clinician to suspect its presence. The only characteristic and pathognomonic sign of this condition is the roentgenologic demonstration of the large bowel between the diaphragm and liver. The author believes that ptosis of the liver may have something to do with this anomaly. In general, it is found but rarely and is of very little clinical significance.

SAMUEL BROWN, M D

Interposition of the Colon between the Liver and Diaphragm J Tremolieres and Andre Tardieu *Arch d mal de l'app digestif*, December, 1931, VII, 1154-1198

Often these conditions are looked upon as constituting a harmless abnormality or as due to flatulence, but after the authors had studied 19 such cases in one year, they were confirmed in their first observa-

tions, namely, that this condition results from perivisceral adhesions. The authors have reported certain pathologic findings and diagnostic peculiarities, which clear up the symptomatic significance.

In a radiologic study of this anomaly, following its suspicion from percussion, one notices below the diaphragmatic spherical vault, in the middle of the hepatic shadow, a region of lesser density, and, outside of this area, a clear area of variable extent which may be as large as the hand, uniform or streaked by a fold of the colon.

An opaque substance ingested from seven to ten hours before examination reveals the right half of the colon, or the barium enema finds its way into the clear pocket outside of, or in front of, the liver.

Usually the hepatic flexure is found between the anterior surfaces of the liver and diaphragm, rarely between the liver and the axilla. Occasionally the shadow is that of a very long sigmoid colon or possibly the cecum. It is not always permanent and may disappear upon the patient's changing position. It is more apt to be present when the patient is in the erect posture, and the weight of food or barium may displace it below the liver.

Besides the various etiologic factors brought out by different authors, such as change in abdominal pressure, diminished volume of the liver as a result of disease or change in the ligaments, adhesions as a result of appendicitis, gall-bladder disease, gastric ulcers, inflammation of the cecum, and any other condition that may produce peritoneal irritation must be added. This has been proven by cases upon which operation has been done; three showed the presence of ulcers, new or old, 10, chronic appendicitis, four, chronic colitis of obscure origin, in some cases complicated by chronic cholecystitis, one evidenced cholecystitis alone. All showed adhesive perivisceritis. Pericolitis appears to be an element common to these various conditions, and it is primary or secondary to the subhepatic region. The colon is then necessarily adhesive to the liver, the flatulence forcing its interposition.

Treatment consists of hot applications to the abdomen, antispasmodics as bromides and valerian, mixed vaccines, bismuth, kaolin, charcoal, and other treatments of colitis and limitation of fermentative hydrocarbons. Heliotherapy, ultra-violet and infrared rays, and diathermy may be tried for the perivisceritis. Massage and gymnastics may help. If no relief is obtained, resort may be had to surgery.

B J DELAUREAL MD

GENITO-URINARY TRACT (DIAGNOSIS)

Hydronephrosis James Christiansen Med Bull Veterans' Administration, December 1931 VII 1162-1164

Complete obstruction of the urinary tract usually results in the cessation of secretion of urine by the kidney on the involved side, before the pelvis is dilated. However, intermittent or partial obstruction results in dilatation of the kidney pelvis. This dilatation may continue until the kidney tissue is completely destroyed so that only a thin wall of cortex may remain as a lining of the hydronephrotic sac. Obstruction of the urinary tract may result from the following causes: Inflammatory strictures, enlargement of the prostate or seminal vesicles, urinary calculi, angulation or kink of the ureter, and reflux from the bladder.

Hydronephrosis usually causes pain of a colicky character, and on physical examination tenderness and a palpable tumor may be found. Cystoscopic and roentgenologic examinations are valuable aids in establishing the diagnosis. The pyelogram will show the enlarged pelvis and will determine the size of the hydronephrotic sac.

The treatment of this condition consists of the removal of the obstruction and emptying of the pelvis. In those cases in which total destruction of the kidney pelvis has occurred nephrectomy is advisable.

The author reports a series of cases and discusses the diagnostic and therapeutic methods employed.

J N AVE, MD

GENITO-URINARY TRACT (THERAPY)

The Relation of Cystocele to the Upper Urinary Tract. Jefferson C. Pennington Urol and Cutan Rev, January, 1932, XXXVI, 1-8.

The author discusses the importance of the association of cystocele and lesions of the upper urinary tract, and urges the closest co-operation of the gynecologist and urologist in the treatment of these cases. While the causes of cystocele are very numerous, it is believed that most frequently it results from trauma and perineal lacerations following childbirth. Congenital tissue weakness, senility, uterine tumors, and general abdominal ptosis are other etiologic factors. The prominent symptoms are those due to vesical irritability.

Cystocele when far advanced is very easily recognized. Cases of lesser degree may escape detection if only casual inspection is resorted to. Cystoscopy is found a valuable aid in many cases. Employing the technic of H G Pretty, X-rays have been found serviceable in these cases. A 10 per cent solution of sodium iodide is injected into the bladder, while the patient is lying on her back on the table. She is then placed in the vertical position

and the X-ray tube centered over the symphysis pubis. The roentgenogram is taken while the patient is in the act of "bearing down."

Cystoceles do occur without associated pathology, and, in the opinion of the author, they should be severe enough to interfere with bladder function before they require especial attention. A cystocele with retention of urine is analogous to retention of urine in the male caused by prostatic obstruction. Cystitis follows as a result of retention of urine, and the infection spreads by direct continuity through the blood stream and lymph channels to the ureters and pelvis of the kidneys.

Cystocele is very frequently associated with rectocele, which, in turn, results in intestinal stasis. The lymphatic systems of intestines and kidneys have been shown to be closely associated and this serves as a route of infecting organisms. It is also known that colon bacilli in passing through the kidneys will frequently attack the kidneys if for some reason the patient's general resistance has been lowered. As a result, the patient may have a pyelitis, nephroptosis, and rectocele associated with the cystocele.

The author is of the opinion that these patients should be examined carefully and thoroughly, so that rational and beneficial therapeutic methods may be planned.

J. N. ANE, M.D.

Radiation Therapy of Malignancies of the Bladder and Prostate. Ira I. Kaplan. Urol and Cutan Rev, January, 1932, XXXVI, 40-42.

It is generally agreed that, as in malignancy situated elsewhere, the best treatment for early lesions of the bladder and prostate is surgery, followed by irradiation. Unfortunately, however, the disease is surely well advanced in the average case before the diagnosis of malignancy is made. Radiation therapy of these organs requires as careful and thorough a technic as the surgical form of therapy.

Radiation therapy in genito-urinary work advanced with the advent of the manufacture of glass tubules of radium gas by Dominicci. While the results obtained at first were found encouraging, it was observed that marked necrosis of all tissues followed the application of these tubules. The metal filtered tubules were found very much more satisfactory, as the metal filtered off to a large extent the corrosive rays of the radium emanation and produced a much more efficient gamma effect on the irradiated tissues.

Regaud reaffirmed the axiom that the best form of radium therapy is that produced by applying to the lesion a small quantity of radium properly filtered,

over a long period of time. Utilizing this theory, there has been devised a method of treating cancer of the cervix uteri, which has replaced operative procedures for this condition in most of the clinics here and abroad. This technic replaced the older intratumoral puncture method in the treatment of cancer of the rectum and cervix in the author's service. The results were so favorable in these cases that he next devised a technic for the application of this form of irradiation to malignancies of the bladder and prostate.

In the case of cancer of the bladder, after a preliminary suprapubic cystotomy, a stay suture is placed in the bladder wall in close proximity to, and on either side of, the lesion. This suture is so inserted as to leave a loose loop between needle holes in the cavity, and the ends of the sutures are brought out in the suprapubic opening. The radium tube is then placed in a rubber tube which is tied at both ends with the long ends of the thread remaining. The radium tube is then placed in position about the lesion to be treated. The long threads from the tube are carried under the loop of the stay sutures on either side of the lesion, brought out through the suprapubic opening, and anchored on the abdominal wall by adhesive tape. From one to four tubes are used about the periphery of the lesion. The dosage employed depends upon the size of the lesion and varies from 2,000 to 5,000 milligram-hours. The tubes, containing from 5 to 15 milligrams of radium or radon, are filtered through from 1 to 15 millimeter thickness. The bladder is irrigated daily with boric acid solution.

At the conclusion of the treatment one end of the stay suture is cut close to the suprapubic orifice and traction applied to the other end, the stay suture being withdrawn from the bladder. The other suture is released in the same manner and the radium tube is drawn through the suprapubic opening.

Radium therapy is applied to the prostate by exposing the prostate through the usual perineal incision. The levator muscles are separated and the urethra and rectum separated from the prostatic capsule by blunt dissection. Then holes are made through the capsule and extended into the gland proper by means of a large curved artery forceps. After the radium tubes are pushed into these holes, the wound is packed with iodoform gauze, and closed in the usual manner, leaving a skin opening at one side from which the ends of the tube threads and the iodoform gauze protrude. From 5 to 15 milligrams of radium are used in each tube and a total dose of from 200 to 500 milligram-hours is given. In cases in which symptoms of urinary obstruction are present, a suprapubic cystotomy is done for bladder drainage before radiation treatment is given. This wound can usually be closed after radium treatment.

J. N. ANE, M.D.

tions, namely, that this condition results from perivisceral adhesions. The authors have reported certain pathologic findings and diagnostic peculiarities, which clear up the symptomatic significance.

In a radiologic study of this anomaly, following its suspicion from percussion, one notices below the diaphragmatic spherical vault, in the middle of the hepatic shadow, a region of lesser density, and, outside of this area, a clear area of variable extent, which may be as large as the hand, uniform or streaked by a fold of the colon.

GYNECOLOGY AND OBSTETRICS

The Pre-operative Irradiation of Uterine Carcinoma. A Mayer Strahlentherapie, Nov 14, 1931, XLII, 759-768

During the period from July, 1926, to October, 1931, the author observed 91 cases of uterine carcinoma irradiated before operation. From 1927 to 1929, there was no operative death and the total mortality in five years amounted to only four, or 4.3 per cent. Two of these cases died from cachexia, one from heart disease, and only one after operation, from peritonitis. Roentgen rays and radium were used in combination, or radium alone. No definite information as to the radiosensitivity of the tumor could be obtained either from the clinical picture or from the histologic study of a section. It also appeared that temporary clinical cure and permanent or anatomic cure do not always run parallel. Of 101 women who were operated on, three months after irradiation the carcinoma had disappeared from the surface in 56 cases, while in only 20 of these microscopic examination of the removed uterus revealed no cancer tissue. No definite statistical figures as to five-year cures can be given at the present time.

The author concludes that undoubtedly pre-operative irradiation improves the chances for operation. It helps in rendering the operative area aseptic and decreases, therefore, the percentage of post-operative peritonitis. As a preliminary figure of cures, he gives 41.3 per cent for pre-operative irradiation and operation, as compared with 31 per cent for operation alone.

ERNST A. POHLE, M.D., Ph.D.

The Influence of the Irradiation of the Hypophysis upon the Female Genitals S. Suzuki Japanese Jour Obst and Gynec, October, 1931 XIV, 393-399

The relationship of the hypophysis to other endocrine organs has been proved by many investigators. Long and Evans, and later Aschheim and Zondek demonstrated the effect of the pituitary hormone upon the genitals. The author studied the secondary effects upon the female genital organs caused by irradiation of the hypophysis. Albino rats were chosen as experimental animals and immobilized so that only the heads of the rats were irradiated. The factors employed were as follows: Effective voltage, 159 K.V., 2 ma., skin focal distance, 23 cm., filtration, 1 mm Al plus 0.5 mm Zn, the shortest wave length, 0.09-0.095 A.E.

The rats were divided into three groups and designated as A, B, and C. A group was irradiated for a period of twenty minutes, seven or eight times at intervals of from one to five days. B

group received three irradiations of forty-five minutes each at intervals of from two to seven days. C group was irradiated three times at intervals of one or two days for a period of sixty minutes, each time. From 137 to 166 days were required for the experiment.

Immature rats were also employed and divided into three groups, these groups receiving ten, fifteen, and twenty minutes' irradiation, respectively. These animals received eight treatments, for at the onset of estrus the irradiation was discontinued and changes in the body weight and sexual cycle observed. This study lasted 166 days.

Of the five cases irradiated eight times for a period of twenty minutes each time, two cases showed a lengthening of the sexual cycle, and in the remaining three cases the change was not so marked. Of the five cases irradiated three times for a period of forty-five minutes each treatment, a definite change and lengthening of the sexual periodicity occurred, no change occurring in the other two cases. Of five cases irradiated for a period of sixty minutes from four to six times, four revealed a longer interval and one case showed no change. While the immature rats, which had been irradiated from fifteen to twenty minutes, revealed a marked decrease in rate of growth, none of the animals showed any change in the onset of estrus as compared with normal controls.

The author concludes that secondary changes do occur in the ovaries, as a result of irradiation of the hypophysis. He further believes that the results obtained in the irradiated immature rats prove the existence of a hormone accelerating the bodily development in the hypophysis.

Using identical material and methods of irradiation, the author studied also the effects of adrenalin, pilocarpine, and barium on the uterine movement of the irradiated and normal control animals. It was observed that the extirpated uterus of the irradiated rat demonstrated a decrease in sensibility to adrenalin and barium. However, in some cases the reverse effects were noted following the use of adrenalin. Very little or no decrease in sensibility to pilocarpine was noted.

The author is of the opinion that irradiation of the hypophysis produces an atrophy and consequent hypofunction in this organ which results in a secondary atrophy of the genital organs and decrease in sensibility to the usual uterine stimulants.

J. N. ANÉ, M.D.

THE JOINTS

Synovial Fluid. Editorial Jour Am Med Assn, Dec. 26, 1931, XCVII, 1969

The composition of the synovia is not constant but differs in rest and motion of the joint.

There is a notable distinction between the fluid and blood plasma or ordinary lymph, presumably due to a mucin-like substance in the synovia. The exact nature of the mucinous constituent remains unknown.

Fremont-Smith and Dailey concluded that the equilibrium between plasma and synovial fluid is of the same nature as that between plasma and peritoneal or pleural effusions. Kling found the viscosity of normal, and the majority of pathologic, synovial fluids to be higher and the range of variation greater than that found in plasma and exudates. The mucinous substance is recognized to be a physiologic product. Inflammation and irritation tend to increase its output. Kling believes the structure and function of the synovial membrane are twofold, one part being for mechanical binding of the epiphyses and the other for maintenance of smooth motion and lubrication. The secretory element is best developed in the knee joint and less well developed in the wrist and tarsal joints. Motion is the natural stimulus for the secretion of synovia, as is food for the secretion of gastric juices. The detrimental effect of immobilization, especially in knee joints, is therefore explained by the interference with this secretion in a joint highly adapted to it.

C G SUTHERLAND, M D

Patella Partita Werner Feistkorn Röntgenpraxis, Oct 15, 1931, III, 945-951

The differentiation of a patella partita from a fracture of the patella is not always easy. Comparison of the affected knee with the other knee is very important, if one wants to avoid mistakes, which are especially disagreeable in insurance cases. In the majority of cases, this anomaly is found bilateral.

The case described showed multiple separate portions of the patella. The pathogenesis of the patella partita is not yet clear. Some authors think of a congenital deformity caused by separate centers of ossification, while others consider an osteochondritic lesion (with "Umbrozonen") similar to Osgood-Schlatter's disease. A slight trauma and excessive muscle traction might be factors. In the case described no fracture could be shown, except a very small fragment. However, many months afterwards the picture of a patella multipartita appeared. Both knees showed several centers of ossification.

LEAD POISONING

Röntgenologic Diagnosis of Lead Poisoning in Infants and Children Edward C Vogt Jour Am Med Assn Jan 9, 1932 XCVIII, 125-129

Since August 1929, thirty-two cases have been

diagnosed in his clinic. Quite a number were detected in the roentgenograms before otherwise suspected. The most frequent source is from paint off furniture, woodwork, and toys. Symptoms occur most commonly between the ages of one and two years, and are chiefly neurologic and gastro-intestinal. A secondary anemia is usual. Basophilic stippling of the red blood cells is considered one of the most reliable observations. The lead line in the gums is seldom seen in children.

A roentgenologic sign is a dense band at the growing margins of all bones, being most evident at the ends of the long bones and anterior ends of the ribs. It must be differentiated from rapidly healing or recently healed rickets, or changes following severe nutritional disturbances with retarded growth of bone.

C G SUTHERLAND, M D

RADIATION

Fluctuations of the Lactic Acid Content of the Blood Following Roentgen Exposures of Normal and Pathologic Body Tissues J Heeren and R. Hummel Strahlentherapie, Nov 14, 1931, XLII, 784-792

In a series of patients who received X-ray deep therapy the lactic acid content of the blood was determined. It appeared that if normal tissues of patients who had no malignancy were irradiated, there was no increase of the lactic acid content in the blood, no patients showed a decrease immediately following irradiation. Patients with malignant neoplasm responded as a rule with an increase in the lactic acid content of the blood immediately after irradiation. If they were treated over normal tissues, as, for instance, over the thigh on another occasion, the lactic acid content of the blood was found decreased immediately after irradiation. The irradiation of tuberculous or other pathologic tissue, with the exception of neoplasm, also brings about a decrease of the lactic acid content of the blood. This change is usually of short duration, two hours after irradiation it may have already disappeared.

ERNST A POHLE, M D, Ph D

Sources of Radiation and Their Physical Characteristics W W Coblenz Jour Am Med Assn, Dec 26, 1931, XCVII, 1965-1967

Recent additions to the physical therapist's armamentarium are the so-called cold red ray and cold quartz ultra-violet ray lamps. The term "cold ray" is a misnomer. Thermal radiation of all wave lengths (whether ultra-violet, visible, or infra-red rays), when absorbed, produces heat. The reason these two

sources do not have a sensible heating effect and the burners do not become highly heated is that very little electric power is put into the lamps and little radiant power is emitted

A description of the light and comparison of units are given

He comments on the difference in the physiologic action of ultra-violet rays of wave lengths less than 265 millimicrons in artificial sources and those from 310 to 315 millimicrons, which are very intense in sunlight. It will require a long time to inform the public of the importance of timing the sunbath to avoid severe burns. Many painful burns could be avoided by warning

ROENTGEN-RAY (INDUSTRIAL APPLICATION)

Practical Application of X-ray Diffraction Methods in the Study of Quench and Temper Structures of Carbon Spring Steels N P Goss Trans Am Soc. Steel Treating, 1931, XIX, 182-192.

X-ray diffraction methods show that quenching and temper structures are quite independent of each other. The ill effects of improper quenching cannot be removed by tempering, which only facilitates the precipitation of Fe,C, the α -Fe matrix is not changed. X-rays will determine whether the proper quench structure was obtained, even though the steel has been tempered. Diffraction patterns are given

CHEMICAL ABSTRACTS

Radiography by the Use of Gamma Rays Robert F. Mehl, Gilbert E. Doan, and Charles S. Barrett. Trans Am Soc. Steel Treating, 1930, XVIII, 1192-1227, Jour Inst. Metals, 1931, XLIV, 606

A preliminary paper on the examination of metals by γ -rays from radio-active substances. Radiographs were obtained of steel, the thickness of which far exceeds that possible for X-rays. Ten inches of steel has been penetrated with slight success. Three methods were used (a) Ionizing effects of the γ -ray, (b) fluorescent screen, and (c) photographic film. The last gave best results. Exposures of one hour per inch of thickness of steel, with 18 inches photo-distance source to film, gave good results. Photographs are given

THE SINUSES (DIAGNOSIS)

The Relation of the Sphenoid Sinus to Dysfunction of the Pituitary Gland S. Bockoven Med Bull Veterans' Administration, January, 1932, VIII, 43, 44

Anatomically, the pituitary gland is separated from the sphenoid sinuses by only a thin layer of bone. The optic chiasm is situated almost immediately in front of the pituitary, which accounts for the findings in the eye grounds which are sometimes observed in posterior sinus disease. In like manner, pathologic changes in the optic tract in some cases result from disease of the sphenoid sinuses.

The author emphasizes the necessity of a complete and careful study of the sphenoid sinuses in all cases of pituitary dysfunction, such as is found in diabetes insipidus. He cites the case of an ex-service man who was admitted to the hospital because of polyuria, nocturia, and a disturbance in vision. A careful examination of his sinuses, including lipiodol injection and roentgen examination, revealed definite evidence of sphenoid disease. The sphenoid sinuses were treated, and the patient experienced considerable relief of his symptoms.

The author is of the opinion that further study along these lines may reveal other evidence of disturbance in the function of this gland, due to irritation in this region, secondary to definite disease of the sphenoid sinuses.

THE SKIN (GENERAL)

Acne A Statistical Study of Possible Related Causes Ruby L. Cunningham and C. J. Lunsford Calif and West Med, July, 1931, XXXV, 22-26

In this study of acne the authors have used young women students entering the University of California. The physical examination showed acne in 23.7 per cent, or 2,974 students. They selected 3,185 students out of those without acne to represent a control group. They compared the weight of these groups as to overweight and underweight. Very little difference in percentage was found in the two groups, namely, "acne present" and "acne not present." Again, a comparison, using the complexion, showed very little difference. Using the menstrual history, the difference was found to be very small.

Regarding infections, such as boils, appendicitis, tuberculosis, tonsillitis, constipation, headache, etc., one is again struck by the similarity of percentages in the two groups. A little difference was found in

the adolescent enlarged thyroid groups, the "acne present" group showing 27.2 per cent as against 21.8 per cent in the "acne not present" group. Again, comparing the nose, tonsils, and eyes, we have a very little increase in percentage in the "acne present" group over the other.

In their conclusions, the authors note "If we accept the theory that acne is due to an infection, this study would indicate that the infection is little influenced by systemic conditions."

FRANCIS B SHELDON, M.D.

THE SKIN (THERAPY)

A Case of Calcinosis Universalis, and a Suggested Method of Treatment. John Craig and Alexander Lyall. British Jour Child Dis., January-March, 1931, XXVIII, 29-34

A case of calcinosis universalis is reported in a child of five years. Hard lumps could be felt beneath the skin and X-ray plates showed diffuse calcification in the subcutaneous tissues. The child was given iodides, with massage, for three months without benefit.

Di-sodium phosphate by mouth was then substituted, in half-drachm doses three times daily for a week, then one drachm four times daily. In six weeks' time the masses had almost gone and very little calcification remained, as shown by subsequent X-ray examination. The authors give a short discussion of the rationale of this treatment.

E C VOGT, M.D.

Light Therapy in Skin Diseases. Walther Schultze. Strahlentherapie, May 20, 1931, XL, 601-610

This is a brief general discussion of the present status of light therapy in dermatology. The various schools of teaching are mentioned, and the importance of medical supervision is stressed. As far as the dosage of light is concerned, the author feels that the reproducibility of doses applied to the patient is a necessity.

"However," he states, "we do not know enough to day concerning the biologic effect of various parts of the spectrum to permit the adoption of a definite unit similar to the r in roentgen therapy."

ERNST A POHLE, M.D., Ph.D.

A Few Remarks about the Treatment of Rhinophyma. Albert Martin Cuadran. Med Ann Jour, November, 1931, XXVI, 589-591

Rhinophyma is the monstrous hypertrophy of the

end of the nose. This deformity is the final evolution of the rosacea, with folliculitis.

The local treatment of rhinophyma differs according to the stages of its evolution. At the onset, when it is still a rosacea, strong sulphurated lotions, and, notably, cryotherapy give excellent results. Carbonic dioxide snow is the treatment of choice for the rosacea when it presents but little folliculitis and fine telangiectasiae. Massage is a good adjunct.

At a later stage, when the skin is hypertrophied and the small veins which run into it are numerous and dilated, and folliculitis is marked, we must have recourse to more active measures. Positive electrolysis will block the vessels. Crossed linear scarifications will chop the telangiectasia and the sebaceous glands. Careful applications of filtered X-rays will diminish the recurrence of folliculitis. Nevertheless, these diverse treatments are insufficient when the affection becomes a genuine rhinophyma and the nose develops extraordinary proportions. We must then act energetically to free the patient from this deformity.

Decortication is the operation to be adopted. This consists in removing the surplus tissue, care being taken not to go too deeply, in order to leave sufficient tissue for epithelialization. Some authors recommend the use of high frequency currents, employed either for coagulating the rhinophyma or for endothermic ablation. The author does not recommend this procedure, because it is lengthy and uncertain in its results.

X-rays and radium are not of any use to reduce a rhinophyma. We would have to use such high doses as to cause severe radiodermatitis long before the nose would diminish in size.

The author presents photographic reproductions to illustrate one case treated by the surgical method.

L I CARTER, M.D.

The Distribution of Roentgen Rays in the Skin. V Wucherpfennig. Strahlentherapie, Oct 24, 1931, XLII, 544-550

The author states that isodose charts for radiation used in skin therapy have not been measured so far. It is necessary, therefore, to calculate the distribution of radiant energy in the skin. The accuracy of such a calculation depends, greatly, of course, on the conditions found in the individual case. A method is shown which permits the determination of the depth dose in superficial therapy by using the mass absorption coefficient for air and water. The results are recorded in a schematic cross-section of the skin, thus enabling the radiologist to read off the "depth dose" for radiations with a half value layer in Al from 0.25 to 4.0 mm in the first 12 mm of skin.

ERNST A POHLE M.D., Ph.D.

Action of Roentgen Rays of Different Quality on Psoriasis G A. Rost and Ph Keller Strahlentherapie, Oct 24, 1931, XLII, 539-543

The biologic effect of roentgen rays of different wave length has been most frequently compared on the basis of the skin erythema. The authors used a different reaction, namely, the changes produced in psoriatic lesions. The following qualities of radiation were used: 45 K.V., no filter; 75 K.V., no filter; 75 K.V. 1 mm Al; 138 K.V. 4 mm Al; 138 K.V. 0.5 mm Zn. The half value layers in Al were 0.3, 0.5, 1.5, 8.0, and 12.0 mm, respectively. Their therapeutic action on the skin lesions amounted to 150 per cent, 110 per cent, 110 per cent, 100 per cent, and 100 per cent, respectively, for the various qualities used. As a rule, the authors applied 100 r three times at ten-day intervals. It is also sometimes possible to remove the lesion in one sitting by from 300 to 400 r of a radiation with 0.5 mm Al H.V.L. If 600 r were applied, the lesions healed temporarily but recurred soon again.

From these observations the authors conclude that the longer wave length radiation is preferable. It would be possible to give 100 r two or three times at ten-day intervals over the scalp without producing epilation, provided a radiation with the H.V.L. in Al of 0.3 mm was used. If a higher H.V.L. was chosen, epilation often occurred. It must be remembered, however, that the soft radiation cannot be measured well with the Sabouraud-Noire pastille. It is necessary to correct for penetration. According to their experience, one Sabouraud-Noire dose corresponds to 550 r for a half value layer in Al of 0.28 mm., to 443 r for a half value layer in Al of 0.35 mm., to 317 r for 1 mm H.V.L., to 248 r for 1.5 mm H.V.L., to 293 r for 2.5 mm H.V.L., and 224 r for 3.4 mm. H.V.L.

ERNST A. POHLE, M.D., Ph.D.

THE SKULL (DIAGNOSIS)

Our Experience in Encephalography in Some Diseases of the Nervous System of the Child Piero Sighinolfi and Carolina Viola La Radiologia Medica, December, 1930, XVII, 1432-1456

The authors have performed encephalography on ten young patients for purely diagnostic purposes using Biengel's method. Although the cases selected were in extremely serious conditions, no operative mortality followed, nausea and vomiting were the only consequences observed.

The diagnostic points observed were undoubtedly precise, but the authors, nevertheless, think that encephalography is to be resorted to only in very special cases, because very little is to be gained, as far as curative treatment is concerned, by knowing exactly the position of a cerebral tumor.

They believe that pre-operative roentgenotherapy is advisable in conjunction with Biengel's method, because it will prevent sudden increases in liquid pressure.

L. MARINELLI

A Special Technic in X-ray Stereoscopy DeWitt R Austin South Med and Surg, October, 1931, XCIII, 755

The technic described is for use with the Bucky diaphragm at a distance of twenty-seven inches, and consists in shifting just half the usual distance with the tube. This furnishes a geometric correction for the increased distance between object and film, when using the Bucky grid. It is especially useful in securing stereoscopic films of the head.

W W WATKINS, M.D.

Arterial Encephalography Egas Moniz Bruxelles-Méd., Nov 1, 1931, XII, 22, 23

By the method of producing opacity of the arterial cerebral plexuses, the author has been able to localize tumors which clinical symptoms have failed to reveal.

Patients are prepared on the night preceding the operation, or on the morning of the operation, by luminal, with a view to avoid or diminish the epileptic symptoms which usually follow the injection, either of the internal carotid or of the common carotid. The vessel is exposed, if the common carotid is selected, the external carotid is temporarily obliterated with a Martins forceps in order that the opaque liquid may pass exclusively through the internal carotid.

The patient is placed under the X-ray tube, and is injected with from 5 to 6 c.c. of a solution of chemically pure sodium iodide, 22 or 23 per cent. A Martins forceps clamps the artery below the needle so as to momentarily block the circulation, although this precaution is not essential to allow the visibility of the cerebral arteries.

The one contra-indication is advanced arteriosclerosis, however, if the sodium iodide is chemically pure, complications are very rare.

The encephalographic test demonstrates the visibility of the internal carotid, especially its cavernous portion and the ophthalmic, anterior choroid, the sylvian group, and sometimes the anterior cerebral and its subdivisions.

The localization of certain very vascular tumors is detected by the visibility of their circulations. Their arteriographic aspects are different. Paucity of vascularity is found in cysts and cholesteatomas.

quite the contrary being found in meningoblastomas and other highly vascularized tumors

Arterial displacements facilitate the diagnosis of tumors of the frontal, parietal, and temporal lobes and, among others, of the regions of the chiasma and ponto-cerebellar angle.

HENRY BAXON, M D

Skull and Brain Traumas Their Sequelæ. Mark Albert Glaser and Frederick P Shafer Jour Am Med. Assn, Jan 23, 1932, XCVIII, 271-276

Two hundred and fifty-five cases were followed, one as long as five years after the accident. The series was subdivided into groups, depending on the presence and location of fracture the diagnosis of which was determined by roentgenography. Rupture of the ear membrane, with resulting hemorrhage or a distended bluish membrane, occurs with sufficient frequency to be utilized as a practical criterion of fracture through the petrous portion of the temporal bone. Mental disturbances and convulsive states were the only changes that manifested themselves at a period later than three months after injury.

In patients suffering from depressed fractures symptoms are less likely to develop than in those without fracture. Combined fractures of the base and vault are the most serious. The younger the patient, the less likely it is that symptoms or signs will develop. Headache was the most frequent complaint and developed more often in cases without skull fracture. Headaches persisting over one and a half years usually were permanent. Dizziness occurred more frequently in fractures of the base. Very little opportunity for recovery was evident when it persisted over one and a half years. Results of trauma affecting various nerves are reviewed. Positive neurologic signs occurred in 32.5 per cent while 80 per cent presented subjective complaints.

C G SUTHERLAND, M D

THE SPINE (DIAGNOSIS)

Absence of the Cervical Spine Klippel-Feil Syndrome George I Brumman Jour Am Med Assn, Jan 9, 1932, XCVIII, 129-132

Anomalies in the cervical spine are uncommon and especially rare are those described under the obscure term of the Klippel-Feil syndrome. This consists of a numerical variation in the cervical vertebrae accompanied in some cases by spina bifida or other anomalies. About thirty such cases have been reported, mostly in the French literature, three cases have been reported in America and one in England.

Five cases are reported and reviewed. Inability to dissociate the movements of the two hands, a phenomenon designated as mirror movements, was seen in four. The changes are all intra-uterine. A developmental anomaly primary in the nervous system, with an accompanying or resulting bone anomaly, may be assumed in a large percentage of cases. No treatment is of any benefit. Operations or active treatment should be avoided by a correct diagnosis.

C G SUTHERLAND, M D

Typhoid Spine. L K Wang and Leo J Miltner Chinese Med. Jour, January, 1932, XLVI, 1-11

The name "Typhoid Spine" was given by Gibney, in 1889, to a condition of the spine occurring in the wake of typhoid fever and characterized by pain and tenderness of a part of the vertebral column. Bone marrow in common with lymphoid structures offers a favorable location for the growth and multiplication of typhoid bacilli. After the general infection has subsided, the bacilli may be destroyed by the protective agents present, or may remain quiescent for a time, later becoming active. Muscle strain, trauma, fatigue, and exposure are considered as possible etiologic agents.

The three types of typhoid spine recognized pathologically are as follows: (1) Diffuse periostitis and perispondylitis with roentgenologic appearance similar to osteo-arthritis, (2) the localized or common type, with early destruction of the intervertebral disc. In this type healing occurs promptly, and (3) extensive destruction, as in osteomyelitis, with pronounced gibbus formation. Roentgenograms show at first marked bone destruction, and later filling out of the destroyed areas with marked osteogenesis between the vertebral bodies. The intra-articular facets, pedicles, transverse processes, and laminæ are not involved in any of these types except late in the healing stage, at which time these structures may show evidence of osteo-arthritis.

The onset may be insidious or sudden, with rise in temperature and severe pain in the affected region. Local tenderness and rigidity are nearly always present. Various sensory disturbances in regions supplied by the nerves of the affected levels have been described. The blood count is considered of no value in the diagnosis.

Tuberculosis of the spine, osteomyelitis of the spine, and low back pain of arthritic nature must be considered in the differential diagnosis of typhoid spine. At the onset of clinical symptoms of sufficient importance to demand attention in tuberculosis of the spine, the X-ray usually reveals the existence of an extensive lesion, whereas in typhoid spondylitis an early X-ray examination shows either no change or slight destruction of the intervertebral disc. If the history of typhoid fever is indefinite

and the X-ray suggests the possibility of either condition, the Widal test aids in the diagnosis. In typhoid spine, as a rule, there is definite roentgenographic evidence of bony condensation and ankylosis of the involved vertebrae within three or four months' time, whereas in tuberculosis of the spine similar evidences of healing, if present, occur usually from two to ten years after the onset. The presence of a spinal abscess is strongly in favor of tuberculosis. In acute osteomyelitis of the spine the local phenomena are intense and the leukocyte count is, as a rule, very high. Low back pain of arthritic nature may be eliminated by the history of onset, the absence of a history of typhoid fever, and the absence of changes demonstrable by the X-ray.

The prognosis in this condition is almost always favorable and with proper treatment very little deformity results. The treatment consists of proper immobilization of the spine during the acute stage, typhoid vaccine, foreign protein therapy, colonic irrigations, and complete rest in bed until all pain has passed and the roentgenograms show evidence of healing of the affected vertebrae.

The authors report two cases of typhoid spine, one of which also presented a sacro-iliac arthritis of similar etiology.

I. N. AVÉ, MD

Scoliosis Etiology, Pathogenesis, and Prevention of Experimental Rotary Lateral Curvature of the Spine. Eben J. Carey. Jour. Am. Med. Assn., Jan. 9, 1932, XCVIII, 104-110.

Scoliosis is now definitely known as rotary lateral curvature of the spine. It is a spinal sign of the muscle-bone imbalance of the back, and not a specific disease entity. The kind and degree of scoliosis are dependent on the extent of imbalance caused by the possible multiple combinations and permutations of the paralyzed muscles of the body as a whole.

The problem of scoliosis is one of prevention of all conditions that upset the normal balance of muscle and bone during growth, such as chronic inanition and malnutrition and the various types of chronic disease which lead to undernourishment of the growing child.

C. G. SUTHERLAND, MD

An Hemangioma of a Vertebra, Demonstrated Roentgenographically. A Reisner Rontgenpraxis, Oct 1, 1931, III, 900-903.

Hemangiomas of a vertebra are not rare in autopsy material (from 10 to 12 per cent). Clinically they occasion symptoms only when they cause pressure on the spinal cord. The roentgen appearance

of a vertebral hemangioma is typical, if one consults the literature. The bony portion of the vertebra (usually a lower thoracic or upper lumbar) only is attacked, the discs are intact, the normal bone structure is changed into dense, calcified strands, which run mainly in a vertical direction and enclose areas where calcium is absent. A case is described which showed all these signs in the tenth dorsal vertebra.

H. W. HEFKE, MD

Evaluation of the Different Symptoms in Diagnosis of Conditions of the Vertebrae. Hans Hellner. München med Wochenschr., Sept. 4, 1931, LXXVIII, 1511-1515.

In the diagnosis of injuries and diseases of the spine, the roentgen findings are usually of more value than the clinical examination alone. The X-ray gives more detail as to conditions of the body of the vertebra, the inter-vertebral disc, the degree of bone destruction, and of accompanying spondylitis or synostosis. Fractures occur most frequently in the twelfth dorsal and first lumbar vertebra. Regarding the type of fracture, the compression leaving a wedge-shaped body is the most common. With increasing force of the impact, the vertebra receives the shape of a disc, with the anterior portion of the body protruding in front of the spine, and even breaking off in a triangular shape. Luxation plus fracture is due to a tearing off of the lateral portion of the vertebra. Tuberculosis also has its place of predilection. Bergmann found, in 342 cases, the twelfth dorsal in 24.6 per cent, the eleventh dorsal in 20.5 per cent and the first lumbar in 18.7 per cent of the cases involved. The majority of cases has more than one involved. The inter-vertebral disc is usually affected. A gibbus, with angulation of the spine occurs early. Roentgenologically, the disc is not narrowed in fractures. Only in very severe cases of compression do we find a narrowing, but in tuberculosis one frequently finds a moth-eaten defect. This can be used for differential diagnosis between a healed fracture and a tuberculous process. Even if a fracture has resulted only in an injury to the disc and has injured the anterior part of it, with bridge formation, the rest of the disc is smooth—a condition which can never be seen in tuberculosis although there are many ways to determine tuberculosis by the X-rays.

In some cases a healed fracture cannot be distinguished from a case of healed spondylitis (Kohler). The changes produced by typhoid, paratyphoid, gripppe, or pneumococcal spondylitis are similar to those of tuberculosis and can be recognized only by considering also the clinical side of the case. Acute purulent osteomyelitis is characterized by the

acute septic condition of the patient and also by the almost ever-present purulent spinal meningitis. On the X-ray one finds destruction frequently in the arc of the vertebrae. In malignancy the metastasis may produce changes similar to those one sees in tuberculosis, but usually the formation of a gibbus is late. If the lesion is in the spongiosa it must be larger than the size of a pea in order to be recognized on the film. The differential diagnosis between carcinoma and myeloma is very difficult. Besides these osteoclastic types of lesions, the osteoplastic carcinoma and Paget's disease must be mentioned.

E A MAY M.D.

A Case of Congenital Dorsal Scoliosis Associated with Bilateral Traumatic Paralysis of the Klumpke Type Giulio Faldini L'Ateneo Parmense (Suppl.), 1931, III, 108-116

The radiographic examination showed a scoliosis of the right dorsal spine, with a steep curve, due to the subsequent malformations.

Interpretation of the case is difficult, owing to the fact that factors of various nature are encountered in a limited anatomic space, which must be evaluated in conjunction with each other in order that a clinically logical explanation of the syndrome may be reached. The paralysis was marked by characteristic atrophy, but without sensitive phenomena. The author concludes that the pathogenesis of the paralysis is not to be sought in the congenital deformity but that this must be regarded as merely a slight and occasional concomitant factor.

W W WHITELOCK Ph.D.

Calcification of the Nucleus Pulposus of the Intervertebral Disc. Renato de Bernardi Archivio di Radiologia, May-June, 1931, VII 537-556

The author thinks that this lesion is part of a morbid process which involves the whole intervertebral disc and is not a lesion *per se*. This process is of an inflammatory nature, due to some generalized infection which may manifest itself in the advanced stages, either as spondylitis deformans or as spondylitis of Bechterew's type.

E T EDDY M.D.

An Erroneous Diagnosis of Fracture and Dislocation of the Second Cervical Vertebra Emil Kleinhaus Röntgenpraxis, Sept 15, 1931 III 836-839

A diagnosis of fracture of the dens of the second cervical vertebra with anterior dislocation had been made in a patient, who suffered an injury to the head. The anteroposterior film through the open

mouth showed no pathologic changes. On the lateral view the second vertebra seemed to be definitely dislocated anteriorly. This, however, can be explained by a wrong technic. The head and the first cervical vertebra were in a straight lateral position, while the rest of the cervical spine was rotated only 45 degrees. The same appearance could be duplicated in a normal person. The head and the cervical spine must necessarily be projected on the film from the same angle, in order to avoid diagnostic mistakes as the one described above.

H W HEPKE, M.D.

Sacralization R Hirsch Fortschr a d Geb d Röntgenstr , August, 1931, XLIV, 215-226

True sacralization, that is, synostosis of the fifth lumbar and first sacral segments, was not found in 1,000 lower spines studied during five years. Pseudo-sacralization, that is, uni- or bilateral articulation between the transverse processes of the fifth lumbar vertebra and the sacrum, was found in 13 per cent of these cases. In 24 per cent, the transverse processes of the fifth lumbar vertebra were smaller than those of the fourth, and also 24 per cent of lumbarizations or sacralizations were found.

It is demonstrated from case histories that the symptomatology attributed so often to sacralization, enlargement of the fifth lumbar transverse processes, etc., is even more frequently encountered in especially small fifth lumbar transverse processes. The disease entity postulated for sacralization, therefore, must be denied, and radical surgical procedures as advocated and practised, especially in France, are to be replaced by conservative methods.

HANS V JARRE, M.D.

SYPHILIS

Gastric Syphilis K. J Yeo British Jour Radiol, October, 1931, IV, 510-512

Serial roentgenologic observations were made of a married woman, 21 years of age, who for six months had suffered from gnawing epigastric pain, worse immediately after eating, of rather continuous character, associated with a considerable weight loss. On first roentgenologic examination nothing other than a mild hour-glass type of spasm in the pyloric region was noted. Weight loss continued. A year later a second X-ray observation was made, at which time extreme narrowing, with some shortening of the lower part of the stomach, was observed. The affected area was 5 centimeters long, the diameter of the lumen varying from less than 1 to less than 3 centimeters. The narrowed part appeared rigid and showed no peristalsis. The pylorus was continuously open with resultant rapid emptying. Wassermann

and the X-ray suggests the possibility of either condition, the Widal test aids in the diagnosis. In typhoid spine, as a rule, there is definite roentgenographic evidence of bony condensation and ankylosis of the involved vertebrae within three or four months' time, whereas in tuberculosis of the spine similar evidences of healing, if present, occur usually from two to ten years after the onset. The presence of a spinal abscess is strongly in favor of tuberculosis. In acute osteomyelitis of the spine the local phenomena are intense and the leukocyte count is, as a rule, very high. Low back pain of arthritic nature may be eliminated by the history of onset, the absence of a history of typhoid fever, and the absence of changes demonstrable by the X-ray.

The prognosis in this condition is almost always favorable and with proper treatment very little deformity results. The treatment consists of proper immobilization of the spine during the acute stage, typhoid vaccine, foreign protein therapy, colonic irrigations, and complete rest in bed until all pain has passed and the roentgenograms show evidence of healing of the affected vertebrae.

The authors report two cases of typhoid spine, one of which also presented a sacro-iliac arthritis of similar etiology.

In some cases a healed fracture cannot be distinguished from a case of healed spondylitis (Köhler). The changes produced by typhoid, paratyphoid, grippe, or pneumococcal spondylitis are similar to those of tuberculosis and can be recognized only by considering also the clinical side of the case. Acute purulent osteomyelitis is characterized by the

points from a single case report. He believes that in most cases the diagnosis of thymoma can be made with considerable certainty from the clinical findings alone, while in some this may be impossible, even on necropsy and histologic examination.

At necropsy on a woman, who had shown all the clinical signs of severe myasthenia, the anterior mediastinum was found to contain a hard tumor corresponding histologically to Schmincke's lympho-epithelial tumor. Apparently it was benign, no metastases being found. Histologic examination of the musculature of the diaphragm, tongue, throat, esophagus, and abdominal wall showed degenerative changes in the muscles themselves, reactive and chronic inflammatory changes in the perimuscular and perivascular connective tissue, and, in places, dense round-cell infiltration (Buzzard's lymphorrhagia). Possibly these changes were due to a toxic agent produced by the thymus.

F CAVERS, D.Sc.

THE THYROID (THERAPY)

Concerning the Question of the Treatment Method of Toxic Goiter E. Hayer Strahlentherapie, Oct 24, 1931, XLII, 414-424

The fundamental difference between surgical and radiologic treatment of toxic goiter is outlined. While the operation seeks to remove in one sitting as much of the thyroid tissue as can be safely done without producing myxedema, irradiation causes a slow regression of the functioning cells. It seems that from 40 to 60 r are sufficient to reduce the secretion. The author has grouped his seventy-six cases of irradiated thyrotoxicosis according to the basal metabolic rate.

The first group consists of cases with +70 or more, the second group with from +40 to 70, and the last group +40 or less. In the first group there were twenty-four patients, nine of whom were cured, nine considerably improved, four not improved, and two died. The respective figures for thirty-five cases belonging to the second group are eleven, twenty, three, and one, and for the third group of seventeen cases they are four, eight, four, and one.

An analysis of the statistics shows that the most severe cases responded well, while those of simple hyperfunction received the least benefit from irradiation. It is necessary to select the proper cases for radiation therapy, for instance, large nodular struma should be treated surgically. Very often there are other glands of internal secretion involved. In such cases the author has seen good results from an additional exposure of the hypophysis. He concludes that at present no final decision can be made as to the efficacy of X-ray therapy in toxic goiter.

ERNEST A. POMIE M.D. Ph.D.

Concerning the Radiation Treatment of Thyrotoxicosis Robert Gantenberg Strahlentherapie Oct. 24, 1931, XLII, 401-413

The author first discusses the literature concerning radiation therapy of Basedow's disease and then presents a tabulation of the statistics published so far. In his own clinic he observed ninety-three cases which were subjected to radiation therapy. Fields of 6 X 8, 8 X 10, and 10 X 10 sq cm were used at 30 cm FSD, 180 K.V., 3 ma, 0.5 Cu + 1 Al. The left and right lobe of the thyroid received from 20 to 30 per cent H.E.D., very often from 10 to 20 per cent were applied as a single dose in acute and severe cases. The thymus area was exposed with 30 per cent H.E.D. Intervals of from two to three days were observed between the exposures. The total dose of an entire series amounted to from 70 to 90 per cent H.E.D. Then followed an interval of from four to eight weeks before another series was started. The effect of the radiation was controlled by basal metabolic rate determinations, if it had dropped to from 20 to 25 per cent, treatment was usually discontinued.

The author differentiates the true Basedow's disease with all the classical symptoms from the so-called "hyperthyroid complex," in which the signs are hyperfunction with struma but without exophthalmos. The rôle of the basal metabolic rate in determining the improvement is analyzed in detail. It is also important to follow the subjective symptoms as, for instance, excessive perspiration, tachycardia, tremor, and gastro-intestinal disturbances. The end-results are compiled in a table where cases are divided into those of true Basedow's disease and hyperthyroidism. In each group the patients are arranged according to the severity of symptoms. There were sixty-four cases of Basedow's disease, thirty severe, twenty-two moderately severe, and twelve beginning cases. Of the first group, six were cured, seven considerably improved, eleven temporarily improved, and six did not respond. The respective figures for the second group were four, eight, eight, and two, and for the third group, four, two, three, and three. There were twenty-nine cases with hyperthyroidism. Five of these were severe cases, none of those was cured, two were considerably improved, two temporarily improved, one remained unchanged. Of the remaining twenty-four moderate and early cases, nine were cured, three considerably improved, nine temporarily improved, and three remained unchanged.

In conclusion, the author states that about 50 per cent of the cases with hyperfunction were cured or considerably improved, while 20 per cent of the patients with true Basedow's disease were completely cured. He feels that radiation therapy in toxic goiter may be given a trial unless there are definite indications for immediate operation. Cases which do not show any improvement after three or four

and Kahn tests were strongly positive, a fractional gastric analysis showed complete achlorhydria.

Under anti-syphilitic treatment the symptoms rapidly disappeared and the normal weight was quickly regained X-ray studies during treatment and after completion of it showed slight but definite changes in the form of a widening of the affected portion of the gastric lumen

J E HABBE, M D

Considerations on Two Hundred Cases of Congenital Syphilis T Valledor Boletin de la Sociedad Cubana de Pediatría, June, 1931, III, 221-230

The author introduces here a good outline on the subject. He states that specific osteochondritis and periostitis occur in about 5 per cent of the cases, as shown by X-rays of this series. According to him, the most common symptoms are splenomegaly, hepatomegaly, mucopurulent corvza, cutaneous syphilitides, painful insomnia, testicular tumefaction, digestive disturbances, *et cetera*

N G GONZALEZ, M D

The Diagnosis of Syphilitic Aortic Insufficiency and Its Difficulties According to Statistics of Eighty-four Cases of Solitary Aortic Insufficiency of Adults, with Autopsy (Radioscopic Examination, Pt XIV, 573-577) L Gallavardin and L Gravier Jour Med de Lyon, Oct 5, 1931, XII, 567-583

The authors enter into an exhaustive and impartial discussion of the results obtained by radioscopic examination of the aorta during the course of aortic insufficiency, a subject fraught with difficulties. They point out that although in some cases the evidence of syphilitic aortitis is well demonstrated, it may, in others, be entirely absent, aortic insufficiency in itself being capable of imprinting on the aorta important changes which may in no way be associated with syphilis. The subject is divided into the following:

(a) Aortic insufficiencies with radiologic findings, diagnostic of syphilitic aortitis, such as a sacciform aneurysm of the aortic arch, or those cases of large dilations of the vessel reaching or even exceeding 5 centimeters. Such dilations cannot be due to senile changes nor to atheroma, they are to be regarded as true stigmas of aortic syphilis.

(b) Syphilitic aortic insufficiencies without radiologic signs of syphilitic aortitis. These are numerous, especially in patients relatively young, from 45 to 50 years of age, in whom the aortic diameter is scarcely 2 or 3 mm in excess of the normal at that age.

(c) Endocardial aortic insufficiencies which, from the very existence of insufficiency, are accompanied

by important modifications of the aortic shadow. Even in young patients, the differential pressure rises as the aortic regurgitation and the left ventricular hypertrophy increase, causing the aorta to enlarge frequently from 2 to 4 mm beyond its normal diameter, according to the patient's age. It is more especially at ages over 55 years that radioscopy discloses frequent notable changes of the aortic shadow, these changes involving particularly the caliber and opacity of the aorta, however, the authors have never seen the aorta reach 5 centimeters.

(d) Radioscopy in aortic insufficiencies of doubtful etiology, whether syphilitic or endocardial. Here the authors discuss at length the diagnostic value of accentuation of the curves of the arch, the aortic caliber, and the exaggeration of aortic opacity, this last sign being considered by some as the most significant of syphilitic aortitis.

The authors conclude that radiology fails to yield all the assistance to the subject which could apparently have been expected by those who believe that alterations in the aortic walls are always indicative of syphilitic aortic insufficiencies. It has demonstrated that the same condition may be found, although less frequently, in endocardial aortic insufficiencies of older patients. But even though radioscopy often fails to solve the etiologic problem of a diastolic aortic murmur, its importance should not be underestimated. In a few cases, at least, it demonstrates the syphilitic nature of vascular specific aortitis. Besides, in a large percentage of cases, radioscopy furnishes useful information which, although not having in itself an absolute value, is of very material clinical assistance.

HENRY BAYON, M D

THE THYMUS (DIAGNOSIS)

Congenital Enlargement of the Thymus Gland Report of Case Henry E Stafford Arch Pediatrics, June, 1931, XLVIII, 386-389

A case is reported of a newborn infant whose chief symptoms were dyspnea, cyanosis, and mucus in the throat. Particularly on account of the improvement which followed radiation therapy, the author was quite convinced that he was dealing with an enlarged thymus.

E C VOGT, M D

Diagnosis and Treatment of Thymoma L F Craver Med Chn N America, September, 1930, XIV, 507-525 (Reprinted from "Cancer Review" by permission)

In this excellent paper the author limits his discussion to the clinical diagnosis and irradiation treatment of thymic tumors, and illustrates most of his

points from a single case report He believes that in most cases the diagnosis of thymoma can be made with considerable certainty from the clinical findings alone, while in some this may be impossible, even on necropsy and histologic examination

At necropsy on a woman, who had shown all the clinical signs of severe myasthenia, the anterior mediastinum was found to contain a hard tumor corresponding histologically to Schmincke's lympho-epithelial tumor Apparently it was benign, no metastases being found Histologic examination of the musculature of the diaphragm, tongue, throat, esophagus, and abdominal wall showed degenerative changes in the muscles themselves, reactive and chronic inflammatory changes in the perimuscular and perivascular connective tissue, and, in places, dense round-cell infiltration (Buzzard's lymphorrhagia) Possibly these changes were due to a toxic agent produced by the thymus

F CAVERS, D Sc

THE THYROID (THERAPY)

Concerning the Question of the Treatment Method of Toxic Goiter E Hayer Strahlentherapie, Oct 24, 1931, XLII, 414-424

The fundamental difference between surgical and radiologic treatment of toxic goiter is outlined While the operation seeks to remove in one sitting as much of the thyroid tissue as can be safely done without producing myxedema, irradiation causes a slow regression of the functioning cells It seems that from 40 to 60 r are sufficient to reduce the secretion The author has grouped his seventy-six cases of irradiated thyrotoxicosis according to the basal metabolic rate.

The first group consists of cases with +70 or more, the second group with from +40 to 70, and the last group +40 or less In the first group there were twenty-four patients, nine of whom were cured, nine considerably improved, four not improved, and two died The respective figures for thirty-five cases belonging to the second group are eleven, twenty, three, and one, and for the third group of seventeen cases they are four, eight, four, and one

An analysis of the statistics shows that the most severe cases responded well, while those of simple hyperfunction received the least benefit from irradiation It is necessary to select the proper cases for radiation therapy, for instance, large nodular struma should be treated surgically Very often there are other glands of internal secretion involved In such cases the author has seen good results from an additional exposure of the hypophysis He concludes that at present no final decision can be made as to the efficacy of X-ray therapy in toxic goiter

ERNST A PONILE M D Ph D

Concerning the Radiation Treatment of Thyrotoxicosis Robert Gantenberg Strahlentherapie Oct 24, 1931, XLII, 401-413

The author first discusses the literature concerning radiation therapy of Basedow's disease and then presents a tabulation of the statistics published so far In his own clinic he observed ninety-three cases which were subjected to radiation therapy Fields of 6×8 , 8×10 , and 10×10 sq cm were used at 30 cm FSD, 180 K.V, 3 ma, 05 Cu + 1 Al The left and right lobe of the thyroid received from 20 to 30 per cent HED, very often from 10 to 20 per cent were applied as a single dose in acute and severe cases The thymus area was exposed with 30 per cent HED Intervals of from two to three days were observed between the exposures The total dose of an entire series amounted to from 70 to 90 per cent HED Then followed an interval of from four to eight weeks before another series was started The effect of the radiation was controlled by basal metabolic rate determinations, if it had dropped to from 20 to 25 per cent, treatment was usually discontinued

The author differentiates the true Basedow's disease with all the classical symptoms from the so-called "hyperthyroid complex," in which the signs are hyperfunction with struma but without exophthalmos The rôle of the basal metabolic rate in determining the improvement is analyzed in detail It is also important to follow the subjective symptoms as, for instance, excessive perspiration, tachycardia, tremor, and gastro-intestinal disturbances The end-results are compiled in a table where cases are divided into those of true Basedow's disease and hyperthyroidism In each group the patients are arranged according to the severity of symptoms There were sixty-four cases of Basedow's disease, thirty severe, twenty-two moderately severe, and twelve beginning cases Of the first group, six were cured, seven considerably improved, eleven temporarily improved, and six did not respond The respective figures for the second group were four, eight, eight, and two, and for the third group, four, two, three, and three There were twenty-nine cases with hyperthyroidism Five of these were severe cases, none of those was cured, two were considerably improved, two temporarily improved, one remained unchanged Of the remaining twenty-four moderate and early cases, nine were cured, three considerably improved, nine temporarily improved, and three remained unchanged

In conclusion, the author states that about 50 per cent of the cases with hyperfunction were cured or considerably improved, while 20 per cent of the patients with true Basedow's disease were completely cured He feels that radiation therapy in toxic goiter may be given a trial unless there are definite indications for immediate operation Cases which do not show any improvement after three or four

(but not exceeding six) months should be operated on. The same holds true of patients with acute symptoms. In the remaining cases of toxic goiter, radiation therapy combined with medical treatment is the method of choice.

ERNST A. POHLE, M.D., Ph.D.

THE TONSILS

Tonsillectomy Following Irradiation in Lymphosarcoma of the Tonsils A Successful Case without Recidivation for Six Years D G W Van Voorthuysen Geneeskundig Tijdschr voor Nederlandsch-Indie, Dec 1, 1931, LXXI, 1425-1427

Malignant tumors of the tonsils show, according to their nature, varying prognoses. Lymphosarcomas seem to offer the greatest hope, as they are very responsive to irradiation, and at times disappear with astonishing rapidity, although recidivation after a longer or shorter period generally serves to destroy the early satisfaction in the apparent recovery. With the improvement in roentgen technique and the employment of radium better results have undoubtedly been obtained, although recidivation is still very frequent.

The author reports a case of lymphosarcoma of the tonsils, in which biopsy was indecisive, with regional metastases of the lymphatic glands of the lower jaw and neck, as shown by extirpation. The sarcoma finally disappeared, following roentgen irradiation. There was speedy recidivation, but the sarcoma again disappeared following renewed irradiation, and after tonsillectomy failed to reappear. There was no further recidivation for six years, down to the time of the patient's death, which was from other causes.

W. W. WHITELOCK, Ph.D.

TUBERCULOSIS (DIAGNOSIS)

Diagnosis and Treatment of Tuberculosis of the Small and Large Intestine Lawrason Brown and Homer L. Sampson Jour Am Med Assn, Jan. 2, 1932, XCVIII, 26, 27

Intestinal tuberculosis may be primary or secondary, the former being largely of surgical interest, while the latter is almost always associated with pulmonary tuberculosis and constitutes its most frequent amplification. Of 1,801 consecutive patients at the Trudeau Sanatorium, 8 per cent had definite intestinal tuberculosis.

The roentgen method of diagnosis reveals only the presence of intestinal ulceration, but, when associated with pulmonary tuberculosis, especially if the pulmonary disease is at all advanced, it is safe to

make a diagnosis of intestinal tuberculosis. Roentgen technic may not reveal the whole extent of the involvement.

Suggestive symptoms of beginning intestinal tuberculosis include, among others, any digestive disturbances, marked constipation, failure of the pulmonary condition to improve, an irregular temperature with subnormal fluctuations, possibly a decrease of pulmonary symptoms (while the patient is no better), alternating diarrhea and constipation, and marked nervousness.

Symptoms are often absent and abdominal and proctoscopic examinations are often negative. One must, therefore, turn to a study of the barium meal at the seventh, eighth, ninth, and tenth hours, and again at the twenty-fourth hour. The barium enema usually confirms the fact that the ulcerated cecum or other portions of the colon may fail to receive or to retain the barium.

C. G. SUTHERLAND, M.D.

The Diagnosis of Co-existing Emphysema and Pulmonary Tuberculosis W. C. Nalty Med Bull Veterans' Administration, January, 1932, VIII, 50-52.

Emphysema, a dilatation of the alveoli of the lungs, characterized by a change in the shape of the chest and by changes in the breath sounds, may be the result of whooping cough, asthma, bronchitis, or tuberculosis. It is considered difficult to attempt the diagnosis of tuberculosis upon the history and physical examination alone in a patient having emphysema, either with or without a co-existing asthma or bronchitis, because the findings of the latter conditions overshadow the usual findings of pulmonary tuberculosis.

The history of cough and expectoration is of little value, as these symptoms are common to tuberculosis, asthma, and bronchitis. On inspection an emphysematous chest may be mistaken for an exceedingly well-developed chest. Palpation may reveal negative findings, and, on percussion, a hyperresonance, rather than the usual dullness, may be elicited. On auscultation the usual breath sound changes of emphysema overshadow the findings of tuberculosis. The associated bronchitis or asthma may likewise hide the usual signs of pulmonary tuberculosis. A sputum positive for tubercle bacilli will prove the association of tuberculosis and asthma. However, pulmonary tuberculosis should not be eliminated because a negative sputum is obtained. The author is of the opinion that in many of these cases X-ray examination is usually the only means of establishing a diagnosis of pulmonary tuberculosis. In those cases in which the diagnosis has been made by other means, X-ray examination offers the only method of establishing the amount

of lung tissue involved. The author reports several cases of emphysema associated with tuberculosis, which illustrate the difficulty of the differential diagnosis of these conditions.

J N ANE, MD

The Epitheloid-cellular Type of Lung Tuberculosis (Sarcoid) Held Röntgenpraxis, Oct 15, 1931, III, 927-932

The author describes three typical cases of tuberculosis of the lungs which correspond to the so-called sarcoid. Their appearance is much like the disseminated type of Hodgkin's disease of the lungs. All of them began with an erythema nodosum. Histologic examination in one case confirmed the diagnosis of tuberculosis. Tubercl bacilli could not be demonstrated in the sputum. The spread of the infection probably takes place by way of the blood stream from diseased hilum glands. Enlargement of the hilum glands seems to be a more or less constant finding in roentgenograms of patients with this disease. Why it does not lead to an acute miliary tuberculosis can be explained only by the immune state of the patient. The localization of the foci in the interstitial tissue of the lungs is probably explainable by this positive anergy.

H W HEFKE, MD

Tuberculosis of the Jejunum Franklin W White and I R Jankelson Jour Am Med Assn, Jan 2, 1932, XCVIII, 23-26

At autopsy there are signs of tuberculosis of the bowels in approximately 50 per cent of those who die of pulmonary tuberculosis. Intestinal involvement may occur at any stage of the pulmonary infection, being more common in the advanced and active cases. Multiple lesions are the rule, the most common location being the lower ileum and ileo-cecal region. The jejunum is frequently involved in the terminal stage of an extensive tuberculosis of the bowels. It is rare to find isolated tuberculosis of the jejunum without tuberculosis elsewhere in the bowel. Symptoms of intestinal tuberculosis may be absent or very vague. The present-day roentgen technic does not readily visualize the jejunum. Tuberculosis of the jejunum is one of the most frequent causes of jejunal stenosis.

Two cases are reviewed and discussion of the pathology, symptoms, and diagnosis follows. The technic of the roentgen examination includes the "scout" film, valuable only when the bowel is distended above the lesion, and frequent observations in the first six hours after the barium meal, since evidence of partial obstruction is apt to be transitory.

C G SUTHFRLAND, MD

Roentgenologic Diagnosis of Pulmonary Tuberculosis Walter R Wynne Med Bull Veterans' Administration, December, 1931, VII, 1153-1159

The author discusses the important factors in the roentgenologic diagnosis of pulmonary tuberculosis. Proper technic, with attention to all details, is considered of the utmost importance. A competent roentgenologist should supervise all roentgenographic examinations in the department and this should never be left to the judgment of the technician.

Contrast, detail, and density, in proper relation, are necessary to make a good roentgenogram, and when any one of these is left out, there results a film that should not be interpreted. Contrast is controlled chiefly by the amount of X-ray energy applied to the films, and detail by the size of the focal spot of the tube and also by the film focal spot distance. The author believes that stereorontgenograms, made with the patient standing, offer more valuable assistance in the routine case than those taken in other positions. The author also emphasizes the importance of a careful dark room technic.

In the interpretation of chest films the stereorontgenograms should be studied only in the position in which they were taken. The quality of the films should always be noted, and if found unsatisfactory the examination should be repeated. The size and shape of the chest should next be studied. The position of the trachea, and the size, shape, and position of the blood vessels and heart should then be observed. Special notes are made of normal or abnormal markings of each dome of the diaphragm and of both costophrenic angles.

In studying the lungs the trachea should be traced down to the carina, and the hilum observed for abnormalities. The trunk markings should next receive the attention of the roentgenologist and each trunk should be followed from the hilum to the periphery. In localizing foreign bodies in the right lung it is well to remember that the pulmonary artery enters the lung below the trunks to the upper lobe and above those to the middle and lower lobes. In the normal lung the structures just under the pleural surface cannot be seen.

In pulmonary tuberculosis we see a fight staged for the establishment of the tubercle bacilli on the one hand and a defensive reaction on the other to repel the invasion. Once the exudation has started in a primary lobule, it immediately involves all the others making up one of the secondary lobules, but this reaction does not extend through the septa until ulceration takes place. In adult apical pulmonary tuberculosis there occurs an involvement of many secondary lobules near the pleural surface in the upper part of the lung. At this time, no other known pathologic conditions can produce such changes. A few other conditions, such as influenza and septic pneumonitis, may involve the secondary lobules in the upper portion of the lung and just

under the pleural surface, but in these other conditions the involvement is all in one stage and not in crops, as seen in tuberculosis. The puerile and basal involvement of pulmonary tuberculosis cannot always be distinguished from other diseases. Other pulmonary diseases, likewise, may produce enlargement and calcification of the glands and thus closely simulate the glandular form of pulmonary tuberculosis, this form, however, showing evidences of caseous changes as well as calcification.

Dunham believes that miliary tuberculosis is always the result of reinfection of an old focus. This form of pulmonary disease is believed to be the result of a lack or loss of immunity. Many cases of healed miliary tuberculosis are being found in X-ray laboratories with modern technic and interpretation. The appearance is that of a fine, sharp, discrete studding, more or less evenly distributed throughout all the lobes. In the more recent cases distribution is similar, but instead of studding, there is a fine mottling which has not reached the definitely calcareous stage.

J N AVÉ, MD

affirmatively to the above question, at least as regards cases not entirely obscure in etiology or rendered deceptive by a completely misleading aspect, both on the basis of a study of the literature and of a personal case in which the definite diagnosis of "primitive tuberculous splenomegaly" was later confirmed by anatomic investigation.

The present-day methods of investigations, although they have not overcome the inherent difficulties of diagnosis in the more obscure cases, show distinct advance over those of an earlier date and permit recognition of primitive tuberculous foci and signs of latent activity of the disease. In addition direct radiographic examination of the splenic tumor has been suggested for possible demonstration of calcified nodules attributable to the specific process. In this connection, however, the siderotic-calcareous nodules of the Gamma type must be borne in mind as a possible cause of the shadow. In any event, radiologic investigation serves as an adjuvant to disclose the connections of the organ with adjacent viscera, and also, naturally, the presence of other plastic and calcified masses.

W W WHITELOCK, PhD

The Present Conception of Pulmonary Tuberculosis W Jost. Schweiz med Wehuschr, Aug 22, 1931, LXI, 789-792

The author first questions which teaching one should believe the old, which conceives the typical involvement to be primary with gradual extension or the new, which conceives the origin to be acute affecting any portion of the lung, with extension in acute stages. The fact that the "früh-infiltrat" has comparatively, only recently achieved much attention, despite the fact that roentgenographic technic has changed little, argues for an increasing incidence of the acute type.

Since the acute "früh-infiltrat" is variable in location, gives few clinical signs, and may be found in an individual who appears to be healthy, X-ray examination is extremely important. It is far better to make too many radiographs than too few.

H C OCHSNER, MD

Forms of Pulmonary Tuberculosis in Early Infancy Edgar Filgueiras Archivos de Pediatría, Rio de Janeiro, January, 1931 Reprinted in Boletín de la Sociedad Cubana de Pediatría, June, 1931, III, 233-236

The purpose of this paper is to call the attention of physicians to the frequency of pulmonary tuberculosis in infancy and the necessity of an early diagnosis and proper treatment.

To the author, the most important symptoms are Failure to gain weight or loss of weight, restlessness, loss of appetite, afternoon fever, cough, and digestive disturbances. He states that the X-ray always either confirms or makes the diagnosis.

N G GONZALEZ, MD

Primitive Tuberculosis of the Spleen Pathogenetic and Clinical Notes Enrico Greppi Riv d Patol e Clin d Tuberc, Dec. 31, 1931, V, 1025-1036

Is diagnosis, or at least a diagnostic suspicion founded on a concrete basis, possible in the living subject in this obscure disease on which pathologic and clinical text-books have so little to say that is of a definite and helpful nature?

The author believes himself justified in replying

Silicosis and Pulmonary Tuberculosis J C Herrick Med Bull Veterans Administration, November, 1931, VII, 1063, 1064

It is generally believed that silica dust is the most injurious of all the various materials which produce pneumoconiosis. Particles of silica carried into the lung tissues dissolve slowly, react chemically upon the cells containing them, and cause cell death. The dead cells collect and block up the lymph chan-

nels and glands. The necrotic tissue so caused forms a lodging place in which the tubercle bacilli grow. In those cases uncomplicated by tuberculosis the final result is the formation of fibrous tissue, which in time replaces the normal alveolar structure of the lungs.

Of importance is the fact that, once the silica dust has gained access to the lungs, the silicotic process continues to advance, even after complete withdrawal from exposure. A tuberculous infection in a lung containing silica particles runs an unusually rapid and fatal course. Silicosis, uncomplicated by tuberculosis, may also terminate fatally.

The author reports two cases of miners, with sputa positive for tubercle bacilli, in which evidences of silicosis were found by clinical and roentgenologic examinations. Both cases terminated fatally after severe pulmonary hemorrhages. An autopsy was performed in one case.

J N ANÉ, MD

The Onset of Pulmonary Tuberculosis in the Adult Radiologic Part Luigi Turano *Il Giornale di Tisiologia*, Nov 30, 1931, X, 303-318

The author discusses the value of radiology in determining the existence of incipient pulmonary tuberculosis, but points out the necessity of constant collaboration of radiologist and clinician. Without anatomic-pathologic control, it is impossible to judge accurately as regards the significance of certain radiologic findings. With this reservation, he formulates the following conclusions:

Radiologic investigation, especially in the form of radiographs, is absolutely indispensable in determining the existence of incipient tuberculosis in the adult. Examinations should be made at varying intervals, always employing the same technic.

Even when the clinical examination is absolutely negative, radiologic investigation may reveal important alterations, such as Assmann's infiltration, which, although it may occur in any part of the lung, shows preference for the subclavical region. In no case, however, can it determine whether this infiltration is actually the primary tuberculous lesion in the adult, or merely represents a halting place of apical foci, whether visible or not by roentgen rays, this question can be settled only at autopsy. The radiologic discovery of the infiltration is highly important as regards the early start of treatment, because its presence generally indicates the establishment of a tuberculous process.

The diversity of the statistics regarding the infiltration of Assmann and apical tuberculosis is to be attributed not alone to the nature of the material used (from dispensary or sanatorium), but also mainly to the lack of a suitable standardized radiographic technic of the thorax. The following technic is, therefore, suggested. In addition to the radio-

scope, a previous radiograph or rapid exposure at the distance of 15 meter, during the pause after inspiration, then two radiographs of the apical region, one with the technical note of Albers-Schönberg and the other with inverted incidence of the caudal side.

Radiographic examination, even the most exact, if negative, cannot exclude the existence of an apical lesion.

The statement based on radiologic findings that tuberculosis of apical origin is always less virulent, in contrast to the conception that general phthisis originates in extra-apical regions, does not as yet appear to have been demonstrated. On the contrary, Aschoff's observation that every reinfection starts with the anatomic-pathologic characteristics of an early infiltration, in whatever part of the lung, deprives the discussion of all value. On the other hand, numerous radiologic findings in genuine progressive phthisis of apical origin seems to show that this hypothesis lacks a secure basis.

The discovery of old foci in the apex is equally important, as it has been fully demonstrated that from reactivating of the same there may result genuine phthisis. Not alone the reinfection of Puhl, but also the calcified foci of Simon must be regarded as old foci. The presence of a circumscribed or of a diffused shadow should always serve to direct attention to the various possible causes of error.

The hypothesis of reinfection in the adult, with ileal origin and ascending extension, first, toward the subclavical region and then into the apex, has been demonstrated neither by anatomic-pathologic means nor radiologically, and, according to the author, rests upon an error of interpretation.

The radiologic manifestations indicating the onset of pulmonary phthisis in the adult become less frequent according as they start more posteriorly.

W W WHITELOCK, PhD

Acute Miliary Pulmonary Tuberculosis W E Hamlin *Med Bull Veterans' Administration*, October, 1931, VII, 973, 974

The author reports the case of a male, 35 years of age, who was admitted with a diagnosis of moderately advanced chronic pulmonary tuberculosis. Roentgenologic examination showed evidence of an old healed tuberculous process at the left apex, but no evidence of active tuberculosis in either lung. Seven months later the patient was discharged as absent without leave. During his stay in the hospital he gained twenty-nine pounds.

One year subsequent to his desertion he was readmitted. He had lost thirty-three pounds during the one-year period and at the time of admission he appeared ill, with a yellowish tinge to the skin.

under the pleural surface, but in these other conditions the involvement is all in one stage and not in crops, as seen in tuberculosis. The puerile and basal involvement of pulmonary tuberculosis cannot always be distinguished from other diseases. Other pulmonary diseases, likewise, may produce enlargement and calcification of the glands and thus closely simulate the glandular form of pulmonary tuberculosis, this form, however, showing evidences of caseous changes as well as calcification.

Dunham believes that miliary tuberculosis is always the result of reinfection of an old focus. This form of pulmonary disease is believed to be the result of a lack or loss of immunity. Many cases of healed miliary tuberculosis are being found in X-ray laboratories with modern technic and interpretation. Forms of Pulmonary Tuberculosis in Early Infancy Edgar Filgueiras Archivos de Pediatría, Rio de Janeiro, January, 1931 Reprinted in Boletin de la Sociedad Cubana de Pediatría, June, 1931, III, 233-236

The purpose of this paper is to call the attention of physicians to the frequency of pulmonary tuberculosis in infancy and the necessity of an early diagnosis and proper treatment.

To the author, the most important symptoms are Failure to gain weight or loss of weight, restlessness, loss of appetite, afternoon fever, cough, and digestive disturbances. He states that the X-ray always either confirms or makes the diagnosis.

N G GONZALEZ MD

Silicosis and Pulmonary Tuberculosis J C Herrick Med Bull Veterans Administration Novem ber, 1931, VII, 1063, 1064

It is generally believed that silica dust is the most injurious of all the various materials which produce pneumonoconiosis. Particles of silica carried into the lung tissues dissolve slowly react chemically upon the cells containing them and cause cell death. The dead cells collect and block up the lymph chan-

tuberculosis in which the anatomic substratum of the connective elements is sufficiently extended and marked to constitute the predominant, if not the unique, factor of the clinical symptomatology and of the anatomic-pathologic picture of the type of pulmonary tuberculosis in question

It is indispensable for the diagnosis of this particular type of pulmonary tuberculosis to point out briefly the most important and most characteristic radiologic findings First in line must be mentioned alterations as regards shape of the skeleton, such as asymmetry, costal retractions, deviations of the vertebral column, even of very low grade, when the physico-semiology is but faintly apparent and radiologic examination proves a most valuable recourse.

The ordinary findings as regards the respiratory apparatus consist primarily of modifications in the normal transparency of the pulmonary fields in the form of more or less marked and extended opacity corresponding to the sclerotic zones In some cases it is impossible in the involved hemithorax to recognize the pulmonary outline save for brief moments At times the more or less dense shadows appear in linear form, running in the direction of the interlobular fissures There may be immobility and opacity of the costal diaphragmatic sinuses, upward stretching of the diaphragm, or pericardic-diaphragmatic adhesion, sometimes in the form of pinnae

The pulmonary field opposed to the sclerotic field may preserve its normal transparency, or even appear emphasized in cases of vicarious emphysema, or opaque zones due to pleuritic or parenchymatic processes of various types and extension may be observed

In addition to the ordinary radiologic picture pointed out above, there are certain indirect signs equally characteristic, which have been the object of special study by Italian authors (Pescatori, Casati, etc) Among these the following are worthy of special mention Deformity and displacement of the pulmonary hilus and of the interlobular fissures, the phenomenon of Rist and de Abreau, or the movement of hemithoracic balance, the phenomenon of Kienböck, the phenomenon of the mediastinal pendulum of Holzknecht and Jacobson, dislocation of the shadows of the heart and large vessels, and deviation of the images of the trachea and esophagus

As regards deformities and displacements of the pulmonary hilus and of the interlobular fissures, certain French authors speak of the elevation of the pulmonary hilus in cases of bilateral retraction of the lungs, when, on the other hand, the lesion is unilateral at the height of the corresponding hilus we have, in addition, loss of visibility of the latter through retraction of the mediastinum, whereas the hilus on the opposite side becomes free

The altered interlobular fissures may suffer im-

portant displacement by a kind of balance movement, so that they appear oblique from within outward and from below upward In roentgenograms in anterior-posterior as well as lateral projection, a peculiar fan-like arrangement of the pleural fissures may be observed, upwards or downwards according to the seat of the process of pulmonary retraction The displacements upward often cause the hilus shadow to rise to the height of the aortic arch, while in the downward displacements the hilus shadow often remains covered by that of the heart

There is stretching of the hilus also in cases of sclerosis and retraction of the interlobular pleura

The phenomenon described by Rist and de Abreau consists of the dissociation of the movements of the anterior and posterior region of the diaphragm or the hemithoracic balance movement determined by sclerosis partly localized in the anterior region of the lung This phenomenon may be observed by placing the patient in profile, when it is seen that the posterior half of the diaphragm falls normally during inspiration, while the anterior half rises slightly

In cases of displacement of the heart and large vessels toward the left, the right outline of the heart either does not appear at all, merges with the shadow of the vertebral bodies, or is found on the left among these bodies The study of the orientation of the heart and large vessels is made in a more exact manner by means of orthodiaphy in various projections, or, even better, by the method of plastic reconstruction of the heart as suggested by Palmieri In this manner, a rotation of the heart on its great axis may be stabilized, so that the point of the left ventricle is carried from the left toward the right and from the rear toward the front The aorta and the vena cava are displaced toward the right and rear, while the pulmonary cone approaches more closely to the anterior thoracic wall, moving toward the right

In one case of partial retraction observed by the author, the sclerotic process, limited to the right lobe, revealed under radiologic examination dense opacity of the upper portion of the pulmonary field, limited by the interlobular field The mediastinal shadow appeared displaced toward the right in its upper portion (trachea and great vessels), while the heart was in its normal place

Tuberculosis of the Tracheobronchial Glands Joseph C Savage, Calif and West Med, July, 1931, XXXV, 32-34

The proper diagnosis of tracheobronchial glands is of the greatest importance to the infected child, for hilum tuberculosis not adequately treated may

Blood examination revealed a marked anemia, bronchovesicular breathing and increased whispered voice above the second rib on the right was noted on physical examination Roentgen examination showed evidence of tuberculosis in both upper lobes

After one month of hospitalization the patient's temperature began to rise, and the pulse rate increased X-ray examination at this time revealed evidence of numerous small discrete shadows of miliary size and type throughout both lung fields The patient lived for three months after the diagnosis of acute miliary tuberculosis was made

J N ANÉ, MD

A Case of Generalized Tuberculosis of the Lymph Nodes Accompanied by Appendicitis and Cholecystitis
Enrico Dotti Riv di radiol e fisica med, December, 1931, IV, 200-205

A woman, 22 years of age, came to the hospital complaining of pain in the right abdomen X-ray examination showed cholecystitis, without stone, and appendicitis

Examination brought out the fact that the patient also had tuberculosis of the cervical, axillary, inguinal, thoracic, and abdominal nodes At operation the diagnosis of cholecystitis and appendicitis was confirmed. The nodes in the abdomen were enlarged and some were calcified, others being caseated. The patient made a good recovery and is clinically well

Another interesting point brought out by this case is that notwithstanding the enormous destruction of lymphopoietic tissue, the differential leukocyte count was normal

E T LEDDY, MD

The Subapical Form of Incipient Pulmonary Phthisis G F Bume National Med Jour China December, 1931, XVII, 687-700

In 1922, Assmann published his observations on infraclavicular tuberculous infiltrations and in 1926, Redeker, who previously had devoted his studies exclusively to tuberculosis in childhood, approved the conclusions of Assmann However, before this time Wessler and Jaches, as a result of roentgen-ray studies, concluded that the earliest evidences of pulmonary tuberculosis were found far more frequently in the infraclavicular region than in the apex of the lung Assmann defined these infiltrations as "well circumscribed, round shadows of homogeneous character whose borders contrast distinctly, but without sharp outlines from their surroundings The size varies from that of a ten-cent piece to that of a one-dollar piece" The first cases were composed of students, young doctors, and young nurses, whose duties offered opportunities for reinfection Their

complaint was a slight general malaise Physical examination revealed negative results, but on roentgen-ray examination, Assmann discovered the subapical foci for the first time

While the existence and the frequent occurrence of infraclavicular infiltrations are now fairly beyond dispute, opinions regarding their origin still differ Assmann believed in a secondary, exogenous, respiratory reinfection but did not deny the possibility of occasional hematogenous reinfection Romberg and Lydtin explained the subclavicular infiltration as a perifocal reaction, either around an infected bronchial or tracheal gland, or around a parenchymatous reinfection focus in adults According to Loeschke, it begins as an exudative, bronchopneumonic affection by metastatic formation from an earlier, proliferative apical lesion As an exudative tuberculous lesion, it may be entirely absorbed and heal without leaving any vestiges It may, on the other hand, undergo fibrous transformation, encapsulation, and calcification, or it may lead to caseation and excavation, spreading into the neighboring parts of the lung

Three groups may be distinguished in regard to clinical findings The first division includes those young individuals who are exposed in their work, and who complain of malaise, subfebrile temperature, night sweats, and loss of weight A second group of cases is described as developing symptoms of influenza, with acute onset of high fever A third class of patients experiences acute and more or less profuse hemoptysis The past histories fail to reveal any symptoms suspicious of pulmonary tuberculosis On physical examination of the patients of these groups, no, or very little, evidence of pulmonary disease is found Roentgen-ray examination is generally believed to be the classical method of demonstrating these subapical lesions

Regarding the prognosis of subclavicular pneumonic lesions, it has been definitely proven that they may disappear completely, as other pneumonic infiltrations do However, the author agrees with most writers that, without therapeutic measures, progressive phthisis is the most frequent sequel

In the author's opinion all exposed persons, members of tuberculous families, students living with persons suffering from active tuberculosis, and those stricken with influenza in which the symptoms of pneumonia are absent, should be periodically subjected to roentgen-ray examination in order to demonstrate freshly infected cases as early as possible

J N ANÉ, MD

Pulmonary Tuberculous Sclerosis Achille Segal Riv d Pitol e Clin d Tuberc Dec 31 1931 V 1058-1070

From the clinical point of view we must allocate to the sclerosis group those forms of pulmonary

now occupies a position between the two extremes, ready to accept results on the basis of practical experience.

In the case of a medication of this kind, which is mainly adapted to the obtaining of partial and symptomatic results—but which are not on that account negligible—a just interpretation of the general effect is difficult, especially in view of the infinite variations presented by the disease.

In the course of five years' employment of the therapy in question, the authors observed no serious accidents More worthy of attention than the slight temporary disturbances listed are the local reactions with increase of auscultatory indications, pleural manifestations, and, at times, with accentuation of the radiologic shadows, this latter being an outstanding proof of a reaction on the part of the tuberculous granuloma The importance of these signs in the curative process cannot be disputed

In fresh and not too extended cases, radiologic *nettoyage* of the secondary disseminations may be obtained This appears so closely bound up with the aurotherapy as not to permit of doubt regarding the dissolving effects of the latter

W W WHITELOCK, PhD

Results of Roentgenotherapy in Tuberculosis of the Bones and Joints in the Surgical Clinic of the University of Kiel (1918-1927) Annemarie Dornmann Strahlentherapie, 1931, XLII, 201-218

In this paper the author discusses the results of roentgenotherapy in tuberculosis of the bones and joints, based on a survey conducted in 1929 In the first period, from 1918 to 1921, roentgen rays filtered through from 3 to 4 mm of Al and a dose of from 10 to 15 X ($E D = 25 X$) were used, in children usually only 5 X as measured with the Sabouraud-Noire pastille This dose was repeated at four-week intervals perhaps from six to eight times In some cases from ten to fifteen treatments were given during the period of from two to three years Beginning in 1922, the doses were reduced, and from 1924 on, deep therapy, with 0.5 mm Zn + 1 mm Al filtration, was employed The single dose amounted to from 20 to 30 per cent $E D$ and was somewhat lower in children All patients received general treatment as indicated in tuberculosis

In the compiled tables the patients are arranged according to the site of the lesions The disease was located in the wrist in twenty-four cases, in seven of which there was abscess formation Of the remaining seventeen, six healed with full function, three with limited function, four with ankylosis, three died, and one remained unchanged The respective figures for the seven patients with fistulae are one, two, one, two, and zero (one patient in

this group is not classified) This brings the total number of cured cases to seventeen out of twenty-four

There were twenty cases in which the ankle was involved, seven of these had fistulae Of the thirteen remaining, five healed with full function, one with limited function, two with ankylosis, three died, one grew worse, and one remained unchanged The respective figures for the seven cases with fistulae were two, one, two, two, zero, and zero In this group there were thirteen cases cured out of a total of twenty

Twenty patients with tuberculosis in the elbow joint were seen, seven of which had fistulae Of the remaining thirteen, five healed with full function, one with limited function, two healed with ankylosis, three died, one grew worse, and one remained unchanged Of the seven patients with fistulae, the respective figures are two, one, two, two, zero, and zero This means thirteen cases were cured out of a total of twenty

Forty-four patients had involvement of the knee joint, eleven of whom had fistulae Of the remaining thirty-three, twelve healed with full function, one with limited function, six with ankylosis, two were improved, eight needed operation in addition to X-ray therapy, three died, none grew worse, and one remained unchanged The respective figures for the eleven cases with fistulae are two, one, one, zero, one, three, one, and two This amounts to twenty-three cures out of a total of forty-four cases

Five patients had the process in the shoulder joint, one of whom had a fistula Of the remaining four, one healed with full function, one with limited function, one with ankylosis, and one died The one case with fistula had to be operated on There are then three cures in a total of five cases

Seventeen patients had tuberculosis of the hip joint and thirteen of these had fistulae Of the remaining four, two were cured and two died Of the thirteen cases with fistulae five were cured, three improved, four died, and one grew worse This means a total of seven cures in seventeen patients

Tuberculosis of the small bones (metacarpus, metatarsus, calcaneus, and *spina ventosa*) was seen in forty-six patients, twenty-three of whom had fistulae Of the remaining twenty-three, ten healed with complete function, one with limited function, two with ankylosis, six had to be operated on, two died, one grew worse, and one remained unchanged Of the twenty-three with fistulae, eighteen healed with full function, two with limited function, one with ankylosis, and two died In this group thirty-four were cured out of a total of forty-six

Miscellaneous cases of bone tuberculosis (ribs, sternum, long bones, clavicle) are compiled in a table of twenty-eight Sixteen of these had fistulae, of the remaining twelve, eleven were cured and one

become active and be a menace to other children. Whereas Stoloff considers only the roentgenologic examination and the tuberculin reaction to be of value in diagnosis of this condition, the author believes the history of contact with a tuberculous patient of great importance. Roentgenograms must be properly taken, in postero-anterior and straight lateral positions, and a proper interpretation must be made of these.

The National Tuberculosis Association has expressed itself as follows: "Interpretation of films should be made by an experienced physician who is familiar not only with chest films in general, but with films of children's lungs in particular. He should also have a clinical background, and the interpretation should not be independent of careful consideration of history, symptoms, and physical examination."

We have no clear understanding of what is a perfectly normal chest, because different men vary in their opinions as to the importance of the same shadows, therefore interpretation of the X-ray findings should go hand in hand with the history, the clinical, physical, and laboratory data. Most of the hilar shadows are made up of the larger vessels and not the bronchi. Normal lymph glands do not cast a shadow and cannot be recognized unless they contain calcium or encroach on pulmonary fields.

The author also discusses the clinical signs and symptoms of this condition, among which are mild disturbance of nutrition, fatigue, irritability, and a slight daily rise in temperature.

FRANCIS B SHELDON, MD

TUBERCULOSIS (THERAPY)

Arrested Pulmonary Tuberculosis Louis H Fales
Med Bull Veterans' Administration, December,
1931, VII, 1121-1127

The author considers the present classification of the American Sanatorium Association unsatisfactory in determining the existence of arrest in pulmonary tuberculosis. Considerable progress has been made since the last modification of this classification was adopted, in 1922, and suggestions of criteria of arrest are offered.

Brunn made an exhaustive study and spent considerable time in experimental work on cadavers, coming to the conclusion that râles of the most usual type heard in pulmonary tuberculosis—which occur in showers during inspiration following an expiratory cough—do not mean active tuberculosis or even tuberculosis at all. They are not due to moisture and are more of the nature of atelectatic râles. Heise, of Saranac, studied the records of 412 cases over a six-month period and demonstrated that the increase or diminution of râles in pulmonary tuberculosis was of no value in determining the patient's

progress. It is, therefore, believed that râles are of no value in determining progression and retrogression of a tuberculous lesion and that they have no place in a scheme of classification.

Latent pulmonary tuberculosis is relatively common in children and also occurs in adults. A parenchymal infiltration as seen on the roentgenogram is often the only evidence that these patients are ill. In these cases, as in those of children, if proper treatment is not instituted, the lesion usually progresses and in months or years the late manifestations will develop. Likewise, it was formerly believed that pulmonary tuberculosis could be arrested in a few months but the roentgen ray has demonstrated that, although clinical symptoms may disappear in a few months, the tuberculous lung pathology clears and fibroses very slowly, healing only after years of prolonged and continuous rest. Amberson emphasized the importance of serial roentgenograms in order to determine the progression or retrogression of the pulmonary lesions. Gerald B. Webb and McPhedran also consider the roentgen ray of utmost value, not only in diagnosis but also in determining the exact changes occurring in the lungs during treatment. The author is of the opinion that bacilli in the sputum and all constitutional symptoms that are reasonably certain to be due to tuberculosis should be absent for at least one year before the case is considered arrested. Even then, serial roentgenograms should be the deciding factor before final conclusions are reached. The roentgen-ray criteria for a healed lesion should consist of the following: (1) A stable or stationary lesion, (2) a hard, well-fibrosed lesion, (3) a lesion which has remained stationary for months. The above points should be determined by a competent roentgenologist using a proper technic and satisfactory roentgen-ray equipment.

Clinical studies have stressed the importance of complete rest and care in the inauguration of graduated exercise. After the lesion has remained hard, fibrosed, and stationary for six months, as demonstrated by serial roentgenograms, and an additional six months have elapsed with carefully graduated exercise and observation without reactivation of the disease, the case may be considered arrested.

J. N. ANÉ, MD

Indications and Results of Aurotherapy in Pulmonary Tuberculosis V De Benedetti and Felice Tocco Ria d Patol e Clin d Tuberc, Dec. 31, 1931, V, 1076-1085

After the early unjustified enthusiasm and the following inevitable distrust of aurotherapy, opinion regarding this form of treatment as in the case of other curative measures has been modified until it

now occupies a position between the two extremes, ready to accept results on the basis of practical experience.

In the case of a medication of this kind, which is mainly adapted to the obtaining of partial and symptomatic results—but which are not on that account negligible—a just interpretation of the general effect is difficult, especially in view of the infinite variations presented by the disease.

In the course of five years' employment of the therapy in question, the authors observed no serious accidents. More worthy of attention than the slight temporary disturbances listed are the local reactions with increase of auscultatory indications, pleural manifestations, and, at times, with accentuation of the radiologic shadows, this latter being an outstanding proof of a reaction on the part of the tuberculous granuloma. The importance of these signs in the curative process cannot be disputed.

In fresh and not too extended cases, radiologic *nettoage* of the secondary disseminations may be obtained. This appears so closely bound up with the aurotherapy as not to permit of doubt regarding the dissolving effects of the latter.

W W WHITELOCK, Ph D

Results of Roentgenotherapy in Tuberculosis of the Bones and Joints in the Surgical Clinic of the University of Kiel (1918-1927) Annemarie Dornmann Strahlentherapie, 1931, XLII, 201-218.

In this paper the author discusses the results of roentgenotherapy in tuberculosis of the bones and joints, based on a survey conducted in 1929. In the first period, from 1918 to 1921, roentgen rays filtered through from 3 to 4 mm of Al and a dose of from 10 to 15 X (E.D. = 25 X) were used, in children usually only 5 X as measured with the Sabouraud-Noire pastille. This dose was repeated at four-week intervals perhaps from six to eight times. In some cases from ten to fifteen treatments were given during the period of from two to three years. Beginning in 1922, the doses were reduced, and from 1924 on, deep therapy, with 0.5 mm Zn + 1 mm Al filtration, was employed. The single dose amounted to from 20 to 30 per cent E.D. and was somewhat lower in children. All patients received general treatment as indicated in tuberculosis.

In the compiled tables the patients are arranged according to the site of the lesions. The disease was located in the wrist in twenty-four cases in seven of which there was abscess formation. Of the remaining seventeen, six healed with full function, three with limited function, four with ankylosis, three died, and one remained unchanged. The respective figures for the seven patients with fistulae are one, two, one, two, and zero (one patient in

this group is not classified). This brings the total number of cured cases to seventeen out of twenty-four.

There were twenty cases in which the ankle was involved, seven of these had fistulae. Of the thirteen remaining, five healed with full function, one with limited function, two with ankylosis, three died, one grew worse, and one remained unchanged. The respective figures for the seven cases with fistulae were two, one, two, two, zero, and zero. In this group there were thirteen cases cured out of a total of twenty.

Twenty patients with tuberculosis in the elbow joint were seen, seven of which had fistulae. Of the remaining thirteen, five healed with full function, one with limited function, two healed with ankylosis, three died, one grew worse, and one remained unchanged. Of the seven patients with fistulae, the respective figures are two, one, two, two, zero, and zero. This means thirteen cases were cured out of a total of twenty.

Forty-four patients had involvement of the knee joint, eleven of whom had fistulae. Of the remaining thirty-three, twelve healed with full function, one with limited function, six with ankylosis, two were improved, eight needed operation in addition to X-ray therapy, three died, none grew worse, and one remained unchanged. The respective figures for the eleven cases with fistulae are two, one, one, zero, one, three, one, and two. This amounts to twenty-three cures out of a total of forty-four cases.

Five patients had the process in the shoulder joint, one of whom had a fistula. Of the remaining four, one healed with full function, one with limited function, one with ankylosis, and one died. The one case with fistula had to be operated on. There are then three cures in a total of five cases.

Seventeen patients had tuberculosis of the hip joint and thirteen of these had fistulae. Of the remaining four, two were cured and two died. Of the thirteen cases with fistulae five were cured, three improved, four died, and one grew worse. This means a total of seven cures in seventeen patients.

Tuberculosis of the small bones (metacarpus, metatarsus, calcaneus, and spina ventosa) was seen in forty-six patients, twenty-three of whom had fistulae. Of the remaining twenty-three, ten healed with complete function, one with limited function, two with ankylosis, six had to be operated on, two died, one grew worse, and one remained unchanged. Of the twenty-three with fistulae, eighteen healed with full function, two with limited function, one with ankylosis, and two died. In this group thirty-four were cured out of a total of forty-six.

Miscellaneous cases of bone tuberculosis (ribs, sternum, long bones, clavicle) are compiled in a table of twenty-eight. Sixteen of these had fistulae, of the remaining twelve, eleven were cured and one

died. Of the sixteen cases with fistulae ten were cured, one died, one had to be operated on, two grew worse, and two remained unchanged. This results in twenty-one cured patients of a total of twenty-eight.

Ten cases of tuberculosis of the pelvis were seen and all had fistulae, four were cured and six died.

Six cases of tuberculosis of the skull had fistulae, four were cured, one needed operation, and one grew worse under the treatment.

Of ten cases of spondylitis tuberculosa, eight had fistulae, of the remaining two, one was healed with motion, and one had a gibbus. Of the eight cases with fistulae two healed with motion, two with gibbus, two were improved, and two grew worse. There was then a total of five cures out of ten patients.

Multiple tuberculosis was seen in twenty-five patients, twenty of whom had fistulae, of the remaining five, three were cured with full function, and two grew worse. Of the twenty with fistulae, four were cured with full function, one with limited function, three were improved, four had to be operated on, seven died, and one grew worse. The end-result was, therefore, eight cures out of a total of twenty-five cases.

A grouping of the patients according to age clearly shows that the benefit derived from roentgenotherapy decreases with the age of the patient. Careful investigations were also undertaken in order to determine the percentage of roentgen late injuries. In only one case, treated in 1919, for tuberculosis of the ankle joint, was there a skin defect which discharged slightly. Pigmentation, bluish discoloration of the treated skin, and telangiectasis were seen occasionally. Disturbance of the growth in children who had been treated was very small, sometimes hardly measurable. Two cases in this group are particularly interesting, brief histories of these patients being given.

The first patient was a boy of 17 years, who underwent treatment, in 1918, because of an involvement of the elbow, the pelvis, the bladder, and inguinal glands. He received a total of 80 X over the ilium and 30 X over the gluteal region. Within nine months' time all fistulae healed and the patient could resume his work. At the re-examination, in 1929, it was found that all tuberculous processes had remained healed. The patient, who was 29 at that time, showed a definite feminine appearance in the face as well as in the body. The whole picture was very indicative of an injury to the sex glands. This was further supported by the fact that he had been married for four years without having children.

The second patient was a girl, 17 years of age, who was treated, in 1918, because of tuberculosis of the ribs. The diseased area in the region of the right breast received a total of 50 X. Re-examination November 1929 showed normal skin in the

irradiated field but an infantile right breast. Such a retardation in the development of one breast following irradiation has been described by other clinicians.

In another set of tables, the author's results are compared with those of the Surgical Clinic of the University of Rostock, where the treatment method was very similar. It appears from both statistics that a cure with complete function may be expected in at least one-fourth but not in more than one-half of all cases of tuberculous bones and joints. Late injuries are not very common, and roentgenotherapy of this disease is further recommended as an auxiliary method if applied in doses small enough to almost assure the avoidance of late injuries.

ERNST A. POHLE, M.D., Ph.D.

The Roentgen-ray Treatment of Experimental Tuberculosis John W. Spies Am. Jour. Roentgenol. and Rad. Ther., November, 1931, XXVI, 716-725

Clinical results in the treatment of skin and glandular tuberculosis by roentgen rays have been reported to be good in general, although there have been enough of unsatisfactory results obtained to stimulate laboratory investigation in an effort to further elucidate the problem of this form of radiation therapy of an inflammatory process.

The writer's laboratory material consisted of 115 guinea pigs and eight rabbits injected with varying amounts of a very virulent and a scarcely virulent strain of tubercle bacilli. Sixty-nine of the guinea pigs and four of the rabbits were irradiated according to four different plans, the remaining animals, used for controls, were inoculated but not irradiated. Effects of radiation were essentially negative, except that guinea pigs irradiated the day of inoculation exhibited acceleration of the disease in the form of ulcers and abscesses at the site of injection and regional lymphadenomegaly, although duration of life and extent of lesions at autopsy were not affected. Animals submitted to repeated irradiation prior to inoculation developed local evidences of the disease more slowly but showed no differences in the later stages of the disease.

Histologic findings were as follows. Slight increase of connective tissue at the site of irradiation, rarity of giant cells, presence of both caseous and proliferative forms of tubercles, and a proliferative hepatic cirrhosis.

The above findings offer by no means a complete answer to the clinical problems presented, for, admittedly, until a chronic tuberculous lymphadenopathy can be successfully produced in a laboratory animal, a carefully conducted evaluation of the results of roentgen therapy in this form of inflammatory disease cannot be made.

J. E. HADDE, M.D.

Phrenic Exeresis in the Treatment of Unilateral Pulmonary Tuberculosis George M Landau Illinois Med Jour, LX, November, 1931, 408-412

This article is based on a ten-year experience as radiologist at the Cook County Tuberculosis Hospital, during which time, between 15,000 and 20,000 films have been studied.

If the results of operative procedures show that surgery has great value in the treatment of pulmonary tuberculosis, as an adjunct to sanatorium treatment, then there is every reason to justify the enthusiasm following the results of such treatment.

The writer says that if we can show by our records cases of clinical cure or arrest, such as the following, then this procedure must merit our attention. The patient, a physician without previous symptoms, had a severe hemoptysis, X-ray examination showing a large cavity in right lower lobe. Positive sputa and high temperature continued in spite of bed rest. Repeated X-ray examination revealed an increase in size of cavity and lower lobe mottling. Right phrenic extraction was done and immediate improvement noted, less sputa, drop in temperature and decrease in size of the cavity. In three months, a gain of 25 pounds in weight, normal temperature, negative sputa, absence of mottling, and practically complete obliteration of the cavity resulted.

In the program as carried out by Otto Schlack and Jerome Head, there has been no operative morbidity or mortality and no patient has been made worse by the treatment.

In conclusion the author states "It is probably not within the province of the radiologist to draw conclusions or elucidate on the indications and contra-indications to phrenic exeresis other than those conclusions which he deduces from the roengenogram itself, but certainly after following such a series of studies of such cases as we have, one cannot help but conclude that in a disease as serious as pulmonary tuberculosis and in which such an agent as this has proved of such great therapeutic value, I do not see how one can escape the conclusion that this remedy should be applied as completely and effectually as possible, regardless of the fact that the patient may get well without it."

CHARLES H DEWITT, M D

The Treatment of Tuberculosis of the Female Genital Organs H Martius Strahlentherapie, Oct 24, 1931, XLII, 471-484

This is a detailed discussion of the author's indications concerning the treatment of tuberculosis of the female genital organs. Operation is contraindicated if other organs, as, for instance, the lungs,

are also involved. In some cases operation is necessary, because a diagnosis can be made definitely only after laparotomy. The use of small doses is urged in order to maintain the ovarian function. From 60 to 110 r are suggested as a single dose, the intervals and frequency of the treatments being adapted to the individual case. The exact mechanism of the effect is not definitely known. From the author's own statistics it appears that, of thirty-five cases treated during the years from 1917 to 1923, fifteen died, fifteen were cured, and five improved. Of twenty-two cases seen during the years from 1924 to 1930, one died, twelve were cured, five improved, and four have not healed so far.

ERNST A POHLE, M D, Ph D

Successful Radiotherapy of Two Cases of Pelvic-peritoneal Tuberculosis in Women M Mathey-Cornat Bull et Mem de la Soc de Radiol Méd de France, June, 1931, XIX, 297-300

The first case, a female, 34 years of age, had "intestinal grippe," in March, 1930, with rapid pulse and fever from 38° to 40° C, lasting for ten days, with loss of appetite, asthenia, vomiting. In April, 1930, all symptoms subsided except fever, tenderness in the lower abdomen, diarrhea, and fetid feces, and anemia with leukorrhea. Examination showed an abdominal pelvic tumor mass of the uterus and adnexal masses, adherent, diagnosed as bilateral pyosalpinx, either of gonococcic or tuberculous origin. Laboratory tests for gonococci were negative. Two series of X-ray therapy in May and July, 1930, were given, totalling 1,600 and 2,000 roentgens, respectively, in divided dosage. The tumor receded in size, diarrhea ceased, and pelvic pain was less. The temperature became normal. Normal menstruation reappeared in January, 1931, and by May, 1931, she appeared perfectly well, with slight local tenderness in the lower abdomen only.

The second case, a female 26 years of age, began having irregular and excessive menstruation with pelvic pain, in March, 1926. She was hospitalized in October, 1926. In July, 1929, a sero-fibrinous pleurisy developed on the left side, requiring thoracentesis on two occasions. The fever ranged from 39° to 39.5° C. Pelvic examination revealed bilateral adnexal masses the size of two chestnuts, fixed, with a fibro-ascitic fluid in the left iliac fossa. In July, August, and September, 1929, three series of X-ray treatments were given, totalling 4,000 roentgens at each series through three portals of entry, each lateral port receiving 1,600 roentgens and the central port 800 roentgens, using 180 peak kilovolts (filtration not stated). By January, 1930, the uterus had become partly mobile, the adnexal masses had practically disappeared, and the fever had subsided. By August, 1930, all abdominal pain

had ceased. In May, 1931, no local signs could be found as sequelæ of the tuberculous pelvic peritonitis, and examination of the lungs was negative.

CHARLES S CAPP, M D

The Treatment of Empyema Carl A Hedblom
Jour Am Med Assn, Dec. 26, 1931, XCVII, 1943-1950

Empyema may be classified as pyogenic and tuberculous, the pyogenic being subdivided into the acute and chronic, the tuberculous practically always becoming chronic.

The pneumococcus, streptococcus, and staphylococcus are the most common infective organisms in the order named. Empyema cavities vary greatly as to position and size. Bronchial fistulae may result from rupture of a pulmonary abscess into the pleural cavity, or from perforation of an empyema into a bronchus.

Differentiation of types depends essentially on examination of smear and culture for pyogenic organisms. Treatment differs radically. The fundamental principle of treatment is drainage, instituted early, by a method that will not embarrass respiration or circulation and maintained until the cavity is obliterated.

Closed drainage is the method of choice in all early acute cases, in severely ill patients, and in infants. Rib resection and pus drainage is the alternative method and the method of choice in cases with large bronchial fistulae.

Drainage is contra-indicated in sterile tuberculous empyema. Without associated pulmonary tuberculosis, air is substituted for the pus. With associated active pulmonary tuberculosis, pneumothorax is continued. If pus continues to form, a plastic obliteration of the cavity is brought about, as for the non-tuberculous type.

C G SUTHERLAND, M D

TUMORS (DIAGNOSIS)

Encephalography and Ventriculography W Löffler
Schweiz med. Wehnschr., Aug 29, 1931, LXI, 816-824

Thirty-six cases have been studied, eight of which involved the region of the hypophysis. Of the four methods, direct puncture of the lateral ventricle and cisterna puncture are most used. The author injected a little air in an effort to produce a minimum of trauma. The technic is described.

Patients with extreme hydrocephalus, Parkinson's disease, and encephalitis lethargica stand the examination well, but untoward symptoms may arise in

patients who have brain tumors. The author describes the complications. Good transient therapeutic results were obtained in some cases.

Seven cases of tumor of the hypophysis are reported. The findings are differentiated by Stenvers from those of hydrocephalus of the third ventricle by the more regular encroachment on the sella, seen in the hypophyseal tumors. The author found that the "regular" type of encroachment was common to four benign tumors, whereas in four malignant tumors there was an irregular enlargement of the sella with little or no hydrocephalus, but compression of the lateral and third ventricles.

H C OCHSNER, M D

Irradiation as a Means of Differentiating Certain Varieties of Tumors A U Desjardins Med. Clin. North America, November, 1930, XIV, 619-638. (Reprinted from "Cancer Review" by permission.)

The author points out that the radiologist can frequently distinguish between different tumors by the rate and extent of their regression after irradiation. In some cases, such as the lymphoblastomas and embryonic testicular carcinoma, this means of differentiation has proved to be nearly as accurate as histologic examination. He discusses, in addition to lymphoid and testicular tumors, bone tumors, and cites cases in support of his contention.

F CAVERS, D Sc.

Xanthomatosis (Schüller-Christian's Disease, Lipoid Histiocytosis) Merrill C Sosman Jour Am Med Assn, Jan 9, 1932, XCVIII, 110-117

Xanthomatosis is a disease of lipid metabolism in which storage tumors of lipid appear in various places and in various organs, sometimes profoundly affecting the bodily health and welfare. There are five clinical entities included under this heading, namely, Gaucher's disease, Niemann-Pick's disease, Schüller-Christian's disease, the xanthomas occurring in icterus, diabetes, and pregnancy, and the so-called essential xanthomatosis.

Schüller-Christian's disease occurs chiefly in young children; it is characterized by involvement of the bones of the skull (occasionally other bones), with frequent association of diabetes insipidus, exophthalmos and gingivitis, less commonly dwarfism, adiposogenital dystrophy, and jaundice; it is not racial or familial, and is fatal in about one-third of the cases. Histopathologic studies have demonstrated that we are dealing with a phagocytic action of the reticuloendothelial system, which either removes an excess of lipoids from the tissues, or stores an excess of

lipoids in areas in which trauma or infection may have stimulated a collection of histiocytes. Chemical studies have proved that different lipoids are at fault in the different diseases. These cases are reviewed. Treatment includes diet and the administering of endocrine glands or their extracts. Schuller-Christian's disease is liable to spontaneous remission. Roentgenotherapy has given a uniformly beneficial result as far as local deposits in the bones are concerned. Recurrences may take place in the same place or in other bones.

C G SUTHERLAND, M D

Malignant Giant-cell Tumor of Radius with Recurrence and Metastasis Report of a Case H Kokita Chinese Med Jour, January, 1932, XLVI, 64-68.

The author reports the case of a Chinese woman, 47 years of age, who presented a tumor of the right wrist of one year's duration. Physical examination revealed nothing of importance except the local condition. The tumor, which involved the distal third of the forearm, was firm and slightly tender on palpation. X-ray examination revealed bone destruction of the distal third of the radius, with expansion of the cortex. The expansion, however, was not symmetrical, as the radial side of the expanded shell remained intact and served as a connection between the undestroyed articular surface and shaft. At operation, the tumor was excised and a portion of the fibula transplanted. Pathologic examination of the specimen revealed a malignant giant-cell tumor, with no regularity in size and shape of the cells and with many mitotic figures.

Five months after operation the patient returned with a recurrent tumor. The growth was irregular in shape and had four firm prominences covered with shiny, tense, bluish-red skin which in places discharged a serosanguineous thin fluid. Roentgenograms revealed complete destruction of the distal third of the ulna and extensive destruction of the middle and remaining distal third of the radius. The bone graft was apparently not involved in this process. Metastases were found involving several ribs, both pleura, and the base of the right lung. The arm was amputated and the metastatic lesion involving one of the ribs was removed. The patient died several months later.

The author discusses the importance of considering the two different elements found present in giant-cell tumors. These are giant cells and the stroma. The characteristic feature of the tumor is the presence of numerous giant cells, which, however, play a very insignificant rôle when the question of malignancy is considered. The activity of the tumor depends primarily upon the stroma cells. In the majority of giant-cell tumors the stroma cells are

mature, fibroblastic cells, which are uniform in size, spindle shaped, and contain no mitotic figures. These tumors are essentially benign. There is, however, a small number of cases which, though indistinguishable from benign giant-cell tumor clinically, roentgenologically, and according to their macroscopic morphology, show a significantly different microscopic picture. The difference here lies in the microscopic appearance of the stroma cells, for the giant cells are similar in appearance in these two types of tumors. In the malignant type, the stroma cells appear immature, irregular in size and shape, and show active mitosis, which is a definite indication of rapid growth and malignancy.

J N ANE, M D

The Triad of Symptoms in the Diagnosis of Intrathoracic Tumors Guillermo Bosco Rev Med Cubana, January, 1932, XLIII, 99-103

The aim of this article is to point out the importance of a triad of symptoms which simplifies the diagnosis of intrathoracic neoplasms. Without this triad the internist relies on the roentgenologist for diagnosis when even the latter is unable to give a positive diagnosis. To help out in this difficulty the author offers the following triad of symptoms:

(1) *Thoracic Pain*—According to the writer this sign has triple meaning and is a constant symptom. It is intense in character, constant, and radiating. This pain is so intense that even rest has no influence over it, being relieved by active medication only. Obviously, the relief lasts only while the medicinal effect endures. The pain, so intense that no other condition simulates it, is usually found anterior to the growth. The radiation has an almost localizing character. Lesions of the superior lobe radiate their pain to the head, neck, shoulder, and arm. Lesions of the middle lobe radiate their pain, together with lesions of the inferior lobe, along the thoracic wall. This is due to the fact that these lesions affect the intercostal nerves.

(2) *Homolateral Contortion*—The author calls attention to a finding which he has observed in patients having intrathoracic tumors. This sign—a homolateral bending of the entire trunk toward the affected side—is best observed when the patient is in the upright position and all the clothing has been removed. Some patients may become conscious of this deformity and try to correct it while being examined. If this does not happen, the finding, which the author attributes to a muscular rigidity caused by the lesion, is quite constant.

(3) *Tumor Shadow on the X-ray Film*—This shadow resembles that of any thoracic neoplasm. It is dense in consistency, irregular in shape (depending on its length of growth), with a sharp or hazy border. It is difficult and at times even impos-

sible to say whether it is benign or malignant. The author, through an original observation, claims that he can tell whether a growth is malignant or not. He combines a detailed history, a complete physical examination, and X-ray plates made at different angles. According to his observation, all malignant neoplasms adhere to the mediastinum. This sign is present, irrespective of the density, shape, or size of the neoplasm.

JOSEPH MALDONADO, M.D.

A Statistical Review of Tumors of the Locomotor Apparatus Observed in the Istituto Ortopedico Rizzoli during the Years 1929 and 1930 Giulio Faldini and Oscar Scaglietti Riv di radiol e fisica med., December, 1931, IV, 179-199

This review is of thirty-three cases of tumor seen in Rizzoli's institute during 1929 and 1930, which, according to the classification of Putti and Camurati, fall into the following groups. Tumors of the soft parts, three; osteogenic sarcomas, nine; giant-cell tumors, six; metastatic tumors, eleven; benign tumors, three; and myeloma, one.

Thirteen of these were diagnosed histologically, and the remaining twenty by clinical and radiographic data. Four of the metastatic tumors came from an undiscovered primary.

The clinical histories, the treatment, the radiologic and the pathologic findings in these cases are given in outline. The report is given to supplement the other studies of the material coming to the Institute.

E. T. LEDDI, M.D.

Pituitary Tumor Causing Trifacial Neuralgia Eugene F. Bogen Med Bull Veterans' Administration, November, 1931, VII, 1067-1069

The author reports the case of an ex-service man, 35 years of age, who complained of neuralgia and nervousness of long standing. Physical examination of the patient revealed coarse features and a broadened nose. The hands were immediately noticeable because of their large size. The blood Wassermann and urine examinations were negative. A special examination of the eyes revealed cupping of the left optic disc. Stereoscopic roentgenographic examination of the skull showed erosion of the anterior and posterior horns of the ethmoid processes and of the floor of the sella turcica. This was considered suggestive of brain tumor.

From the clinical and X-ray findings the diagnosis of acromegaly, due to pituitary gland tumor, and trifacial neuralgia, due to pressure of the tumor on the trifacial nerve, was made.

While trifacial neuralgia resulting from the pressure of a tumor on the trifacial nerve or its ganglion

is not common in occurrence, the author believes that in cases of persistent trifacial neuralgia, in which no adequate local cause can be found, the possibility of a tumor producing pressure on the nerve or its ganglion should be considered and the patient referred for a radiologic examination.

J. N. ANÉ, M.D.

Sarcomatous Epulis Attributed to Irritation by Broken Nerve-extracting Needle. A Catterina. Clin Chir, November, 1930, XXXIII, 1292-1306 (Reprinted from "Cancer Review" by permission)

A girl, 19 years of age, was treated for caries of a central upper incisor by a dentist who inserted a peg tooth. Ten months later a soft tumor was seen at the gingival border between the central incisors. X-ray examination showed that from the apex of the root, which was perforated by the metallic peg tooth, about 1 cm of a nerve-extracting needle projected into the alveolus. The tumor was removed and found to be spindle-celled fibrosarcoma. Four months later there was recurrence, a second and more radical operation was performed, but the patient died three months after this, owing to orbital invasion and cerebral metastases.

F. CAVERS, D.Sc.

Malignant Adenomas of the Colon. E. J. Kilfoyle Am Jour Surg, August, 1931, XIII, 283-290 (Reprinted from "Cancer Review" by permission)

The author discusses adenomas of the colon and reports an unusual case in which multiple adenomas of the large and small variety have undergone malignant changes. The polyps vary in size from a simple hyperplasia to tumors 5 or 6 cm in diameter and with pedicles up to 6 cm in length. Recurrence took place at the site of the old operation and about the colostomy opening, as a result of transplanted tissue from the Mikulicz resection and not removing enough of the colon. The tumor increased in spite of vigorous diet and X-ray treatment.

In a very large percentage of cases single adenomas are malignant, while in the multiple type they may become malignant if they increase in size sufficiently to undergo malignant changes. Adenomas occur most frequently in the large bowel. They occasionally are seen in the small bowel, and may be found throughout the gastro-intestinal tract. All adenomas are potentially malignant, and the type of operation and post-operative treatment should be left to the surgeon and to the nature of the individual cases. Adenomas in the colon and secondary implants in the abdominal wall are very resistant to

deep X-ray therapy. Malignant changes begin in the periphery of the larger polyps, rarely occurring in the smaller ones.

W T WARWICK, MA

Sarcoma of the Lacrimal Region in an Eleven-year-old Child. N Puente Duany, A Oteiza, and E. Fonts Boletin de la Sociedad Cubana de Pediatría, June, 1931, III, 217-220

This case is here presented because of its being so rare. A child eleven years old, four months previous to admission to the hospital, noticed a small nodule in the median angle of the right eye, which grew gradually without affecting the child in any visible way. On admission, the lesion was found to be about the size of a Brazil nut, ulcerative, painless, and firm, with a sero-sanguineous fluid and very sharp edges. A radiograph failed to reveal any bone changes around the lesion. At biopsy, the diagnosis of sarcoma was reaffirmed. Treatment consisted of X-ray therapy.

N G GONZALEZ, MD

Cerebral Tumor as a Cause of Generalized Epileptic Attacks of Long Standing. E A Blake Pritchard Lancet, Oct 17, 1931, CCXXI, 842-844

The author presents five cases which show that it is possible for a cerebral tumor to give rise to generalized convulsions and to status epilepticus for many years before localizing signs are present. In general, such tumors are slow-growing and originate beneath the cerebral convolutions.

Epileptic attacks cannot be regarded as resulting from a rise in intracranial pressure, since, as shown in his cases, they may be present for many years before other signs of an increased intracranial pressure are manifest. Nor does an increase in intracranial pressure later increase the frequency of epileptic attacks.

Inference, from these considerations, is drawn that persons of middle age, who develop convulsions which occur repeatedly, should be regarded as possibly having an intracranial tumor and should be kept under repeated observation.

F L GRANDSTAFF, MD

Two Cases of Oligodendrogloma, with Remarks on the General Clinical Features of Such Cases. J Purdon Martin Brain, 1931, LIV, Part 3, p 330-349

The author reports two cases of oligodendrogloma in detail and also reviews a number of the cases which have been reported in the literature.

He states that in 16 of the 19 cases reported in the literature, the tumor lay laterally in the cerebral hemisphere where it did not interfere directly with the circulation of the cerebrospinal fluid. Fourteen of these tumors were situated in the frontal or parietal lobes, and one each in the temporal and occipital lobes. In three cases the tumor lay across the midline of the brain and had no calcified deposits. All of the tumors which were situated laterally in the hemispheres contained sufficient calcium to be seen in the roentgenogram.

The author states further that the differential diagnosis of the nature of the tumor by means of the shadow is not possible because the calcareous deposits lie chiefly in the walls of the arteries and capillaries.

CORNELIUS G DYKE, MD

Capillary Hemangioma of Cerebrum. W G Barnard and F M R Walshe Jour Path and Bacteriol, May, 1931, XXXIV, 385-387

These tumors are so rare above the tentorium that eminent authorities doubted their existence. A case is here reported with post-mortem findings.

E C VOOGT, MD

Necrotic Angioma. L E Pierini and P Beranger Rev de Especial, October, 1930, V, 1411-1413 (Reprinted from "Cancer Review" by permission.)

An angiomatic tumor on the face of an eight-day-old infant showed areas of necrosis, with destruction of the skin over the cheeks, of the lobes of both ears, of the left nostril, and of the nasal septum. The authors administered salvarsan (though there were no signs of syphilis or other infection), methylene blue, and deep X-rays, but these were all unavailing.

F CAVERS, D Sc

TUMORS (THERAPY)

Bladder Tumors Clinical Manifestations Report of Cases. Louis Clive Jacobs and Abelson Epstein Calif and West Med, September, 1931, XXXV, 207-212

In the diagnosis of bladder tumors, the authors find that cystographic findings have not received the attention and importance they deserve. Cystoscopic inspection should and can be supplemented by cystography but can never be superseded by it. Cystograms should corroborate the cystoscope, but many times because of tumor mass, hemorrhage, vesical detormity, etc., the cystoscope is useless. Cysto-

grams give not only evidence of the size of the tumor but also knowledge of ureteral reflux with secondary ascending kidney infections and evidence of metastases of the bones. Where one finds general carcinomatosis, he will refrain from futile bladder surgery.

Under discussion of treatment, the authors cite fulguration, diathermy, radium, deep X-ray, and resection. They discuss all these various methods of treatment. While they have used radium and deep X-ray therapy on some patients, they are not able to see any brilliant results. In statistics compiled from fifty patients, they find they have five alive and free from symptoms at the end of four years. Of these, four were treated by surgical diathermy alone and one with diathermy and radium. Also, they have three patients treated by transurethral fulguration, in 1916, one of whom had a recurrence with metastasis after eight years. The other two are alive, although one had a recurrence three years ago and again one year ago, the other has had no recurrences. This article is illustrated with several cystograms.

FRANCIS B. SHELDON, M.D.

An Advanced Case of Nasopharyngeal Fibroma Treated by Diathermy Coagulation and X-rays
H. V. Forster Jour Laryngol and Otol, June, 1931, XLVI, 402-404 (Reprinted from "Cancer Review" by permission)

A male, aged 19, was found to have a large polypoid growth completely obstructing the left nasal passage. It bled very freely, even with slight interference, and there appeared to be no doubt but that the tumor was a nasopharyngeal fibroma. The tumor appeared to be invading the maxillary antrum.

A small dose of radium was given without any definite result. Three diathermy operations were then carried out, and as a result the tumor decreased in size. There was a tendency, however, to swelling of the left pharyngeal wall and left tonsil, and palpation suggested advance of the growth over the roof of the nasopharynx. Deep X-ray therapy was then administered and produced immediate improvement, which has been maintained up to the time of publication. Professor Regaud had expressed the opinion that nasopharyngeal fibromas were insensitive to radiation.

P. J. KERLEY, M.B.

Roentgenotherapy in Tumors of the Hypophysis
Karl Frik. Strahlentherapie, Oct 24, 1931, XLII, 437-452

The author reports six cases of hypophyseal tumor which were treated by roentgen rays. The first

case was that of a man, 61 years of age, whose symptoms started two years before he came to the clinic. He had attacks similar to epilepsy, and suffered from loss of memory and insomnia. Besides, there were acromegaly, polydipsia, and polyuria as well as disturbances of the vision. Following two series of deep therapy the acromegaly remained stationary, he had no further attacks, much less headache, and there was considerable improvement of the polydipsia and polyuria. This improvement has lasted, so far, for one and one-half years.

The second case was that of a man, 38 years of age, whose symptoms had begun eighteen months before. He had headache, disturbance of vision, polyuria, and acromegaly. Already, after one series of treatments, he was so much improved that he could resume his work as a taxi driver. Six months later the headache recurred but disappeared following a second series. He has been well now for one year and five months.

The third case was that of a man, 47 years of age, whose symptoms dated back one-half year. He had symptoms in the eyes, headache, right arm paresis, left temporal hemianopsia. The pathology in the right eye could not be influenced and that in the left remained unchanged for a long time. The headache was, however, improved following the first series of treatments. Definite improvement in the left field of vision occurred recently, over two years following the treatment and after five series. The improvement still remains now, three and one-half years after the first exposure. The recurring headache could be eliminated by a sixth series of treatments, two and one-half years before the date of this report.

The fourth case was that of a man, 40 years of age, who had his first symptoms two years before the treatment. His principal disturbances were of vision and memory. Roentgenologically a hypophyseal tumor could be demonstrated. Biopsy showed adenoma. Four weeks after the first series of treatments he could resume his duties as a police sergeant. The improvement lasted for one-half a year, during which time a second series was given. Headache, vertigo, and disturbances of the vision could be improved by a third series, and the patient has remained able to work for one year and three months.

The fifth case, a man, 39 years of age, had symptoms for a year and a half, with a preponderance of disturbances of the vision. Roentgenologically, there was a large hypophyseal tumor, with destruction of the neighboring tissue. Biopsy showed adenoma. After one series of treatments there was considerable improvement and after a second series the patient resumed his work and has been well now for two years.

The sixth case was that of a woman, 65 years of age, with symptoms for only three months. The chief complaint was that of loss of eyesight. This

was accompanied by loss of hair and diabetes insipidus Roentgenotherapy led to a clinical cure which has lasted now for two years Deep therapy radiation was used (178 KV, 6 m_r, 06 mm Cu, 6 X 8 sq cm field, 40 cm FSD) Four fields were usually exposed, two temporal, one frontal, and one occipital, sometimes also a parietal area The average dose per field was 75 per cent H.E.D Slight changes in the technic were made, according to the requirements of the individual case

From his observations, the author concludes that radiation therapy should be regarded as the method of choice in cases with hypophysial tumors If there is no response following the first series, treatment should not be discontinued unless there is a vital indication for operation Caution is indicated in prescribing the dose, fractional irradiation being preferable

ERNST A POHLE, M D, Ph D

Laryngeal Fibrosarcoma. Deep X-ray Treatment Five-year Cure V Texier Ann Mal Oreille, August, 1930, XLIX, 823, 824 (Reprinted from "Cancer Review" by permission)

The patient was a man, 77 years of age, who had for five years been hoarse and lately almost voiceless A small, smooth tumor sessile on the right cord, which was thickened and infiltrated, was removed almost completely and found to be a fibrosarcoma with large spindle cells The treatment was given in seventeen sittings of one hour each, 2 ma, 25 cm distance, 15 mm Al (dosage not stated) After more than five years of freedom from recurrence, the patient died from enteritis

F CAVERS, D Sc

ULCERS (ETIOLOGY)

Ulcers of the Rectum and Sigmoid The Differentiation of Tuberculous Ulcers from Amebic Ulcers, and Chronic Ulcerative Colitis Clement L Martin Jour Am Med Assn, Jan 2, 1932, XCVIII, 27-31

Outside of institutions for the tuberculous, tuberculous ulcers of the rectum and sigmoid are infrequently observed Even in institutional patients they are uncommon, except in those with far-advanced disease Chronic ulcerative colitis and amebiasis with ulceration are the more common lesions seen in ordinary practice The proctoscopic differentiation of tuberculous ulcer, chronic ulcerative colitis, and amebic ulcers is given in detail One case is reported in which pulmonary tuberculosis and chronic ulcerative colitis were co-existent

A negative roentgenogram of the chest and the absence of positive lung findings exclude tuberculosis in the etiology of multiple ulcers in the rectum and sigmoid

C G SUTHERLAND, M D

A Case of Post-operative Gastroduodenal Ulcer Treated Medically, with a Clinical and Radiologic Cure. Dino Agati Archivio di Radiologia, May-June, 1931, VII, 509-524

In a case of pyloric stenosis which had had a posterior gastro-enterostomy by the method of V Hacker, the author found the complete clinical and radiologic findings of secondary gastroduodenal ulcer The patient was treated medically and ten months later he was completely cured The niche and the other direct and indirect signs of ulcer had disappeared

E T LEDDY, M D

Diagnosis of Peptic Ulcers Sam A Overstreet Kentucky Med Jour, August, 1931, XXIX, 394-396

Out of 407 patients with stomach complaints, on X-ray examination, 67 showed peptic ulcer In very many cases the X-ray examination indicated lesions in other organs, and the exclusion of peptic ulcer is frequently just as valuable a discovery as finding one

W W WATKINS, M D

ULTRA-VIOLET LIGHT

Contribution to the Study of the Path of Penetration of the Anti-rachitic Influence of Ultra-violet Rays on the Organism Gino Frontali La Radiologia Medica, November, 1930, XVII, 1316-1333

In order to establish whether or not the curative and preventive action of ultra-violet rays takes place through the inhalation of irradiated air or through direct exposure of the skin, the author selected three groups of albino rats, fed according to McCollum's diet No 3,143 and submitted to the following living conditions The first group was allowed to breathe temporarily irradiated air, from 5 to 120 minutes, in glass vessels from which they were removed without having been directly exposed to the rays, the second group was submitted to direct ultra-violet treatment and inhalation of irradiated air was totally excluded, the third group was given no ultra-violet treatment of any sort Results were founded on radiologic, histologic, and general examinations

grams give not only evidence of the size of the tumor but also knowledge of ureteral reflux with secondary ascending kidney infections and evidence of metastases of the bones. Where one finds general carcinomatosis, he will refrain from futile bladder surgery.

Under discussion of treatment, the authors cite fulguration, diathermy, radium, deep X-ray, and resection. They discuss all these various methods of treatment. While they have used radium and deep X-ray therapy on some patients, they are not able to see any brilliant results. In statistics compiled from fifty patients, they find they have five alive and free from symptoms at the end of four years. Of these, four were treated by surgical diathermy alone and one with diathermy and radium. Also, they have three patients treated by transurethral fulguration, in 1916, one of whom had a recurrence with metastasis after eight years. The other two are alive, although one had a recurrence three years ago and again one year ago, the other has had no recurrences. This article is illustrated with several cystograms.

Roentgenotherapy in Tumors of the Hypophysis
Karl Frik. Strahlentherapie, Oct 24, 1931, XLII,
437-452

The author reports six cases of hypophyseal tumor which were treated by roentgen rays. The first

case was that of a man, 61 years of age, whose symptoms started two years before he came to the clinic. He had attacks similar to epilepsy, and suffered from loss of memory and insomnia. Besides, there were acromegaly, polydipsia, and polyuria as well as disturbances of the vision. Following two series of deep therapy the acromegaly remained stationary, he had no further attacks, much less headache, and there was considerable improvement of the polydipsia and polyuria. This improvement has lasted, so far, for one and one-half years.

The second case was that of a man, 38 years of age, whose symptoms had begun eighteen months before. He had headache, disturbance of vision, polyuria, and acromegaly. Already, after one series of treatments, he was so much improved that he could resume his work as a taxi driver. Six months later the headache recurred but disappeared following a second series. He has been well now for one year and five months.

The third case was that of a man, 47 years of age, whose symptoms dated back one-half year. He had symptoms in the eyes, headache, right amaurosis, left temporal hemianopsia. The pathology in the right eye could not be influenced and that in the left remained unchanged for a long time. The headache was, however, improved following the first series of treatments. Definite improvement in the left field of vision occurred recently, over two years following the treatment and after five series. The improvement still remains now, three and one-half years after the first exposure. The recurring headache could be eliminated by a sixth series of treatments, two and one-half years before the date of this report.

The fourth case was that of a man, 40 years of age, who had his first symptoms two years before the treatment. His principal disturbances were of vision and memory. Roentgenologically a hypophyseal tumor could be demonstrated. Biopsy showed adenoma. Four weeks after the first series of treatments he could resume his duties as a police sergeant. The improvement lasted for one-half a year, during which time a second series was given. Headache, vertigo, and disturbances of the vision could be improved by a third series, and the patient has remained able to work for one year and three months.

The fifth case, a man, 39 years of age, had symptoms for a year and a half, with a preponderance of disturbances of the vision. Roentgenologically, there was a large hypophyseal tumor, with destruction of the neighboring tissue. Biopsy showed adenoma. After one series of treatments there was considerable improvement and after a second series the patient resumed his work and has been well now for two years.

The sixth case was that of a woman 65 years of age, with symptoms for only three months. The chief complaint was that of loss of eyesight. This

Another pathologic condition seems to have arisen among the employees who swallowed radio-active paint. Since 1928, rapidly growing sarcomas have appeared in at least eight cases. In the early cases, mesothorium, which is physiologically more active than radium, predominated, but enough time has elapsed since their exposure to allow the mesothorium to diminish in quantity by its own natural decay to below half its former strength. In the late cases which have resulted fatally, only radium has been detected and this has accumulated in the bony skeleton. Destructive bombardment in the bones produces pathologic changes, giving rise to an anemia and to radiation osteitis, in these areas sarcomas later arise.

Many of the radio-active substances sold to the public may be dangerous to health. The drinking of radio-active waters, containing radon, over long periods of time should be discouraged. Martland likewise cautions against the intravenous injection of long-lived radio-active elements.

The water actually contains a small quantity of the element Ra itself besides much CO₂. The water possesses properties which appear to benefit gastric and intestinal disorders, metabolism disturbances, and other ills.

CHEMICAL ABSTRACTS

Focal Infection Duncan Graham Canadian Med Assn Jour, October, 1931, XXV, 422-424

A large percentage of the patients one sees in both hospitals and consultations suffering from subacute or chronic disease give a history of earlier treatment for the removal of foci of infection. While it is true that many of them have been definitely helped, one is impressed by the fact that the removal of a focus or foci of infection has resulted only too often in little or no improvement in the general health of the patient. Occasionally his disability has been increased. The chief reasons for this are (1) An inadequate appreciation of the causal relation of focal infection to various chronic conditions, (2) an incomplete diagnosis, and, therefore, an incomplete plan of treatment for the individual patient, (3) a lack of co-operation in both diagnosis and treatment between the physician in charge of the patient and the medical or dental specialist who removes the foci, (4) an inadequate follow-up of patients under treatment.

The author discusses the subject from these four standpoints and urges co-operation between the attending physician and the specialist in the examination of the eye, ear, nose, and throat, the gums and teeth, and in the interpretation of X-ray findings, in making a complete diagnosis and outlining a complete treatment.

Simply finding a focus of infection and removing it is not sufficient. By the time a patient consults his physician the effects of a focal infection are seldom restricted to the focus itself. In the treatment of a patient with a badly infected tooth or tonsil, it is not simply a question of its removal. A more important question is the possible existence of systemic disease or metastatic infection, either the result of the focus or co-existent with it. The specialist should call in the physician and the two should co-operate in the search for all the avenues of disease. Only the combined treatment of all the phases of the disease in the individual patient can bring satisfactory results. And only the careful follow-up of the patient can guard against future ill-results not possible of anticipation at the time of the original treatment. An incomplete recovery is always an indication that some avenue of disease has been unexplored at the original date of treatment, and re-investigation is required.

L J CARTER, M D

How We can Meet the Cancer Problem Henry J Ullmann Am Jour Roentgenol and Rad Ther, November, 1931, XXVI, 726-728

The hopelessness with which many people, both among the medical profession and the laity, consider the entire cancer problem should be actively combated, first, because the number of cures is definitely although slowly increasing, and second, because much more than the mere administration of morphine can be done to afford a variable period of relief for cases beyond the possibility of cure. A panacea or specific cure is being eagerly sought by many, but in the opinion of the author it is unlikely that a specific one, applicable to all forms of malignancy, will ever be found.

At the present time, at least, monies made available for cancer work should be devoted to the organizing of the members of the profession in all localities for the early and accurate diagnosis of the disease. Elaborate and costly facilities for most effective therapy should be for the present mobilized in the larger centers where research activities would also be carried on. Continuous effort along the latter line is very essential, but in the meantime every facility for either cure or amelioration should be available to those actively suffering from the disease.

Inhibition of Growth *in Vitro* of Neoplastic Tissue by Methylene Blue Sensitized by Exposure to Ultra-violet Light. A H Roffo Bol Inst Med Exp, December, 1930, VII, 950-969 (Reprinted from "Cancer Review" by permission)

Previous experiments having suggested that in malignant growth the normal oxidation-reduction relation is disturbed, the author experimented with methylene blue in order to ascertain the influence of an oxidizing agent on this relation. His experiments were made with cultures of chick embryo heart muscle and spindle-celled rat sarcoma. In each case one series of cultures was exposed to ultra-violet light before being incubated, a second was grown in plasma containing methylene blue, a third in methylene blue, but also exposed to ultra-violet rays (the effect of which is to sensitize, or accelerate the action of methylene blue), and a

fourth served as controls. In the culture containing methylene blue and exposed to ultra-violet rays, there was total inhibition of growth, but normal growth occurred in the media treated with methylene blue alone or ultra-violet rays alone.

The conclusion is drawn that the inhibition was due to the oxidizing properties of the sensitized methylene blue

F CAVERS, D Sc.

The Effect of Roentgen Rays on Cholesterol Metabolism H Hoehne Arch Gynäkol, 1931, CXLVI, 41-50

In twenty-three of twenty-five instances carcinoma patients after irradiation with X-rays showed a decrease in cholesterol in the blood serum and carcinoma-free patients an increase in cholesterol. The two atypical cases in which carcinoma-free patients gave a decrease in cholesterol were a case with severe inflammatory conditions and a case in which a carcinoma of the uterus had been removed by operation some months before without recurrence. X-rays of relatively long wave length had more effect on the cholesterol content than those of relatively short wave length

Roentgenologic Studies at the Bedside Walter H Ude. *Journal-Lancet*, Aug 15, 1931, LI, 521-528

While bedside roentgenographic work finds its widest application in the study of the bony framework in connection with fractures, the method has other uses also. Very satisfactory chest films can be made, though fine detail is lost because of time of exposure required, but in cases of pneumonia, pleural effusion, or post-operative complications, it is very valuable. Bedside films of the abdomen may be of great help, especially where bowel obstruction is suspected. Several other types of lesions can often be advantageously examined with the bedside unit.

W W WATKINS, M D

Blood Cultures and Focal Infections An Experimental Study with One Hundred Healthy Adults Gordon C Cameron, C A Rae, and George N Murphy *Canadian Med Assn Jour*, August, 1931, XXV, 131-134

The fact that the blood stream of the healthy animal is normally free of bacteria is such a fundamental in our conception of infection that we accept it with little more than a passing thought. It is noteworthy, however, that records of studies to establish this fact are very difficult to find. Our assumption is based upon the fact that in ordinary practice we obtain many negative cultures of blood and when we do encounter positive cultures they are usually of serious import. There is much evidence, however, to indicate that pathogenic organisms do invade the blood stream without necessarily indicating disaster and without the production of significant symptoms. It is felt that one of the most definite indications of this is the frequent occurrence of osteomyelitis of a suppurative type from which staphylococci are obtained and which could result only from hematogenous infection. Also, the not infrequent experience of finding staphylococci or similar micrococci in blood cultures in hospital laboratory practice leaves one in doubt as to whether these organisms are contaminants or potential pathogens. Then, too, one encounters other organisms variously described as "diphtheroids" and "pleomorhic non-hemolytic streptococci," which do not induce disease of serious import.

In view of these considerations it was felt that information might be obtained by performing blood cultures on a large group of persons in good health. This report, therefore, conveys the findings of such an experiment carried out upon 100 students of the Faculty of Dentistry, University of Toronto, who volunteered to submit themselves for blood culture. These subjects were all young men between the ages of 20 and 26 years. An interrogation regarding

the present health and previous experience of disease was conducted and an inspection of the nose, throat, and ears of each was carried out, as well as a detailed examination of the teeth, which included X-ray examination of the full mouth. Complete physical examinations were not made, as it was felt that they would be superfluous in view of the uniformly good histories.

For the sake of uniformity in the investigation, the culture medium was all pooled before its final titration, and the blood cultures, and ear, nose, and throat inspections were all performed on the same day. The technic employed is given in detail.

The results were as follows. Of 100 cultures, 81 remained negative. The discussion must center about the remaining nineteen. Twelve of these were indisputably contaminants. The organism was, in all cases, a spore-forming bacillus. Of the remaining seven, one was evidently an air-borne contaminant. Of the six positive cultures, four were characteristic *Staphylococcus aureus*. The other two were diphtheroids.

With a view to investigating whether or not those who yielded positive cultures were constant harbo-
ters of organisms in their blood streams, new cultures were made about six weeks after the first. These second cultures all remained negative for a month.

Regarding dental examination, there were 25 cases in which the X-ray revealed apical disease in from one to four teeth. These 25 cases all gave negative cultures. None of the six with positive blood cul-
tures showed any tooth abnormality.

Regarding the ear, nose, and throat examinations, there were only 18 cases free of some evidence of inflammation. In only two were the ears involved, and they showed chronic suppurative disease of the middle ear or mastoid cells. One case with a positive culture had a muco-purulent discharge from the nose.

L J CARTER, M D

Personal Experiences with Pyelography C. F Heider *Nebraska St Med Jour*, October, 1931 XVI 385-389

This paper aims to impress on the general practitioner the importance of the pyelogram and ureterogram in the diagnosis of lesions of the upper urinary tract. During the pioneering days of pye-
lography, there were many accidents and some deaths. With the development of proper technic there is now little danger, and contra-indications to the procedure are few, acute infection and marked renal insufficiency being the main ones. The technic of retrograde pyelography and intra-venous urography are given, and slides showing a variety of lesions are reproduced as illustrations in the article.

W W WATKINS, M D

The Etiopathogenesis of Ossifications in Operative Scars E Ruggieri L'Ateneo Parmense (Suppl.), 1931, III, 84-107

The author reports a case of ossification of a scar from laparotomy, which he studied clinically and radiologically. The radiologic examination brought into evidence a niche corresponding to the pylorus on the incline of the lesser curvature, but revealed no signs of neostomy. The radiographs, taken along the anteroposterior axis, showed no manifestations referable to a hard formation of the scar.

Cases of this nature are by no means infrequent, and from the literature on the subject and from his own case the author formulates the following conclusions:

(1) Ossifications of surgical scars, like practically all other heterotopic ossifications, are manifestations of a metaplasia of the connective tissue.

(2) There is no specific etiologic agent present.

(3) The connective metaplasia is based on a defect in local circulation and on the presence, in the immediate neighborhood, of a calcareous deposit which acts simultaneously as a metaplastic stimulus and as material for induration.

(4) The predilection of post-operative ossifications for the median xiphо-umbilical abdominal tract seems due to the natural scarcity of the local blood supply.

Roentgen Diagrams of Human Tissues and Concrements E Saupe Fortschr a d. Geb d. Röntgenstr, August, 1931, XLIV, 204-211

This is a brief review of the most important publications on the subject, showing reproductions of diagrams of several tissues and concrements.

Roentgeniography is used to investigate the molecular structure of tissues (substances in general), thus reaching beyond the limits of microscopy (spectral analysis and crystallography).

HANS A JARRE, MD

CHEMICAL ABSTRACTS

Ultra-violet Irradiation and Catalase Hans Koeppen Arch f Kinderh., 1929-1930, LXXXIX, 1-72

I The Decomposition of Hydrogen Peroxide by Blood — The author studied the liberation of O_2 from H_2O_2 by blood catalase, varying the quantities used, and measuring the O_2 set free and the rates of liberation under different conditions. He found that a definite amount of blood, with a definite catalase content, has a definite H_2O_2 -decomposing power or

energy. This energy can accomplish a definite amount of work. The time required varies with the intensity and the resistance to be overcome. The energy is exhausted in time, converted into work.

II The Decomposition of Hydrogen Peroxide by Ultra-violet Irradiation — Using a similar closed system for measuring O_2 set free from H_2O_2 , the author found that irradiation with ultra-violet light liberates O_2 . With equal intensities of irradiation, the amounts of O_2 set free are the same, for unit periods. Consequently, by standardizing the cell containing H_2O_2 , and by using a standard strong solution, it is possible to measure the intensity of radiation of the quartz lamp.

III The Decomposition of Hydrogen Peroxide by Heat — Heating of H_2O_2 liberates O_2 . Gas bubbles appear at 50°, and the maximum effect is between 60° and 70°. With the quartz lamp the highest temperatures found were from 43° to 45°. Much higher temperatures were found with other types of lamps. It is necessary to exclude the effect of heat in estimating the intensity of radiation by the H_2O_2 method.

IV The Function of Catalase — Catalase takes the O_2 from the oxyhemoglobin of the blood, and unites it to the fatty envelope of the red blood cell. In other words, oxyhemoglobin is reduced by the action of catalase, while the fatty envelope is oxidized.

V The Force Effecting the Decomposition of Hydrogen Peroxide — The author recognizes the oxidative potentialities of ultra-violet light, and thinks that catalase may be a storehouse or accumulator for radiant energy. Investigations on the catalase of blood and milk indicate that catalase belongs, in the widest sense, to the group of materials essential for life.

A New Application of the Differential Filter Method for the Production of Monochromatic Roentgen Rays Hans Kustner Ztschr f Physik, 1931, LXX, 468-491

The author has suggested a method to produce monochromatic roentgen rays by using the secondary radiation produced by roentgen rays in certain selected substances. By employing the same filter in the direct roentgen beam and then in the secondary radiation beam the difference of intensity measured gives the relatively strong characteristic radiation of the beam of the secondary radiation. The two alpha lines can be separated by placing a selectively absorbing filter into the beam of the secondary radiation. By this method monochromatic rays can be produced in the range between 25 and 0.128 Å. units. Several important applications of this method are presented.

OTTO GLASSER, Ph D

The Grating Constant of Calcite Crystals J A Bearden Phys Rev, Dec 15, 1931, XXXVIII, 2089-2098

The precise methods of measuring X-ray wave lengths, now in use, raise two important questions concerning the crystal grating used. First, what variation in the grating constant is to be expected for crystals grown under different conditions? Second, what is the most accurate value of the grating constant? Since calcite crystals are the most used crystals in X-ray spectroscopy, the present work was undertaken to answer as well as possible the above questions for this crystal. The variations in the grating constants of six calcite crystals from four sources (Iceland, Montana, Argentina, and Spain) have been determined by measuring the angle of diffraction for the molybdenum $K\alpha_1$ line in the fourth order. A high precision 2-crystal spectrometer was used for measuring the diffraction angles. The results are given in the table below. The density of these crystals was then carefully determined. From six to nine independent determinations were made at a temperature of $20.00 \pm 0.01^\circ C$. The averages of these values are given for a temperature of $20.00^\circ C$, in the fourth column of the table. The probable error determined by the method of least squares is given in the fifth column. The mass of the crystals used in determining the density is given

The Photographic Action of the Electrons Released by X-rays K Schocken and L Grebe Phot Korr, 1931, LXVII, 21-23

It is known that an intensification of the action of X-rays may be brought about by placing a thin sheet of metal over the photographic film. This is due to liberation of secondary electrons. With thin sheets of Al, Cu, and Pb, and Zeiss Ikon film from a film pack, the authors have found that the electron action increases with increasing frequency of the rays. An experiment in which a thin plate of celluloid was interposed showed that the scattered X-rays and the characteristic rays produced have only a slight action as compared with the electrons.

In the sixth column Considering the density measurements of DeFoc and Compton, the writer gives the density ρ in g/cm⁻³ at $20^\circ C$ as $\rho = 2.71030 \pm 0.00003$. The crystals were then chemically analyzed. The results showed that all samples contained about 0.01 per cent ferrous oxide, 0.01 per cent manganese oxide, and 99.98 per cent calcium carbonate. The angle between the cleavage faces of the calcite crystals was determined by three methods. X-rays were used for determining the angle in the first two methods and an optical method for the third. The results for $20^\circ C$ were $\alpha = 105^\circ 3' 29''$ or $\beta = 101^\circ 54' 4''$, where α is the interior obtuse dihedral angle, and β the angle between the edges of the crystal. The grating constant of the crystal can be calculated from the equation $d = (\pi M / \rho N\phi)^{1/2} = 3.02816 \text{ \AA}$ at $20^\circ C$, $= 3.002810 \text{ \AA}$ at $18^\circ C$. The values of the constants used were, $n = 1/2$, $M = 100.078$, $\rho = 2.71030$, $N = 6.0669 \times 10^2$, $\phi = 1.09594$.

THE AUTHOR.

Taking this into account, the general expression for the intensity of total scattering of X-rays by polyatomic gases previously deduced by the writer is modified, replacing F by F' . The theory is applied to the scattering of X-rays by diatomic gases and the theoretic scattered intensity is actually compared with the absolute measurements made by Wollan on the scattering of Mo $K\alpha$ rays by H₂, N₂, and O₂. The values of F and F' are calculated from the Hartree field. On the whole, Wollan's results support the new formula, though the old one represents in each case the general feature of the scattering curve. It is pointed out that, for the scattering by a diatomic gas of like atoms, Jauncey's theory of the scattering of X-rays by polyatomic molecules consisting of atoms of one kind gives results practically identical with those of the present theory, provided the change of wave length due to the Compton effect is corrected for.

THE AUTHOR.

The Absolute Determination of the r-unit in the Range of Radium Rays Erich Albrecht Strahlen-therapie, Oct. 3, 1931, XLII, 328-336

The author discusses first the general principles of a large barrel ionization chamber and its possible use for the measurement of gamma-rays in r. Wall material is only equivalent to air for this purpose, if the same number of photo and Compton electrons are produced and if these electrons are absorbed exactly as in air. Measurements in the gamma-ray region with the large chamber are dependent upon its diameter and also upon its length. As far as the wall material is concerned, it must have a very definite thickness which has to be determined experimentally for each material. This is of great importance in the standardization with radium according to Solomon's method. Comparative measurements by means of chambers with improper wall thickness will lead to erroneous results. Small ionization chambers can be calibrated against large barrel chambers of proper construction and the isodoses for radium preparations then determined in r.

ERNST A. POHLE, M.D., Ph.D.

The Demonstration and the Intensity of the Mitogenetic Radiation—I H. Schreiber and W. Friedrich Biochem Ztschr., 1930, CCXXVII, 386-400

In an attempt to find a physical detector for the mitogenetic radiation, the authors studied the effect from cultures of *Saccharomyces ellipsoideus* with the photo-electric method, using the Elster and Geitel charging method and registering the string deflections of an electrometer with a photographic arrangement. In twenty-six experiments no positive effect could be detected. The authors call attention to the difficulties in interpreting the results obtained with biological detectors of mitogenetic radiation, and feel that the methods of using various ranges of the spectrum of artificial light sources to produce mitogenetic effects similar to those produced by tissue have led to erroneous conclusions. There are numerous discrepancies in the mitogenetic literature and it seems desirable to carefully go over the reports in order to possibly find and remove sources of error in the various measurements reported.

OTTO GLASSER, Ph.D.

Photo-electric Cells Vereinigte Telephon- und Telegraphenfabriks A.-G. Czeija, Nissl and Co Austrian patent 124,891, May 15, 1931

To deposit an active layer of alkali metal inside the cell, the latter is immersed in a bath of fused

alkali metal salt, and is also partly filled with the fused salt. Electrolysis is then effected so as to cause metal ions to pass from the salt inside the cell into the glass wall of the cell, and the salt in the cell is then removed, the cell replaced in the bath, and electrolysis effected in the reverse direction, so as to drive the alkali metal to the inner surface of the cell. A filament in the cell may act as electrode in the second electrolysis, and prior thereto, the cell may be evacuated and may also be coated inside with Mg by vaporization.

CHEMICAL ABSTRACTS

The Distribution of Radio-active Substances in the Air Josef Priebsch Physik Ztschr., 1931, XXXII, 622-629

An error is found in previous calculations of the distribution in the air of radio-active substances from the earth, which were made by Schmidt and apparently confirmed by the observations of E. Schmid (*Wien Sitzber.*, 1931, IIA, 27-48). The author points out that the observations of Schmid were made in the Graz basin where abnormal air conditions exist. The author also thinks Schmidt assumes too quick a decrease of radio-activity with height and makes new calculations. He obtains values between those of Schmidt and the earlier values of Schmidt and Hess.

CHEMICAL ABSTRACTS

Shadow Photography by, and the Longitudinal Scattering of, Radiant Heat I Plotnikov Phot Korr., 1931, LXVII, 6-10

In radiography by means of red or infra-red rays with any considerable thickness of material, there is often troublesome scattering, this is considered to be connected with reversible transformations in complex molecules. The periodic variation in the scattering of near ultra-violet radiation by pure water, sugar solution, etc., is also described.

CHEMICAL ABSTRACTS

A Heating Arrangement for X-ray Samples G. Wassermann Metallwirtschaft, 1931, X, 922, 923

Disadvantages of other methods are overcome by heating the sample in the stream of an inert gas which has been heated outside of the X-ray apparatus. The sample is mounted vertically in a small porcelain tube, and the gas flows from a cylinder through a furnace and then through a short movable glass tube at right angles to the sample. On the opposite side of the sample, another glass tube of larger diameter is mounted, through which the gas is removed by suction. The distance of the two

glass tubes from the sample can be closely adjusted. The thermocouple for determining the temperature of the sample is placed in the exit tube. Advantages of this method are accessibility of the sample by moving the glass tubes, adjustment of the temperature by varying the gas pressure, and accuracy of temperature measurement.

CHEMICAL ABSTRACTS

Variation in the Effective Lattice Constant of Crystals with Wave Lengths J M Cork. Phys Rev, Jan 15, 1932, XXXIX, 193-196

This investigation is carried out to determine to what extent X-ray wave lengths determined by a calcite crystal are consistent over a considerable wave length range where the refractive index is known to vary. To this end the reflection angles for particular emission wave lengths up to 5.5 Å are observed using a quartz crystal. These angles are combined with corresponding values obtained with calcite. The values for $\log(\lambda_{\text{calcite}})/2 \sin \theta$ (quartz) when plotted with wave length, assuming $(1-\mu)/\sin^2 \theta$ constant for quartz, result in a curve showing the variation due to calcite. A discontinuity exists at the wave length of the K absorption edge for calcium. The nature of the curve is in agreement with a similar one obtained by Larsen from measurements of the index of refraction. The discontinuity is in the sense to be expected from

the dispersion theories of Kallmann and Mark and Kronig. Assuming quartz as ideal in the range of from one to five Angströms, measurements with a calcite crystal are not inconsistent by as much as one-third of one-tenth of a per cent.

THE AUTHOR

Experiments on a Lenard-Cooledge Tube. Wolfgang Gentner. Ann d Physik, 1931, X, 223-243

A cathode ray tube of the Müller Company, in Hamburg, which was continually connected to the evacuating pumps, was used on the valve tube apparatus producing 210 K.V and 4 milliamperes. A broad spectrum of electron velocities was found which is due to the pulsating tension and to the velocity changes in the tube window. The determination of the practical range of cathode rays in aluminium showed a continuous change from slow to very fast cathode rays. In addition to the cathode radiation a very intense roentgen radiation was observed at the tube window. By means of a coil through which a current could be sent the intensity of the cathode-ray beam was concentrated to several times its original value while the roentgen-ray intensity was not changed by this arrangement. The effect of the cathode rays upon a number of materials was studied.

IRRADIATION IN THE TREATMENT OF HYPERTHYROIDISM¹

By GEORGE E PFAHLER, M.D., Sc.D., PHILADELPHIA, PENNSYLVANIA
Professor of Radiology in the Graduate School of Medicine of the University of Pennsylvania

THE importance of hyperthyroidism is indicated by the fact that a great medical organization such as this is devoting an evening to the discussion of its treatment. The fact that you are considering the subject from the standpoint of surgical, roentgenologic, and medical treatment indicates that good results have been accomplished by each method. Four phases of this subject, then, remain for discussion:

1. Is any one method so much superior to others as to make it applicable to all cases, with the abandonment of the other two?

2. Shall the cases be selected according to the indications found in the individual patient?

3. Shall all three methods be combined?

4. What shall be done when any one, or all, of the three methods fails?

It is a great honor and also a great responsibility that has been given me to reply to these queries from the standpoint of the radiologist, whose branch of medicine is very young. As Christie has pointed out, it was about thirty years before the value of the surgical treatment was recognized by the internists, and now, after nearly thirty years, the value of radiologic treatment is being recognized. Each group of practitioners has been called upon to treat the fail-

ures of the others. This has given each of us in turn a sense of superiority, or of humility. But this vacillation probably only demonstrates our general lack of knowledge in the selection of the cases, our lack of skill in the application of the method of treatment, or our fault in not making use, at the proper time, of two or three of these methods.

In dealing with hyperthyroidism, we must assume that the patient has an excess of secretion from the thyroid gland, either because of an over-production of the glandular tissue, or because of an over-activity of the normal amount of glandular tissue. The internist aims to reduce the activity by rest and medication, thus reducing the irritability of the gland. The surgeon reduces the activity by cutting off part of the blood supply, or by removing part, or all, of the gland. And the radiologist aims to reduce the secretion both by the reduction of the hypertrophy and by decreasing the activity of the secreting cells. When a patient is under irradiation treatment, the hyperactivity of the cells is first reduced, as is shown by the clinical observation that the symptoms of thyrotoxicosis disappear more rapidly than the goiter.

In 1923, Weil found that, because of the enormous richness in capillaries, the circulation for 100 gm of the thyroid gland is 500 c.c. of blood per minute, while for the same

¹Presented by invitation, March 16, 1932, before the Bronx County Medical Society, N.Y., in a symposium on hyperthyroidism.

IRRADIATION IN THE TREATMENT OF HYPERTHYROIDISM¹

By GEORGE E PFAHLER, M.D., Sc.D., PHILADELPHIA, PENNSYLVANIA

Professor of Radiology in the Graduate School of Medicine of the University of Pennsylvania

THE importance of hyperthyroidism is indicated by the fact that a great medical organization such as this is devoting an evening to the discussion of its treatment. The fact that you are considering the subject from the standpoint of surgical, roentgenologic, and medical treatment indicates that good results have been accomplished by each method. Four phases of this subject, then, remain for discussion:

1. Is any one method so much superior to others as to make it applicable to all cases, with the abandonment of the other two?

2. Shall the cases be selected according to the indications found in the individual patient?

3. Shall all three methods be combined?

4. What shall be done when any one, or all, of the three methods fails?

It is a great honor and also a great responsibility that has been given me to reply to these queries from the standpoint of the radiologist, whose branch of medicine is very young. As Christie has pointed out, it was about thirty years before the value of the surgical treatment was recognized by the internists, and now, after nearly thirty years, the value of radiologic treatment is being recognized. Each group of practitioners has been called upon to treat the fail-

ures of the others. This has given each of us in turn a sense of superiority, or of humility. But this vacillation probably only demonstrates our general lack of knowledge in the selection of the cases, our lack of skill in the application of the method of treatment, or our fault in not making use, at the proper time, of two or three of these methods.

In dealing with hyperthyroidism, we must assume that the patient has an excess of secretion from the thyroid gland, either because of an over-production of the glandular tissue, or because of an over-activity of the normal amount of glandular tissue. The internist aims to reduce the activity by rest and medication thus reducing the irritability of the gland. The surgeon reduces the activity by cutting off part of the blood supply, or by removing part, or all, of the gland. And the radiologist aims to reduce the secretion both by the reduction of the hypertrophy and by decreasing the activity of the secreting cells. When a patient is under irradiation treatment, the hyperactivity of the cells is first reduced, as is shown by the clinical observation that the symptoms of thyrotoxicosis disappear more rapidly than the goiter.

In 1923, Weil found that, because of the enormous richness in capillaries, the circulation for 100 gm of the thyroid gland is 500 c.c. of blood per minute, while for the same

EDITORIAL OF THE INTERNATIONAL SOCIETY OF RADIOLOGY

Dr. HERBERT S. BEAUMER M.D., B.Sc., F.R.C.P., F.R.C.S.,
Professor of Radiology at the Harvard School of Medicine, Boston, Mass., U.S.A.

The importance of hyperthyroidism is indicated by the fact that a great medical problem such as this is worthy of entering in the discussion of its treatment. The fact that we are considering the subject from the standpoint of surgical, endocrinologic and medical treatment indicates that good results have been accomplished by each method. But perhaps it is easier than difficult to discuss.

It is any one method's, much simpler if there is to make it applicable to all cases with the development of the other methods.

1. Shall we use levothyroxine? In the United States and in the American Hospital?

2. Shall all three methods be used? - That shall be true that any one of all of the three must be used.

It is a great benefit and also a great responsibility that has been given me to write a short article from the standpoint of the physician. This branch of medicine is developing as fast as has general medicine. In the last thirty years has re the value of the medical treatment the recognition by the physician, and now, the result of this work, the following treatment is very important. But some of your writers as you will agree with me think that the thyroid gland is the best treatment for the

cases of one disease. This has great merit, as it can be seen a source of superactivity or overactivity. But this medication is really not necessary in general and it has to be in the selection of the cases. It does not help in the application of the thyroid. I recommend it to you in one situation and at the proper time if it is true that it does help.

In writing this hyperthyroidism, we must assume that the patient has an excess of secretion from the thyroid gland either because of an enlarged gland or the stimulation of the thyroid because of an overactivity of the thyroid or an overactive tissue. The physician aims to reduce the activity of the gland and therefore thus reducing the sensitivity of the gland. The doctor reduces the activity by cutting a part of the thyroid, saying it by removing part of it, if the gland and the surrounding cells to reduce the sensitivity of the gland and to decreasing the activity of the surrounding cells. When a patient is under treatment a reduction the sensitivity of the cells is first reduced as is shown in the figure illustrating that the sensitivity of the thyroid is lowered more rapidly than the gland.

In 1922, I had found the function of the thyroid glands to be normal, the diameter of 17 mm. of the thyroid gland is 5% to 15% of the normal value for the same

IRRADIATION IN THE TREATMENT OF HYPERTHYROIDISM¹

By GEORGE E PFAHLER, M.D., Sc.D., PHILADELPHIA, PENNSYLVANIA

Professor of Radiology in the Graduate School of Medicine of the University of Pennsylvania

THE importance of hyperthyroidism is indicated by the fact that a great medical organization such as this is devoting an evening to the discussion of its treatment. The fact that you are considering the subject from the standpoint of surgical, roentgenologic, and medical treatment indicates that good results have been accomplished by each method. Four phases of this subject, then, remain for discussion:

1. Is any one method so much superior to others as to make it applicable to all cases, with the abandonment of the other two?

2. Shall the cases be selected according to the indications found in the individual patient?

3. Shall all three methods be combined?

4. What shall be done when any one, or all, of the three methods fails?

It is a great honor and also a great responsibility that has been given me to reply to these queries from the standpoint of the radiologist, whose branch of medicine is very young. As Christie has pointed out, it was about thirty years before the value of the surgical treatment was recognized by the internists, and now, after nearly thirty years, the value of radiologic treatment is being recognized. Each group of practitioners has been called upon to treat the fail-

ures of the others. This has given each of us in turn a sense of superiority, or of humility. But this vacillation probably only demonstrates our general lack of knowledge in the selection of the cases, our lack of skill in the application of the method of treatment, or our fault in not making use, at the proper time, of two or three of these methods.

In dealing with hyperthyroidism, we must assume that the patient has an excess of secretion from the thyroid gland, either because of an over-production of the glandular tissue, or because of an over-activity of the normal amount of glandular tissue. The internist aims to reduce the activity by rest and medication, thus reducing the irritability of the gland. The surgeon reduces the activity by cutting off part of the blood supply, or by removing part, or all, of the gland. And the radiologist aims to reduce the secretion both by the reduction of the hypertrophy and by decreasing the activity of the secreting cells. When a patient is under irradiation treatment, the hyperactivity of the cells is first reduced, as is shown by the clinical observation that the symptoms of thyrotoxicosis disappear more rapidly than the goiter.

In 1923, Weil found that, because of the enormous richness in capillaries, the circulation for 100 gm of the thyroid gland is 500 c.c. of blood per minute, while for the same

¹Presented by invitation March 16, 1932 before the Bronx County Medical Society, N.Y., in a symposium on hyperthyroidism.

quantity of kidney it is only 100 c.c., and for the inactive musculature only 12 c.c. per minute. This gives the reason for the enormous amount of toxin which can escape into the blood in a short time.

By transplanting particles of the thymus gland of patients suffering from Basedow's disease, Bircher, also in 1923, was able to produce typical Basedow's disease in dogs. This indicates that not only the thyroid, but also the thymus, is involved in Basedow's disease, explaining why it is necessary for us to include this gland area in our treatment.

It has been found that over-active glandular tissue is more sensitive to irradiation than normal. The fact that normal glandular tissue is not easily affected by the rays explains, in part, why we very rarely observe hypothyroidism after our treatment. For example, Ivy, Orndoff, and others found that it took about six human erythema doses to depress the functions of the submaxillary gland in the dog. This is about twice the amount of the total irradiation given for hyperthyroidism in from six to eight months, instead of one dose as was given to the dogs. We have proof also of the resistance of the normal thyroid tissue in the fact that the enormous amount of irradiation given in the treatment of carcinoma of the larynx is not followed by hypothyroidism.

Walter, Anson, and Ivy² state that the experimental literature at hand indicates that normal thyroid tissue is resistant to X-rays, and conclude from their own studies that "the normal thyroid of the dog is quite resistant to X-rays and degenerative changes are not caused by the dosage used in the experiments, which is a dose known to be of some clinical value," and "in the dosage used do not cause extensive proliferation of connective tissue. The results indicate that the clinical dosage in the

treatment of hyperthyroidism will not injure the parathyroids" None of our patients treated by irradiation has shown any tetany.

It would seem logical that the internist's services would be most valuable, no matter whether a patient is treated by surgery or irradiation. Therefore, when the internist has removed the causes and physiologic rest is not sufficient, then either surgery or irradiation, and sometimes both, must be used.

When surgery seems advisable, one must overcome the objection to operation, the patient must be hospitalized, there are added the shock and risks of an operation, and the surgeon must guess as to how much glandular tissue he shall remove. The more expert surgeon, who has the greatest skill and the keenest judgment, will obtain the best results, for he will know best how much to excise and will do it with the least risk and shock.

When irradiation is decided upon, there is no pain, no discomfort, no shock. With modern skill there should be no risk, and certainly no deaths, due to the treatment. Only rarely need the patient be hospitalized. In many of our milder cases, the patient has continued with his, or her, occupation, and yet good results have been obtained.

Surgery has the advantage of producing more prompt results, but this difference is not so great as would at first appear. With irradiation, we usually see some improvement at the end of a month, and very definite improvement at the end of two months. If the surgeon prepares the patient for two weeks before operation, allows him two weeks to recover from the operation, and a month for convalescence, the difference in time is not so great. At the end of these two months, however, we may generally expect a more complete relief of symptoms from surgery than from irradiation, because the surgeon removes the excess of glandular tissue at once, while with irradiation we reduce the hyperactivity and the hypertrophy,

or hyperplasia, gradually. This is a slow and progressive effect.

If the surgeon has sufficient experience, skill, and judgment to remove just the right amount of glandular tissue, then the patient will be entirely relieved of symptoms. But if he removes too little, there will be only an amelioration, and, if he removes too much, hypothyroidism will develop. In other words, the surgeon has one guess, and the radiologist has from five to eight guesses.

For this reason, it is my custom to give one series in which a 40 per cent erythema dose is given over each of four fields, and then to repeat in three weeks, then in four weeks, after which the interval is governed by the amount of relief of symptoms. It is our aim to produce results, but, generally, we require from five to eight series. If, after three or four such series, there is no definite improvement which justifies us in assuming that the patient will get well, an operation should be urged upon the patient. Very few cases have had to submit to operation.

This naturally raises the question of increased difficulty in operation, when necessary, because of the previous irradiation. There is no theoretic or practical reason for increased difficulty after such an amount of irradiation as indicated above, which involves less than a total of 150 per cent of an erythema dose distributed over a period of three months. When the treatment is carried to the extent of producing a fibrosis, then operation will be made more difficult. It requires more than eight series such as I have described above to produce fibrosis, atrophy, or telangiectasis. In the past, when it was difficult to measure the exact amount of irradiation, or when radiologists failed to take account of the total radiation value, such fibrotic changes were produced. *It is the total amount of irradiation that brings about degenerative changes, whether given in one large dose or many small doses.*

It is the general opinion of radiologists that preliminary irradiation is justified in all cases of hyperthyroidism in which the goiter, if present, is not causing sufficient mechanical pressure or in which the symptoms are not so acute as to make delays dangerous. It has been argued that the delay of two or three months before an operation, if necessary, will lead to damage of the heart. One must realize, however, that it usually takes some time until an operation is decided upon or until the patient will consent. This time can certainly be utilized to advantage by preliminary irradiation. If there is a prompt response, then an operation can be avoided. Holzknecht³ stated that not one case is found in the literature proving that prolongation of the irradiation resulted in unnecessary damage to the heart.

The operations certainly must be confined to those cases in which there is a goiter, whether this be hyperplasia or an adenoma. There are, however, a group of cases of hyperthyroidism in which there is no enlargement of the thyroid, and no palpable tumor. These cases respond to irradiation in the same manner as the goiter cases, furnishing the best proof of hyperactivity of the cells. They also evidence very definitely that irradiation restores such hyperactivity to normal.

In our experience, the toxic adenomas, while they may not entirely disappear, respond to irradiation in the same way as the hyperplastic variety of goiter with hyperthyroidism. Generally, there is at least a reduction. It has been claimed that all adenomas should be removed, because of the danger of later malignant degeneration. Since, however, carcinoma of the thyroid seems to be especially sensitive to irradiation, we may in fact be preventing or curing such early degeneration. In this connection I have been corresponding with Dr. Holmes, Dr. Loucks, Dr. Soiland, Dr. Christie, Dr. Ginsburg, Dr. Orndoff, Dr.

³Guido Holzknecht, Strahlentherapie, 1928, XXX, 605-612

quantity of kidney it is only 100 cc, and for the inactive musculature only 12 cc per minute. This gives the reason for the enormous amount of toxin which can escape into the blood in a short time.

By transplanting particles of the thymus gland of patients suffering from Basedow's disease, Bircher, also in 1923, was able to produce typical Basedow's disease in dogs. This indicates that not only the thyroid, but also the thymus, is involved in Basedow's disease, explaining why it is necessary for us to include this gland area in our treatment.

It has been found that over-active glandular tissue is more sensitive to irradiation than normal. The fact that normal glandular tissue is not easily affected by the rays explains, in part, why we very rarely observe hypothyroidism after our treatment. For example, Ivy, Orndoff, and others found that it took about six human erythema doses to depress the functions of the submaxillary gland in the dog. This is about twice the amount of the total irradiation given for hyperthyroidism in from six to eight months, instead of one dose as was given to the dogs. We have proof also of the resistance of the normal thyroid tissue in the fact that the enormous amount of irradiation given in the treatment of carcinoma of the larynx is not followed by hypothyroidism.

Walter, Anson, and Ivy² state that the experimental literature at hand indicates that normal thyroid tissue is resistant to X-rays, and conclude from their own studies that "the normal thyroid of the dog is quite resistant to X-rays and degenerative changes are not caused by the dosage used in the experiments, which is a dose known to be of some clinical value," and "in the dosage used do not cause extensive proliferation of connective tissue. The results indicate that the clinical dosage in the

treatment of hyperthyroidism will not injure the parathyroids" None of our patients treated by irradiation has shown any tetany.

It would seem logical that the internist's services would be most valuable, no matter whether a patient is treated by surgery or irradiation. Therefore, when the internist has removed the causes and physiologic rest is not sufficient, then either surgery or irradiation, and sometimes both, must be used.

When surgery seems advisable, one must overcome the objection to operation, the patient must be hospitalized, there are added the shock and risks of an operation, and the surgeon must guess as to how much glandular tissue he shall remove. The more expert surgeon, who has the greatest skill and the keenest judgment, will obtain the best results, for he will know best how much to excise and will do it with the least risk and shock.

When irradiation is decided upon, there is no pain, no discomfort, no shock. With modern skill there should be no risk, and certainly no deaths, due to the treatment. Only rarely need the patient be hospitalized. In many of our milder cases, the patient has continued with his, or her, occupation, and yet good results have been obtained.

Surgery has the advantage of producing more prompt results, but this difference is not so great as would at first appear. With irradiation, we usually see some improvement at the end of a month, and very definite improvement at the end of two months. If the surgeon prepares the patient for two weeks before operation, allows him two weeks to recover from the operation, and a month for convalescence, the difference in time is not so great. At the end of these two months, however, we may generally expect a more complete relief of symptoms from surgery than from irradiation because the surgeon removes the excess of glandular tissue at once, while with irradiation we reduce the hyperactivity and the hypertrophy,

²O. M. Walter, B. J. Anson and A. C. Ivy, *Radiology*, January, 1931, XVI, 52-58.

or hyperplasia, gradually. This is a slow and progressive effect.

If the surgeon has sufficient experience, skill, and judgment to remove just the right amount of glandular tissue, then the patient will be entirely relieved of symptoms. But if he removes too little, there will be only an amelioration, and, if he removes too much, hypothyroidism will develop. In other words, the surgeon has one guess, and the radiologist has from five to eight guesses.

For this reason, it is my custom to give one series in which a 40 per cent erythema dose is given over each of four fields, and then to repeat in three weeks, then in four weeks, after which the interval is governed by the amount of relief of symptoms. It is our aim to produce results, but, generally, we require from five to eight series. If, after three or four such series, there is no definite improvement which justifies us in assuming that the patient will get well, an operation should be urged upon the patient. Very few cases have had to submit to operation.

This naturally raises the question of increased difficulty in operation, when necessary, because of the previous irradiation. There is no theoretic or practical reason for increased difficulty after such an amount of irradiation as indicated above, which involves less than a total of 150 per cent of an erythema dose distributed over a period of three months. It requires more than eight series such as I have described above to produce fibrosis, atrophy, or telangiectasis. In the past, when it was difficult to measure the exact amount of irradiation, or when radiologists failed to take account of the total radiation value, such fibrotic changes were produced. *It is the total amount of irradiation that brings about degenerative changes, whether given in one large dose or many small doses.*

It is the general opinion of radiologists that preliminary irradiation is justified in all cases of hyperthyroidism in which the goiter, if present, is not causing sufficient mechanical pressure or in which the symptoms are not so acute as to make delays dangerous. It has been argued that the delay of two or three months before an operation, if necessary, will lead to damage of the heart. One must realize, however, that it usually takes some time until an operation is decided upon or until the patient will consent. This time can certainly be utilized to advantage by preliminary irradiation. If there is a prompt response, then an operation can be avoided. Holzknecht⁸ stated that not one case is found in the literature proving that prolongation of the irradiation resulted in unnecessary damage to the heart.

The operations certainly must be confined to those cases in which there is a goiter, whether this be hyperplasia or an adenoma. There are, however, a group of cases of hyperthyroidism in which there is no enlargement of the thyroid, and no palpable tumor. These cases respond to irradiation in the same manner as the goiter cases, furnishing the best proof of hyperactivity of the cells. They also evidence very definitely that irradiation restores such hyperactivity to normal.

In our experience, the toxic adenomas, while they may not entirely disappear, respond to irradiation in the same way as the hyperplastic variety of goiter with hyperthyroidism. Generally, there is at least a reduction. It has been claimed that all adenomas should be removed, because of the danger of later malignant degeneration. Since, however, carcinoma of the thyroid seems to be especially sensitive to irradiation, we may in fact be preventing or curing such early degeneration. In this connection I have been corresponding with Dr. Holmes, Dr. Loucks, Dr. Soiland, Dr. Christie, Dr. Ginsburg, Dr. Orndoff, Dr.

Stevens, and Dr Portmann Their observations, together with my own, cover over 1,200 cases of toxic adenoma, and none of us has seen a case in which there was found malignant degeneration after irradiation It is likely that, in this number of cases, there were a few in which, if they had been operated upon and examined microscopically, some early malignant degeneration would have been found

Dr A C Ivy, of Chicago, who is doing some excellent research work, writes

We had a young dog with an adenoma of the thyroid on which we did a biopsy and then gave an X-ray series The adenoma disappeared slowly We observed the animal for two years, at the end of which time he was killed No evidence of malignant degeneration was found We wanted to do a large series (10 or 20) of dogs, but did not have funds available That kind of work is quite expensive and dogs are the only animals that quite commonly manifest adenoma of the thyroid spontaneously

Bensley has shown that a high protein diet fed to opossums, when confined to cages, will induce a marked hyperplasia of the thyroid Ivy and his associates have shown that roentgen treatment will prevent this hyperplasia to a considerable extent

Technic—In general, I depend upon the roentgen rays, using the so-called low voltage technic 130 KV, 5 ma, 8 mm at 30 cm distance, filtered through a combination filter of copper and aluminum equal to 6 mm of aluminum With my equipment, this gives 40 per cent of an erythema dose We use two anterior and two posterior fields, each about 5 X 15 cm, to include both the thyroid and the thymus and to expose all parts of the glands equally The larynx and the remainder of the body are protected This series of four doses is given in succession in one day, being repeated in three weeks then in four weeks, increasing the interval according to the improvement

obtained We always aim to give as little as possible, stopping when the basal metabolism falls to +15 or +10

I have not observed an increase of symptoms following the first irradiation Such effects have, however, been observed by others (Pordes, Goette)

We have treated with radium only a few cases which were unsuitable for roentgen therapy Loucks and Ginsburg prefer radium, and have obtained excellent results Surely equally good results can be obtained with radium as compared with X-rays It would seem that radium is preferable for patients who cannot come for treatment, or for whom the excitement caused by the machinery would be harmful In one very acute case in which we applied radium, there was no interruption of the symptoms the patient dying within a few days It was the opinion of all that the patient would have died in the same time if no such treatment had been given

To allay the nervous symptoms, we have been using quinine hydrobromide as recommended by Bram in 5 gr doses, given three times a day during at least the first three weeks It is remarkable, as Bram reports, that these patients can take even larger doses without the symptoms of cinchonism, which would occur in a normal individual We have not found the use of iodine helpful, except in a few cases of exophthalmic goiter in which it was used for a short time It seems to be the general opinion of radiologists that iodine should not be used in conjunction with irradiation Holmes, however, found it useful for a short time Surgeons find iodine useful to prepare for operation, but they do not advise its continuous use

Rest is always helpful and should be carried out so far as is practical In many of our cases the patients have had to continue with their occupations I always advise, however, to get as much rest in bed as is possible, to avoid all unnecessary physical

or mental exertion or excitement, to avoid all stimulants, including tea and coffee, never to stand when they can sit, and never to sit when it is possible to lie down, even for a few minutes. These rules are especially important during the first month.

Results of Treatment.—After all, the final results are what count. Unfortunately, there are at present no large irradiation clinics for hyperthyroid cases, and no comprehensive statistics. But the fact that favorable statistics are gradually accumulating, even with the good results already obtained by surgery, shows that there is value in this method. In a previous paper,⁴ Dr. Vastine and I reviewed the reports of 87 authors.

Krause⁵ has collected 1,342 cases from 31 authors which were reported with sufficient detail to be of value. He found good results on an average in 82 per cent of the cases and poor results in 18 per cent. The general report is that about 65 per cent become symptom-free and remain well, approximately from 15 to 20 per cent more are improved and return to their occupations, and from 10 to 20 per cent do not improve.

The record of my private cases treated for hyperthyroidism have been reviewed for me by my associate, Dr. Jacob H. Vastine. The hospital cases have been more difficult to follow and, therefore, they are not included. The results may be stated briefly as follows:

TABLE I.—SUMMARY OF CASES TREATED

| | |
|---|-----|
| Cases with hyperthyroidism treated with roentgen rays | 361 |
| Cases treated with radium | 4 |
| Non-toxic cases treated | 50 |
| Malignancies | 26 |
| Total cases treated | 441 |
| Simple or non-toxic goiters in which we advised against irradiation, which were not treated | 153 |
| Total | 594 |

⁴G. E. Pfahler and J. H. Vastine, Am. Jour. Roentgenol. and Rad. Ther., October 1930, XXIV, 395-411.

⁵P. Krause Strahlentherapie, 1927, XXVII, 393-412.

Under *hyperthyroidism*, or *thyrotoxicosis*, we have classed all exophthalmic goiters, all toxic adenomas, and those which had a high basal metabolism associated with the characteristic nervous symptoms, even when no goiter and no exophthalmos are present.

We have *classed as cured* those cases in which the basal metabolism, taken routinely since 1921, is between +10 per cent, and —10 per cent, the pulse has returned to normal, the weight has increased, approximately, to what it was before the onset of toxic symptoms, and nervous and other clinical manifestations have subsided, and in which the goiter has either completely disappeared or is so involuted as to be entirely unobjectionable from a cosmetic standpoint.

We have *classed as improved* those cases in which the basal metabolism is within normal limits or is markedly decreased, in which all clinical signs of thyrotoxicosis have disappeared, except a residual myocardial deficiency, which was present before the beginning of irradiation, or inoperable cases given irradiation to reduce the toxicity and to prepare them for operation.

We have divided all cases into "mild," "moderate," and "severe." The summary of results is shown in Table II (see next page).

Discussion.—Table II shows

1. The percentages of cures in the "mild" and "severe" cases are practically the same, 52.7 per cent and 52.3 per cent, and those which are "improved" approximately 31 per cent, or 83.5 per cent which have been cured or greatly benefited.

2. The "moderate" cases show 63.8 per cent of cures, 25.4 per cent improved, and only 10.8 per cent which were not benefited.

3. Taking all groups, approximately 57 per cent are cured, 31 per cent improved, and 12 per cent not improved. The total cured, or markedly benefited, is 87.8 per cent.

4 The average number of treatments (series of four fields usually given on one day) was, for the cured cases, 61, improved, 57, and the unimproved, 37.

5 The average time that these patients were under observation was, for the cured, 52 years, and for the improved 22 years.

Of the 361 cases treated for hyperthyroidism, there were 37 in which there was a hyperactive gland but *no palpable glandular enlargement*.

Of these, 22, or 64.7 per cent, were cured.

Seven, or 20.6 per cent, were markedly improved.

Five, or 14.7 per cent, were not improved.

Three could not be traced.

Of the five patients not improved, one died from hyperthyroidism after only two treatments. One died from tuberculosis, having had only one roentgen treatment. One other case had only one treatment and that without benefit. Two others had five and nine treatments, respectively, without

very marked improvement, and subsequently operations were performed. Of the 361 cases, 28 were subsequently operated upon, or 7.8 per cent. Twenty-five of the 361

TABLE III—HYPERTHYROIDISM—PERMANENCY OF RESULTS IN 293 CURED OR IMPROVED CASES

| Time since treatment | Mild cases | Moderate cases | Severe cases | Total |
|----------------------|------------|----------------|--------------|-------|
| Less than 1 year | 16 | 21 | 14 | 51 |
| 1 to 3 years | 14 | 28 | 25 | 67 |
| 3 to 5 years | 8 | 9 | 26 | 43 |
| 5 to 10 years | 10 | 32 | 39 | 81 |
| Over 10 years | 14 | 25 | 12 | 51 |
| Total | 62 | 115 | 116 | 293 |

cases were post-operative recurrences, or 7 per cent.

Of these, 10 cases, or 40 per cent, were cured.

TABLE II—HYPERTHYROIDISM—361 CASES

| | Cured | Markedly improved | Not improved | Unknown |
|--|-------|-------------------|--------------|---------|
| <i>Mild</i> | | | | |
| Number of cases | 39 | 23 | 12 | 14 |
| Percentage | 52.7 | 31.0 | 16.2 | |
| Average number of treatments | 3.9 | 3.9 | 4.7 | 1.8 |
| Average time observed, years | 4.7 | 1.5 | | |
| <i>Moderate</i> | | | | |
| Number of cases | 83 | 33 | 14 | 8 |
| Percentage | 63.8 | 25.4 | 10.8 | |
| Average number of treatments | 6.6 | 4.9 | 4.1 | 2 |
| Average time observed, years | 5.7 | 1.5 | | |
| <i>Severe</i> | | | | |
| Number of cases | 68 | 47 | 15 | 5 |
| Percentage | 52.3 | 36.2 | 11.5 | |
| Average number of treatments | 6.9 | 7.3 | 2.6 | 1.4 |
| Average time observed, years | 5.1 | 3 | | |
| <i>Total</i> | | | | |
| Number of cases | 190 | 103 | 41 | 27 |
| Percentage | 56.9 | 30.9 | 12.2 | |
| Average number of treatments | 6.1 | 5.7 | 3.7 | 1.7 |
| Average time observed, years | 5.2 | 2.2 | | |
| Total cured or markedly improved—87.8 per cent | | | | |

Ten cases, or 40 per cent, were markedly improved

Five cases, or 20 per cent, were not improved

Eighty per cent were cured or markedly improved

In 19 patients, 25 pregnancies were carried to successful termination without recurrence of the previous goiter or toxic symptoms

Sixteen patients of whom we have a record developed definite telangiectasis, 36 per cent of the 441 cases treated

Metabolic rate below 10 following treatment was produced in only four, or 9 per cent, of 441 cases treated. *In only one of these is thyroid extract necessary to relieve symptoms.*

In three cases which were not responding satisfactorily, we tried treatment over the cervical sympathetic ganglia and over the suprarenals, but with no appreciable effects. Hoarseness did not develop, because the larynx and arytenoids were protected. Two cases developed a severe trachitis, but these two had more than the eight series, and the effects may not have been due to the irradiation.

SUMMARY AND CONCLUSIONS

A review of the literature shows a progressively increasing recognition of the value of both roentgen rays and radium in the treatment of thyrotoxicosis. The results obtained by irradiation are equal to those obtained by surgery, with less shock or risk to the patient. The basal metabolism can be gradually reduced to normal, and there is practically no danger of produc-

ing hypothyroidism. None of my cases has developed tetany. We can assume that no harm has been done to the normal parathyroid.

A review of 361 cases treated for thyrotoxicosis shows cure or marked improvement in 87.8 per cent. It would seem that we must answer our queries as follows:

1. Not surgery, nor irradiation, nor medication can be depended upon to cure all cases and no one is so much superior that we can recommend it to the exclusion of the other two. Our records show almost exactly as many cases referred by us to the surgeon as were referred to us after surgery had failed. Usually the patients do not reach either the surgeon or the radiologist until the internist has failed to obtain satisfactory results.

2. No definite rules can be laid down at present for the selection of the method for the individual patient. It is the general opinion of radiologists that all cases which are not seriously involved by mechanical pressure, or so acute as to make delay of a month dangerous, should be treated by irradiation.

3. Irradiation and every valuable method of medication can certainly be combined to advantage. If there is no definite improvement after two or three months, surgery can still be used. The delay which always precedes operation can be used to advantage in this manner.

4. When irradiation fails, surgery can still be used; when surgery fails, irradiation can be used. Medication and the advice of the internist are of value in all cases, but there will remain a small number in which we all will fail.

4 The average number of treatments (series of four fields usually given on one day) was, for the cured cases, 6.1, improved, 5.7, and the unimproved, 3.7.

5 The average time that these patients were under observation was, for the cured, 5.2 years, and for the improved 2.2 years.

Of the 361 cases treated for hyperthyroidism, there were 37 in which there was a hyperactive gland but *no palpable glandular enlargement*.

Of these, 22, or 64.7 per cent, were cured.

Seven, or 20.6 per cent, were markedly improved.

Five, or 14.7 per cent, were not improved.

Three could not be traced.

Of the five patients not improved, one died from hyperthyroidism after only two treatments. One died from tuberculosis, having had only one roentgen treatment. One other case had only one treatment and that without benefit. Two others had five and nine treatments, respectively, without

very marked improvement, and subsequently operations were performed. Of the 361 cases, 28 were subsequently operated upon, or 7.8 per cent. Twenty-five of the 361

Esophagus—A diverticulum of the upper end of the esophagus, observed in the postero-anterior and lateral directions in Figures 70 and 71, exemplifies the manner in which barium may protrude beyond the normal contour of the esophagus. This illustration also shows the manner in which the neck of the diverticulum joins the esophagus.

An extremely small area of malignant induration of the mucosa, which involves only part of the circumference of the esophagus (Fig. 72), protrudes into the lumen and displaces the barium, thus giving an alteration from the normal contour. This illustrates the first fundamental finding which enables one to detect small pathologic lesions.

Stomach—The contour of the lumen of the normal stomach viewed in profile in various directions has been illustrated in Figure 5. Alterations in the lumen caused by pathologic lesions of the mucosa are evidenced, firstly, by growths of the mucosa or other structures which protrude into the lumen of the stomach, and, secondly, by a break in the mucosa as by an ulcer which allows the "fluid cast" to protrude beyond the normal contour. A case of the first kind is illustrated in Figure 73, where a growth is observed to protrude from the greater curvature of the antrum into its lumen. The surface of the central portion of this growth has been destroyed, resulting in an ulcer. The surgical specimen of this case illustrates the manner in which ulcerating malignancies protrude into the lumen of the stomach (Fig. 75). The diagnosis of neoplasms of this type may be based on a single roentgenogram or, at most, on two or three roentgenograms for the reason that gastric peristalsis, as observed by serial roentgenography, is not essential to the diagnosis.

A break in the mucosa, as by an ulcer, allows the fluid cast to protrude beyond the normal contour and therefore appears as a crater or niche. Such a break is shown in Figure 74. This ulcer was removed by surgery prior to the time that we began our study of the pathology of ulcer, so that a section of that specimen is not available for photographic illustration. However, a photograph of a longitudinal section of a similar ulcer is shown in Figure 76.

Cap—The term "cap" was first applied to two or three cm of the gastrointestinal tract just distal to the pyloric valve in an article published in "Archives of the Roentgen Ray," April, 1912. This area was then described as one of the most important regions in the entire gastro-intestinal tract. The text as it was originally written, more than twenty years ago, so accurately describes the findings as we have now observed them that we are quoting *verbatim* from this original article, and we have had a special page of illustrations (Fig. 77) struck off from the original half-tone plate that illustrated the article and which, fortunately, we still possess.¹ The numbers which the reader will find in the quoted portions of the 1912 article refer to the small figures shown in the sheet of illustrations just mentioned.

The peristaltic waves of the small intestine are so rapid and small that it is

¹The reader will find Figure 77 following Figures 88 and 89, out of its numerical order, this arrangement which makes for better binding was decided on after the figure numbers had been allotted.

PART III

FINDINGS OBSERVED IN THE GASTRO-INTESTINAL TRACT

By THE COLE COLLABORATORS

BY observing barium within the lumen of the gut in roentgenograms of full size, with or without the grid, and in small roentgenograms, with or without the grid and with or without pressure, *findings* are obtained which enable us to determine definite characteristics of the mucosa in various regions of the tract

Four fundamental findings form the criteria for exploring the mucosa of the gastro-intestinal tract

- (1) The lumen of the tract viewed in profile
- (2) Special folds of the mucosa viewed on edge
- (3) Pliability of the mucosa to peristaltic contraction
- (4) The pattern of the mucosal folds or rugae

All of these are well known. Some are so familiar as to be regarded with contemptuous indifference. Still others, with slight modifications, are now the vogue.

The object of this communication is to evaluate these four fundamental findings, regardless of the popularity of prevailing fashions. In this evaluation the gastro-intestinal tract will be considered under five distinct regional headings (1) esophagus, (2) stomach, (3) cap, (4) small intestine, and (5) colon. Each of the four fundamental findings may be observed in each of the five regions.

FIRST FUNDAMENTAL FINDING

(The Lumen of the Tract Viewed in Profile)

The contour of the surface of the mucosa as it appears in the silhouette of the lumen of a hollow viscous when moderately filled with an opaque meal or air, constitutes the first fundamental finding. The esophagus distended in this manner and viewed from different angles (Fig. 20) serves to illustrate this finding. Such a procedure may be likened to one walking around a tree examining its bark and noticing whether it is smooth or rough, bulged as by a growth, or barked as by an ulcer (Fig. 66). Alterations in contour due to physiologic changes are variable and not constant. Any organic lesion which projects into the lumen of the gut diminishes the space occupied by the barium and causes what is known as a "filling defect." Any break in the mucosa, or any abnormal pouching of it, allows the barium mixture to protrude beyond the normal contour of the organ. This protrusion is defined as a crater, niche, or diverticulum. This first finding is applicable in all five regions of the gastro-intestinal tract and will be described and illustrated in each region.

Esophagus—A diverticulum of the upper end of the esophagus, observed in the postero-anterior and lateral directions in Figures 70 and 71, exemplifies the manner in which barium may protrude beyond the normal contour of the esophagus. This illustration also shows the manner in which the neck of the diverticulum joins the esophagus.

An extremely small area of malignant induration of the mucosa, which involves only part of the circumference of the esophagus (Fig. 72), protrudes into the lumen and displaces the barium, thus giving an alteration from the normal contour. This illustrates the first fundamental finding which enables one to detect small pathologic lesions.

Stomach—The contour of the lumen of the normal stomach viewed in profile in various directions has been illustrated in Figure 5. Alterations in the lumen caused by pathologic lesions of the mucosa are evidenced, firstly, by growths of the mucosa or other structures which protrude into the lumen of the stomach, and, secondly, by a break in the mucosa as by an ulcer which allows the "fluid cast" to protrude beyond the normal contour. A case of the first kind is illustrated in Figure 73, where a growth is observed to protrude from the greater curvature of the antrum into its lumen. The surface of the central portion of this growth has been destroyed, resulting in an ulcer. The surgical specimen of this case illustrates the manner in which ulcerating malignancies protrude into the lumen of the stomach (Fig. 75). The diagnosis of neoplasms of this type may be based on a single roentgenogram or, at most, on two or three roentgenograms for the reason that gastric peristalsis, as observed by serial roentgenography, is not essential to the diagnosis.

A break in the mucosa, as by an ulcer, allows the fluid cast to protrude beyond the normal contour and therefore appears as a crater or niche. Such a break is shown in Figure 74. This ulcer was removed by surgery prior to the time that we began our study of the pathology of ulcer, so that a section of that specimen is not available for photographic illustration. However, a photograph of a longitudinal section of a similar ulcer is shown in Figure 76.

Cap—The term "cap" was first applied to two or three cm of the gastro-intestinal tract just distal to the pyloric valve in an article published in "Archives of the Roentgen Ray," April, 1912. This area was then described as one of the most important regions in the entire gastro-intestinal tract. The text as it was originally written, more than twenty years ago, so accurately describes the findings as we have now observed them that we are quoting *verbatim* from this original article, and we have had a special page of illustrations (Fig. 77) struck off from the original half-tone plate that illustrated the article and which, fortunately, we still possess.¹ The numbers which the reader will find in the quoted portions of the 1912 article refer to the small figures shown in the sheet of illustrations just mentioned.

The peristaltic waves of the small intestine are so rapid and small that it is

¹The reader will find Figure 77 following Figures 88 and 89 out of its numerical order, this arrangement, which makes for better binding, was decided on after the figure numbers had been allotted.

PART III

FINDINGS OBSERVED IN THE GASTRO-INTESTINAL TRACT BY THE COLE COLLABORATORS

BY observing barium within the lumen of the gut in roentgenograms of full size, with or without the grid, and in small roentgenograms, with or without the grid and with or without pressure, *findings* are obtained which enable us to determine definite characteristics of the mucosa in various regions of the tract

Four fundamental findings form the criteria for exploring the mucosa of the gastro-intestinal tract

- (1) The lumen of the tract viewed in profile
- (2) Special folds of the mucosa viewed on edge
- (3) Pliability of the mucosa to peristaltic contraction
- (4) The pattern of the mucosal folds or rugae

All of these are well known. Some are so familiar as to be regarded with contemptuous indifference. Still others, with slight modifications, are now the *vogue*.

The object of this communication is to evaluate these four fundamental findings, regardless of the popularity of prevailing fashions. In this evaluation the gastro-intestinal tract will be considered under five distinct regional headings (1) esophagus, (2) stomach, (3) cap, (4) small intestine, and (5) colon. Each of the four fundamental findings may be observed in each of the five regions.

FIRST FUNDAMENTAL FINDING

(The Lumen of the Tract Viewed in Profile)

The contour of the surface of the mucosa as it appears in the silhouette of the lumen of a hollow viscous when moderately filled with an opaque meal or air, constitutes the first fundamental finding. The esophagus distended in this manner and viewed from different angles (Fig. 20) serves to illustrate this finding. Such a procedure may be likened to one walking around a tree examining its bark and noticing whether it is smooth or rough, bulged as by a growth, or barked as by an ulcer (Fig. 66). Alterations in contour due to physiologic changes are variable and not constant. Any organic lesion which projects into the lumen of the gut diminishes the space occupied by the barium and causes what is known as a "filling defect." Any break in the mucosa, or any abnormal pouching of it, allows the barium mixture to protrude beyond the normal contour of the organ. This protrusion is defined as a crater, niche, or diverticulum. This first finding is applicable in all five regions of the gastro-intestinal tract and will be described and illustrated in each region.

by the Reds Dr Tower drew my attention to the fact that the idea of the toga was obtained from the "pilleus." Therefore, in a subsequent article, we discussed the cap under the title, "Physiology of the Pylorus, Pilleus Ventriculi and Duodenum as Observed Roentgenographically."

This cap varies in size, shape, and position, but a normal cap can usually be differentiated from a pathological one. It varies in different patients. Figures 4, 5, and 6 represent different types of the cap. It varies with the posture, but without pressure on the abdomen, as described in the first article, there is no tension on the first portion of the duodenum, the cap is symmetrical, its lines are clear-cut and well defined, as shown in Figure 7. But with the same patient in the erect posture the distended stomach drags on the cap, and there is usually an attenuated appearance of the cap, as shown in Figure 8. Frequently, in cases in which the cap is not completely filled, the level of the chyme is discernible (Fig 9). Occasionally above the chyme an accumulation of gas may be seen, similar to that usually seen in the stomach (Magenblasse). The cap varies during each gastric cycle. Sometimes it sets up on the head of the pylorus in a perfectly proper manner (Fig 10), separated from it by about 3/16 of an inch, at other times it drops down over the head of the pylorus, like the lady's "peach-basket" hat (Fig 11). During the stage of diastole the stomach contents drop away from the cap and it then has the appearance of having been "blown off," as in Figure 12. The cap also varies with the activity of the intestinal peristalsis. If the peristalsis of the second and third portions of the duodenum is so active as to withdraw the food as fast as it passes through the pyloric sphincter (valve), the duodenal cap may not be dilated to its full size.

There may be an angulation of the cap at the pyloric sphincter (valve). The cap may be displaced to the left, or, what is more likely, the pyloric end of the stomach is drawn to the right, while the cap is held in its normal position by the gastrohepatic ligaments. This condition is illustrated in Figure 13. In Figure 14 there is an irregularity on the greater curvature near the pylorus, which may indicate the attachment of adhesions to the pyloric end of the stomach, drawing it to the right.

In other cases the angulation may be due to adhesions binding the pyloric end of the stomach to the lower surface of the liver. This does not allow space for the cap to surmount the head of the pylorus, and it is displaced backward and to the right, as illustrated in Figure 15.

In all of those cases there was more or less evidence of obstruction, but in none of these, except possibly in the last, was there any evidence of adhesions contracting the lumen either of the pylorus or duodenum.

The clear space between the cap, just described, and the bismuth contents of the pyloric end of the stomach during the systole indicate accurately the pyloric sphincter [now known as "valve"]. The breadth of this clear space varies slightly with the muscular development of the patient, but it is one of the most constant factors in gastro-intestinal radiography. It should be 3/16 inch, varying from $\frac{1}{8}$ to $\frac{1}{4}$ inch, both outlines should be clear-cut and well-defined during the gastric systole, as illustrated in Figures 16, 17, and 18. The lumen of the pyloric sphincter should be in the center of the sphincter, and about $\frac{1}{8}$ inch in diameter. The variation of the radiographic appearance of the pyloric sphincter during different phases of the gastric cycle is due in part

difficult to study them either fluoroscopically or radiographically. We can, however, radiographically distinguish the ileum by the coagulated appearance of the bismuth contents, and the jejunum by the flocculent appearance (Fig 1). This appearance is constant in normal cases, but may be modified in pathological conditions and in cases of intestinal motor inefficiency.

The second and third portions of the duodenum are usually readily identified by their shape and position (Figs 2 and 3), unless the intestinal peristalsis is so active as to have a tendency to suck the food away from the pyloric sphincter (valve) more readily than it is allowed to pass through. In such cases I have pursued a method of artificial dilatation of the duodenum, which will be described later on.

The first portion of the duodenum deserves special attention. Anatomically and physiologically it has always been considered a part of the small intestine. Since writing this paper I have learned that Mayo has suggested, both on account of its embryology and its acidity, that the first portion of the duodenum should be considered a part of the stomach. Radiographically it should undoubtedly be considered as a part of the stomach. It is dilated into a cap which surmounts the pylorus, and corresponds in size and shape with the pyloric end of the stomach. It has absolutely no resemblance to the small intestine. Its motor phenomenon corresponds with the gastric cycle, and has no resemblance to the small, rapid, peristaltic contractions of the remaining portions of the duodenum. [The similarity of the motor phenomenon of the cap to that of the stomach has since been proven incorrect and will be described later.] The acidity of the contents of this duodenal cap may account for prevalence of ulcers, over 90 per cent occurring in this portion of the duodenum. Considering its embryology, its acid contents, its motor phenomenon, its surgical importance, and the very important part that its radiological appearance plays in the diagnosis of gastric and duodenal lesions, it should be dignified by a separate name. Its appearance and position, sitting like a cap on the pylorus, immediately suggest its name. Hence, for convenience of description, I shall call the first or ascending portion of the duodenum the "cap."

The "cap" was more popular than scientific and several of my more scientific friends urged that we adopt a scientific term for the region of the gastrointestinal tract which we believed to be so important. At that time I was working on the possible theory of the cap being an analogue of the second stomach in ruminating animals. With this theory in view I consulted with Dr. Tower, who was then curator of the New York Museum of Natural History. He was extremely interested in the subject and after spending a day or two with me we came to the conclusion that the two regions were not of similar origin. I then discussed with Dr. Tower the question of selecting a proper name for the region. Observing the size and shape of the cap as demonstrated roentgenographically, he noted its similarity to a brimless cap which was given to the Roman slaves, when they were liberated, as a token of their liberation, this cap was called "pilleus." The especial similarity attracting his attention was the manner in which the descending duodenum hung down like a tassel. The name which I had previously selected was "toga," because of the similarity of the cap worn as an insignia

by the Reds Dr Tower drew my attention to the fact that the idea of the toga was obtained from the "pilleus." Therefore, in a subsequent article, we discussed the cap under the title, "Physiology of the Pylorus, Pilleus Ventriculi and Duodenum as Observed Roentgenographically."

This cap varies in size, shape, and position, but a normal cap can usually be differentiated from a pathological one. It varies in different patients. Figures 4, 5, and 6 represent different types of the cap. It varies with the posture, but without pressure on the abdomen, as described in the first article, there is no tension on the first portion of the duodenum, the cap is symmetrical, its lines are clear-cut and well defined, as shown in Figure 7. But with the same patient in the erect posture the distended stomach drags on the cap, and there is usually an attenuated appearance of the cap, as shown in Figure 8. Frequently, in cases in which the cap is not completely filled, the level of the chyme is discernible (Fig. 9). Occasionally above the chyme an accumulation of gas may be seen, similar to that usually seen in the stomach (Magenblasse). The cap varies during each gastric cycle. Sometimes it sets up on the head of the pylorus in a perfectly proper manner (Fig. 10), separated from it by about $3/16$ of an inch, at other times it drops down over the head of the pylorus, like the lady's "peach-basket" hat (Fig. 11). During the stage of diastole the stomach contents drop away from the cap, and it then has the appearance of having been "blown off," as in Figure 12. The cap also varies with the activity of the intestinal peristalsis. If the peristalsis of the second and third portions of the duodenum is so active as to withdraw the food as fast as it passes through the pyloric sphincter (valve), the duodenal cap may not be dilated to its full size.

There may be an angulation of the cap at the pyloric sphincter (valve). The cap may be displaced to the left, or, what is more likely, the pyloric end of the stomach is drawn to the right, while the cap is held in its normal position by the gastrohepatic ligaments. This condition is illustrated in Figure 13. In Figure 14 there is an irregularity on the greater curvature near the pylorus, which may indicate the attachment of adhesions to the pyloric end of the stomach, drawing it to the right.

In other cases the angulation may be due to adhesions binding the pyloric end of the stomach to the lower surface of the liver. This does not allow space for the cap to surmount the head of the pylorus, and it is displaced backward and to the right, as illustrated in Figure 15.

In all of those cases there was more or less evidence of obstruction, but in none of these, except possibly in the last, was there any evidence of adhesions contracting the lumen either of the pylorus or duodenum.

The clear space between the cap, just described, and the bismuth contents of the pyloric end of the stomach during the systole indicate accurately the pyloric sphincter [now known as "valve"]. The breadth of this clear space varies slightly with the muscular development of the patient, but it is one of the most constant factors in gastro-intestinal radiography. It should be $3/16$ inch, varying from $1/8$ to $1/4$ inch, both outlines should be clear-cut and well-defined during the gastric systole, as illustrated in Figures 16, 17, and 18. The lumen of the pyloric sphincter should be in the center of the sphincter, and about $1/8$ inch in diameter. The variation of the radiographic appearance of the pyloric sphincter during different phases of the gastric cycle is due in part

to the pressure of the food against the pyloric sphincter, as shown in Figures 19 and 20.

There is some question whether the pyloric sphincter takes part in the motor phenomenon of the stomach [as Cannon calls it, the "keeper of the gate"], contracting and relaxing during each cycle, or whether it remains contracted, the food being forced through it by the peristaltic action of the stomach. Personally, I consider the pyloric sphincter as a "butler," guarding the entrance of the intestine, and closing the door during diastole to prevent the food from passing back into the stomach. I believe that the relative strength of the pyloric sphincter (the butler) to the peristaltic contraction of the stomach (the cook) is one of the most important factors in functional derangements of the digestive tract. If the pyloric sphincter is too strong, the stomach may be over-distended with food, and yet the small intestine may be starved. On the other hand, if the pyloric sphincter is weak and the peristaltic contractions are too strong, improperly prepared food will be served to the intestine.

During the stage of systole, with the patient in the erect posture, the food is pressed up against the surface of the pyloric sphincter, and we have a clear-cut, well-defined outline of the sphincter, as is shown in Figure 21, but during the stage of diastole the food drops away from the pyloric sphincter, and there is a wide space between the bismuth contents of the cap and that of the pyloric end of the stomach, as is shown in Figure 22.

In the interpretation of the radiographic plate, great care should be taken not to interpret this space as evidence of obstruction of, or adhesions to, the pylorus.

The relation of the pylorus to the umbilicus varies with the size, position, and type of stomach. The position of the umbilicus itself also varies with the build and obesity of the patient and the flabbiness of the abdominal wall. The relation of the pylorus to the body of the stomach is much more important, and varies with the type of the stomach, as is shown in Figures 23, 24, 25. The most important point, however, is the relation of the level of the chyme to the pylorus when the patient is in the erect posture. If the upper level of the chyme is three or four inches below the pyloric sphincter (valve), and the peristalsis is inefficient, as indicated in Figure 26, how is the chyme going to get out of the pylorus even if the latter is wide open? Figure 27 is of the same patient in the prone posture, with the abdomen flat on the plate. These two plates illustrate the relative value of the two different postures in determining the shape and contour of the stomach, particularly when the stomach is dilated and atomic.

Artificial Dilatation of the Duodenum.—When the chyme is drawn away from the pyloric sphincter (valve) by unusually active intestinal peristalsis it is difficult to detect the second and third portions of the duodenum. In such cases I have adopted the following method, which was described in my article, "The X-ray Diagnosis of Pyloric and Duodenal Lesions," read before the American Association of Obstetricians and Gynecologists at Louisville, Ky., Sept. 29, 1911. A second paper, on "Artificial Dilatation of the Duodenum for Radiographic Examination," was published in the "American Quarterly of Roentgenology."

The lumen of the entire duodenum and upper portion of the jejunum can be examined by the following procedure. The patient swallows an Einhorn pyloric dilator. This is a small metallic ball and rubber bag attached to a fine rubber tube, the rubber bag collapsing round the tube just behind the ball. The whole

apparatus is as easily swallowed as the old-fashioned pill. This dilator may be administered with the food the day before, or given three or four hours before the examination, the patient assuming a position which will allow it to pass into the duodenum and jejunum.

The small rubber bag, which is surrounded by a silk bag about the size of the lumen of the duodenum, is then inflated with air, and acts as an intestinal obstruction. A meal of bismuth and buttermilk is then given by mouth, and passes readily into the duodenum, the temporary obstruction preventing the bismuth from passing on through the jejunum. The duodenum is dilated by the bismuth and buttermilk, and a radiograph shows perfectly the contour of the dilated duodenum.

I am indebted to Dr Max Einhorn for the case illustrated in Figures 28, 29, and 30. The dilator was passed into the stomach by Dr Einhorn about fourteen hours before the examination. Forty plates were made, with an interval of about five minutes between each two exposures, some before and some after the administration of the bismuth.

The first plate made after the bismuth was administered showed the stomach and cap distinctly, but the second and third portions of the duodenum were not visible. Then the second portion began to fill, as shown in Figure 28, the tube and bag being in the jejunum. Later the third portion filled, and Figure 29 shows the entire duodenum artificially dilated. In both Figures 28 and 29 the bag is not so completely inflated as it should be, but in Figure 30 one readily sees the bag properly inflated.

This case is interesting as showing how far the dilator may pass into the small intestine and yet be withdrawn without causing any unusual sensation. The dilatation of the duodenum would have been more complete if the tube had passed only into the first portion of the jejunum, and the inflation of the bag had been as thorough as in Figure 30.

The following modification of Einhorn's dilator will, I believe, be of great value. The tube is surrounded by a second tube slightly larger than the first. This outside tube terminates just behind the rubber bag, and through it the bismuth and buttermilk may be injected and aspirated directly into or from the duodenum. In this way the exact amount of the distention of the duodenum may be diagnosed.

Radiographic examination, besides showing adhesions from duodenal and gastric ulcers and gall-bladder infection, also enables us to examine the head of the pancreas, which can be more perfectly outlined by the duodenum, as suggested by Dr Crane. In some cases I have been able to clearly demonstrate the shadow of bismuth in the canal of Wirsung. [This was probably a duodenal diverticulum adjacent to the ampulla of Vater, termed by the French "perivaterans".]

This ends the quotation, and as I read the text and carefully observe the illustrations of the original article I marvel that at that time I should have had sufficient material to accurately describe all of these findings. We have already described the manner in which this small region of the tract sets up on the pyloric end of the stomach like a brimless cap, and that this term "cap" is applied because this region does resemble a cap. The term "duodenal" is often erroneously applied to it, and in the past (and by some still) this region was called the first or ascending portion of the duodenum.

However, considering that it has none of the characteristics of the small intestine the terms "duodenum" and "bulbus duodeni" are misnomers.

The appearance of the fully distended normal cap and its similarity in appearance with the pyloric end of the stomach is shown in Figure 37. The similarity in appearance of the cap and pars pylorica is strikingly shown if one covers the pyloric valve with a pencil. The outline of the distended normal cap is clean-cut and smooth. The change in outline of the base of the cap produced by contraction of the fan-shaped muscle of the pyloric canal is shown in Figures 31 and 32.

Alterations in the contour of the cap caused by pathologic lesions are largely limited to an encroachment upon the lumen of the cap. The usual exceptions are the localized dilatations of the uninvolved part of the cap proximal to an area of stenosis (Fig. 85). These are often called "pseudo-diverticula." Diverticula occur frequently in the duodenum close to the cap and are not infrequently erroneously interpreted as being of the cap proper, but true diverticula of the cap are extremely rare. We have never seen one.

Occasionally one sees in profile the crater of an ulcer which projects beyond the margin of an otherwise normal appearing cap. In these cases the inflammatory reaction around the ulcer is so slight that there is no appreciable flattening of the contour of the cap adjacent to the crater (Figs. 78 and 79).

More commonly the crater of an ulcer of the cap protrudes outside of the contour of a cap which is diminished locally in size by induration of the cap wall (Figs. 80 and 81).

Alteration in the contour of the cap by changes which encroach upon the lumen is common and familiar to all. These changes may be an enfolding of the entire thickness of the wall of the cap by a veil or band of adhesions (Fig. 82), induration around an ulcer (Fig. 83), and bands of scar tissue which radiate from the site of an ulcer (Figs. 84 and 85), or which remain as the residual change of a healed ulcer.

Small Intestine.—The variations in contour of the small intestine are principally caused by diverticula into which the barium passes, and the shadows of these diverticula protrude beyond the normal contour of the gut (Fig. 90). The lumen of the small intestine may be diminished in diameter by local bands of adhesions or tuberculous infiltration (Figs. 91 and 92), and occasionally one observes a malignant lesion or a non-malignant polyp which protrudes into the lumen.

Colon.—The contour of the colon may be altered by growths which protrude into it (Figs. 93 and 94), causing filling defects similar to those observed in the stomach and constituting the most important finding in this region, or it may be altered by pouches or diverticula (Fig. 95). Diverticulosis of the colon is a very common finding and, unless the diverticula are the seat of inflammatory reaction, they are of relatively slight clinical significance. However, when these diverticula do become inflamed the mucosa becomes the seat of an area of induration which encroaches upon the lumen of the colon, and causes a filling defect that may completely obstruct it. This is sometimes difficult to differentiate from malignancy.

SECOND FUNDAMENTAL FINDING

(Special folds of mucous situated on edge)

The second fundamental finding is the thickness and appearance of special mucous-membranous folds, such as the plica angularis and the pyloric valve, viewed on edge. The principle involved in this finding is well illustrated by a sandwich (Fig. 67), that is, two slices of bread are likened to the double layer of mucosa and the filling is similar to the submucosa. Thus, by viewing the sandwich on edge, one determines whether or not there are any lumps in the filling, or a piece nibbled out of the side as by a mouse. Thus, one may view the folds and note whether there is a malignant or non-malignant lump in the submucosa, or if the mucosa is nibbled away by a mucosal ulcer.

Sulcus angularis.—The second fundamental finding is observed in roentgenograms of the stomach as the sulcus angularis. This finding is most typically seen in roentgenograms made of the stomach during the phase of diastole of the gastric motor phenomenon and with the patient in the erect posture (Fig. 32). The sulcus is characteristically present in the sthenic and asthenic types of stomachs which have a normal tone of the muscularis propria. The sulcus is the long narrow indentation which projects from the lesser curvature into the barium column between the corpus and antrum of the stomach. During the phase of systole of the gastric motor phenomenon (Fig. 31), the sulcus varies in depth and form because at this time the sulcus corresponds to the peristaltic contracting ring in this segment of the stomach. Although, during a gastric cycle, the indentation in the barium column changes its position, this change in position is only a change in the angle of inclination to a fixed point on the lesser curvature, as the base of the sulcus progresses so slightly that it corresponds to a limited area, namely, the apex of the receding cusp which the surgeon and anatomist observe on the outside of the stomach, that is, the incisive angularis. The sulcus angularis observed in the roentgenograms is produced by the plica angularis, a long mucous-membranous fold which projects into the lumen of the stomach.

The length of the base of the contraction in the longitudinal axis of the stomach, or the thickness of the apron-like fold which projects into the lumen of the stomach, is very constant in different cases (Fig. 95, Nos. 1-6). It is about 0.5 cm. from the proximal surface at the base directly across to the distal surface of the fold at its base. Within this space of 0.5 cm. across the base of the sulcus there is insufficient room for a reduplication of all the coats of the stomach and only sufficient space for a reduplication of the mucosa and muscularis mucosae together with a core of submucosa. This indicates that the peristaltic contraction of the sulcus angularis is the function of the muscularis mucosae and not the muscularis propria. In Figure 31 we have illustrated the increase in thickness of the muscularis mucosae which occurs at the tip of the plica angularis during peristaltic contraction. This increase in thickness of the muscle layer is directly reflected in the sulcus angularis in the roentgenogram as a rounded swelling or bell-like form near the tip of the sulcus (Figs. 31, 31, and 95). The depth of the contraction of the apron-like fold itself, that is, the distance from its base to its tip,

However, considering that it has none of the characteristics of the small intestine the terms "duodenum" and "bulbus duodeni" are misnomers.

The appearance of the fully distended normal cap and its similarity in appearance with the pyloric end of the stomach is shown in Figure 37. The similarity in appearance of the cap and pars pylorica is strikingly shown if one covers the pyloric valve with a pencil. The outline of the distended normal cap is clean-cut and smooth. The change in outline of the base of the cap produced by contraction of the fan-shaped muscle of the pyloric canal is shown in Figures 31 and 32.

Alterations in the contour of the cap caused by pathologic lesions are largely limited to an encroachment upon the lumen of the cap. The usual exceptions are the localized dilatations of the uninvolved part of the cap proximal to an area of stenosis (Fig. 85). These are often called "pseudo-diverticula." Diverticula occur frequently in the duodenum close to the cap and are not infrequently erroneously interpreted as being of the cap proper, but true diverticula of the cap are extremely rare. We have never seen one.

Occasionally one sees in profile the crater of an ulcer which projects beyond the margin of an otherwise normal appearing cap. In these cases the inflammatory reaction around the ulcer is so slight that there is no appreciable flattening of the contour of the cap adjacent to the crater (Figs. 78 and 79).

More commonly the crater of an ulcer of the cap protrudes outside of the contour of a cap which is diminished locally in size by induration of the cap wall (Figs. 80 and 81).

Alteration in the contour of the cap by changes which encroach upon the lumen is common and familiar to all. These changes may be an enfolding of the entire thickness of the wall of the cap by a veil or band of adhesions (Fig. 82), induration around an ulcer (Fig. 83), and bands of scar tissue which radiate from the site of an ulcer (Figs. 84 and 85), or which remain as the residual change of a healed ulcer.

Small Intestine.—The variations in contour of the small intestine are principally caused by diverticula into which the barium passes, and the shadows of these diverticula protrude beyond the normal contour of the gut (Fig. 90). The lumen of the small intestine may be diminished in diameter by local bands of adhesions or tuberculous infiltration (Figs. 91 and 92), and occasionally one observes a malignant lesion or a non-malignant polyp which protrudes into the lumen.

Colon.—The contour of the colon may be altered by growths which protrude into it (Figs. 93 and 94), causing filling defects similar to those observed in the stomach and constituting the most important finding in this region, or it may be altered by pouches or diverticula (Fig. 95). Diverticulosis of the colon is a very common finding and, unless the diverticula are the seat of inflammatory reaction, they are of relatively slight clinical significance. However, when these diverticula do become inflamed the mucosa becomes the seat of an area of induration which encroaches upon the lumen of the colon, and causes a filling defect that may completely obstruct it. This is sometimes difficult to differentiate from malignancy.

the stomach and cap. The appearance of the normal pyloric valve in relation to the normal stomach and cap is illustrated in Figure 37. The margins of the valve are smooth and clear-cut and the lumen of the valve is centric to the lumen of both the cap and the antrum.

The lesser curvature side of the pyloric valve is not an infrequent site of benign ulcers, and the ulcer may involve either the proximal or distal surface of the valve. The structure of both the distal and proximal sides of the valve is gastric in its characteristics and for this reason these ulcers should all be considered as gastric ulcers. When the ulcer involves only the mucosa and there is a very slight inflammatory reaction and induration, the roentgen evidence consists of a slight thickening of one side of the valve (almost without exception the lesser curvature side), together with the projection beyond the main barium column of the barium filling the small crater of the ulcer (Fig. 103). Around large ulcers the induration extends into the wall of both the stomach and cap, and the lesser curvature side of the valve is obliterated (Fig. 104). The induration of the wall of the stomach and cap flattens the contour of this region so that the lesser curvature side of the valve and the adjacent parts of the stomach and cap form a straight or slightly curved surface. As the greater curvature side of this region has retained its normal pliability the lumen of the valve is found to be eccentric to the lumen of both the cap and the stomach (Fig. 104). The induration around still larger ulcers may completely encircle the stomach and cap in the region of the valve (Fig. 105).

When ulcers of either the cap or the stomach lie adjacent to the pyloric valve, the induration may extend across the valve, producing a flattening of the contour and obliteration of one side of the valve (Fig. 106). The differentiation between ulcers of the valve proper and those which lie adjacent to the valve is determined by the location of the crater when this can be visualized, and otherwise by determining whether or not the valve lies at the center of the area of induration. Following healing of an ulcer a flattening of one side of the valve, with eccentricity of the lumen of the valve, may remain as a residual change (Figs. 107 and 108).

Malignant tumors of the stomach do not extend through the wall of the stomach beyond the valve to involve the wall of the cap. This phenomenon is difficult to understand but is a finding which is frequently observed roentgenographically and which often serves to differentiate between a newgrowth and an induration secondary to ulcer or inflammation. Malignant growths which extend to the valve (Fig. 109) or develop adjacent to the valve (Fig. 110) obliterate the proximal lip of the valve because this part of the valve and adjacent gastric wall is rendered non-pliable and there can be no expansion of the involved part of the stomach. If the growth involves the entire circumference of the pyloric end of the stomach, the lumen of the valve remains centric to the lumen of the cap and also to the lumen of the non-dilated antrum (Figs. 109 and 111). When the growth involves only one side of the pyloric end of the stomach the lumen of the valve remains centric to the lumen of the cap, but is eccentric to the lumen of the antrum (Fig. 135). In all malignant growths extending to the gastric side of the pyloric

varies greatly in different cases (Fig 96, Nos 1-6), and in the same case in different postures of the patient and with different degrees of gastric distension (Fig 96, Nos 7-9)

The sulcus angularis is an extremely constant roentgenologic landmark and pathologic changes in this region of the stomach are directly shown by changes in contour and volume of the sulcus. Small, superficial ulcers which involve in depth only the mucosa or the mucosa and the superficial layer of the submucosa, appear in profile as small excavations in either the proximal or distal surface of the sulcus,—a protrusion of barium into the space of the sulcus which appears as if a mouse had nibbled a small hole into one surface of the sandwich (Figs 97-100). These small ulcers are surrounded by such a small area of induration that it does not interfere with the gastric peristalsis, and as the sulcus shifts position with the progress of the peristaltic wave, the small excavation also shifts position in relation to the sulcus. At one phase the excavation may be in the proximal surface of the sulcus, and at another phase the excavation may be in the tip of the sulcus or even in the distal surface of the sulcus. When this occurs we speak of the crater of the ulcer as "riding with the wave of gastric peristalsis" (Figs 97-100).

Larger areas of induration, either malignant or non-malignant, increase the width and shorten the length of the plica angularis and produce similar changes in appearance of the sulcus angularis (Fig 101). When the induration is sufficiently large the fold, and correspondingly the sulcus, is entirely obliterated, and the absence of this characteristic finding is in itself of great significance (Fig 102), but this constitutes the third finding.

Pyloric Valve.—The lumen of the stomach is partly separated from the lumen of the cap during most of the phases of the gastric cycle by a space about 0.5 of a centimeter. This space is universally recognized by radiologists and may be termed the "pyloric valve," "pyloric sphincter," or even "pylorus." We believe that "pyloric valve" is the preferable and more accurate term. Roentgenologically, it is so definite in its character that it has become a monumental landmark for roentgenologists and they use it as a point from which to take measurements, that is, they will state that an ulcer is so many millimeters beyond the valve, or so many centimeters proximal to the valve. Although this finding is very well known to roentgenologists, it is practically unknown to anatomists and surgeons. What they term the "pyloric sphincter" is the abrupt distal end of the fan-shaped muscle that is located at or near the base of the valve. The valve itself (Fig 52), however, is composed only of a double layer of mucosa, muscularis mucosae, and a core of submucosa. It does not contain the regular circular muscular coat (muscularis propria). Therefore, the roentgenologic appearance, measurements, and character of this fold should come, strictly speaking, under the heading of this section.

When the cap and distal part of the antrum of the stomach are distended and the pyloric valve is viewed accurately in profile, the valve appears as a space between the cap and stomach about 0.5 of a centimeter wide which does not contain barium. Centrally located in this space is a small column of barium in the lumen of the valve and connecting the barium column in

scope of radiological exploration of the mucosa of the colon. Too often are these mucosal folds passed without a careful consideration of both their proximal and distal surfaces. The significance of these folds as an aid to X-ray diagnosis is appreciated when one compares an X-ray film with a specially prepared surgical specimen of the colon (Fig. 60).

The anatomists who have written and edited the standard text-books on anatomy have universally stated that the exterior of the colon shows a sacculated condition which is characteristic of the colon. "Between the sacculations are semilunar folds (*plicæ semilunaris coli*), which involve the entire thickness of the intestinal wall, forming crescentic ridges of the mucosa which project into the lumen" (*Morris*). "The exterior of the colon shows the sacculated condition, but there are no folds or *valvulae conniventes* like those of the small intestine, *valvulae conniventes* are also wanting, although there are projections into the large gut involving all or part of the coats internal to the serous tunic" (*Piersol*). The usual conception of the cause of formation of these sacculations is that the "sacculations (*haustra*) are produced by the gut having to adapt its length to three shorter bands (*tæniae coli*) which run the course of the intestine" (*Morris*).

The anatomical descriptions are quite logical as applied to the relaxed gut found at postmortem and in the anatomical cadaver used for dissection. It is impossible, however, to attempt an explanation of findings observed roentgenologically in the living subject by data obtained from such specimens. Here again, as in the stomach, surgical specimens which are preserved immediately after removal and in such a manner that their form and distension are similar to those observed in the living subject, are necessary for comparative study.

Figure 60 is a photograph (2 X magnification) of one-half of a surgical specimen prepared in such a manner, the specimen having been cut longitudinally near the lines of attachment of the mesentery and the epiploic fat pads. Projecting into the lumen of the gut are numerous folds which are directly comparable in size and distribution with the segmental rings which are observed roentgenographically and which divide the colon into the sacculations or *haustra* which are so characteristic of the colon as observed roentgenographically. The illustration shows very clearly that the folds are not a reduplication of the entire thickness of the wall of the colon, as described by anatomists, but only a reduplication of the mucosa and *muscularis mucosæ* together with a core of the submucosa similar to the *plica angularis* of the stomach. Along the superior surface of the colon, as illustrated, there is an indentation of the *muscularis propria* (both the circular and longitudinal layers of muscle), and here the indentation falls directly between two of the folds which project into the lumen and does not enter into their formation. In only one area (*A*) does the *muscularis propria* enter into the formation of a fold which projects into the lumen of the gut, and the relations in this region deserve a more detailed description in that the findings of this type may give an explanation of some of the findings observed in the roentgenograms. The fold at *A* is much broader than all of the other folds shown in this section, and the mucosal surface of the fold has three eminences. The

valve, the distal side of the valve remains normal in contour except occasionally for a slight bulging toward the lumen of the cap (Fig 111). Many extensive newgrowths of the stomach extend close to the pyloric valve but do not involve a narrow zone of the pyloric canal adjacent to the pyloric valve (Figs 112-114).

Small Intestine—The second fundamental finding is observed in the small intestine at the ileocecal valve (Fig 46), where the intestine is inserted in the side of the cecum in a manner resembling a striking cobra, the head of the cobra being pressed into the side of the cecum. The length and thickness of the leaves of the valve are significant in the problem of ileocecal incompetency, but whether or not this condition of ileocecal incompetency is of clinical significance is a most debatable question. Distortion or thickening of the ileocecal valve or a retraction of one lip of the valve may result either from adhesions associated with a diseased appendix or from pregnancy, and occasionally it is thickened by tuberculous infiltration.

The characteristic mucosal folds of the small intestine, the *valvulae conniventes* or *plicae semilunaris*, might logically be considered as special mucosal folds to be discussed under the second fundamental finding. When the small intestine is distended, they are viewed on edge in the same manner in which one views the *plica angularis*, the pyloric valve, and the segmental rings of the colon. The small sulci, which the *valvulae conniventes* form in the barium mold of the lumen of the small intestine, are, however, such an inseparable part of the mucosal pattern that we have chosen to consider them under the fourth fundamental finding.

Colon—The second fundamental finding is observed in the colon in both *Houston's valves* and in the *segmental folds or rings*. The thickness and appearance of Houston's valves, as observed with the barium enema (Fig 115), is very similar to the finding observed in the *sulcus angularis*. These valves may be obliterated or deformed by malignant infiltration or the inflammatory process associated with infected diverticula that occur in the rectosigmoid region.

The *segmental folds* (Fig 116) are so familiar that they are viewed with contemptuous indifference. Yet when one stops to analyze the fold and divide it into a base, stalk, bulb, and tip, and to study the relation of the thickness of each of these regions of the segmental fold, and to question the contents and function of the segmental folds, the motor phenomenon becomes of more than passing interest. The segmental folds in the colon are comparable with the *plica angularis* of the stomach and the *plicae circularis* in the small intestine. They increase the mucosal surface of the colon and incarcerate fecal matter between them, and, while it is collected between the segments, water is absorbed from it so that it becomes more or less solid. In many herbivorous animals—in sheep, for example—fecal matter becomes so solidified between these folds that the latter retain the typical sheep dung shape. Occasionally, similar scaly masses are observed in human beings when they do occur it is evident that they have been formed in these pockets between the segmental rings. These folds when carefully scrutinized increase the

present in folds which produce the sulci observed in the roentgenograms, it was necessary to establish the actual thickness of the various coats. Under normal conditions in the living subject the coats of the colon are much thicker than the coats as observed in the preserved specimen. The thickness as determined in specimens which have been preserved in formalin for several days may, therefore, be accepted as the minimum thickness which could be present under like degrees of distention of the gut during life. The mucosa of the colon varies from 0.25 cm to 0.5 cm in thickness. The submucosa is variable and may be minimal in amount, or in the base of a low fold or the tip of a high fold may reach 0.5 cm in thickness. The muscularis propria has a minimal thickness of 0.5 centimeter. The thickness of the coats as measured in the fresh specimen is greater than these figures, so that in constructing the colonic wall around the roentgenographic outline of the lumen of the gut we must make the thickness of the coats of the wall at the minimum the thickness of the figures given, and actually they should be made thicker in order to compensate for the contraction which takes place in the hardened specimen.

In Figure 117 we have traced the outlines and diagrammatically represented the lumen and thickness of the coats of the colon shown in Figure 60. The diagram has then been reduced to the actual size of the specimen. This diagrammatic representation of the actual specimen will, therefore, serve as a model of the actual condition present, for comparison with a theoretically constructed wall around the lumen as observed roentgenographically.

At first thought the motor phenomenon of the colon appears to be a simple process, but an analysis of the various findings observed roentgenographically and an attempt to explain these findings in terms of motor functions reveal that the contractions of the various muscle elements in the wall of the colon constitute a complicated process. The mere act of constructing the colonic wall around the lumen of the gut (as observed in the roentgenogram) reveals that there is not sufficient space within the sulci produced by the segmental rings for all of the coats of the colon to be present. Figures 118-123 are tracings of several colons, showing the type and contour of various segmental rings which we have observed. Around the contour of the lumen we have diagrammatically constructed the wall of the colon.

These diagrams show clearly that within these sulci there is only sufficient space for a reduplication of the mucosa and muscularis mucosæ, together with a core of the submucosa. Whether or not the muscularis propria may be dipped into the base of the fold by a pull through the submucosa as illustrated in Figure 60 is immaterial, since this would be only a passive change produced by forces extraneous to the muscularis propria and not an actual contraction of the muscularis propria itself.

The appearance of the wall of the gut theoretically constructed in this manner is directly comparable to the actual tracing of the wall of the colon specimen (Fig. 117). The folds are of the same type and the same composition. Figures 118-123 are tracings of segmental rings which were selected because their outlines were clearly discernible and could be traced.

center eminence is continuous with the more narrow fold which extends completely across the specimen and which is sectioned on the superior surface of the specimen. This narrow fold does not contain the muscularis propria. The indentation in the muscularis propria at *A* does not continue around the specimen but terminates a short distance from the cut edge of the specimen, as one can observe in the photograph. The two lateral eminences on the surface of this fold (*A*) also extend for only a short distance away from the cut edge of the specimen, in fact, only as far as the indentation of the muscularis propria. The findings illustrated in this photograph establish two facts. The first is that folds which include all of the coats of the colon are very considerably thicker than the folds which are only a reduplication of the mucosa and muscularis mucosae with a core of submucosa, the second is that on top of a fold due to reduplication or indentation of the muscularis propria there may be several eminences which are foldings of only the mucosa and submucosa.

There is still another finding of note which may be observed in the fold at *A*. The apex of the indented muscularis propria is thinner than the adjacent muscularis propria along the side of the fold. If this fold were due to an active contraction of the muscularis propria, one would expect exactly the opposite relation of the thickness of the muscle. For illustration of this fact refer back to the diagrammatic drawings illustrating the thickening of the muscularis mucosae in the apex of the sulcus angularis (Fig 51), and the pyloric valve (Fig 52). The muscle which is responsible for the formation of a contracting ring or fold must be thickest at the apex of the fold, as this is the maximum point of contraction of the muscle, and, therefore, the area of greatest bulk or thickness of the muscle.

While studying this illustration one should note also that the thickness of the submucosa is very variable. At *A* the mucosa is very thick under all three of the mucosal eminences. This is also the case in one of the shallow folds on the superior surface. In the deeper folds the mucosa is thin in the stalk of the fold, but definitely increased in amount in the tip of the fold. Variations in the bulk of the submucosa in relation to the folds were undoubtedly the basis of part of the formation of Forssell's theory as to the mechanism of formation of the mucosal folds in general.

In specimens of the colon which we have preserved in a similar manner, we have observed sacculations of the colon which have been separated by folds taking in the entire thickness of the wall of the gut and entirely similar to the findings described in the text-books on anatomy. This type of fold is usually observed when the colon is considerably more dilated than is the specimen illustrated in Figure 60. The muscularis propria at the apex of these folds was never thickened but ended in a point. On the outside of the gut the line of indentation was usually marked by blood vessels encircling the gut or by subperitoneal fat accumulations. It is probable that many of these folds of this type are produced by dilatation of the gut around relatively fixed lines in the external part of the wall of the gut.

In order to determine just what parts of the wall of the gut may be

present in folds which produce the sulci observed in the roentgenograms, it was necessary to establish the actual thickness of the various coats. Under normal conditions in the living subject the coats of the colon are much thicker than the coats as observed in the preserved specimen. The thickness as determined in specimens which have been preserved in formalin for several days may, therefore, be accepted as the minimum thickness which could be present under like degrees of distention of the gut during life. The mucosa of the colon varies from 0.25 cm to 0.5 cm in thickness. The submucosa is variable and may be minimal in amount, or in the base of a low fold or the tip of a high fold may reach 0.5 cm in thickness. The muscularis propria has a minimal thickness of 0.5 centimeter. The thickness of the coats as measured in the fresh specimen is greater than these figures, so that in constructing the colonic wall around the roentgenographic outline of the lumen of the gut we must make the thickness of the coats of the wall at the minimum the thickness of the figures given, and actually they should be made thicker in order to compensate for the contraction which takes place in the hardened specimen.

In Figure 117 we have traced the outlines and diagrammatically represented the lumen and thickness of the coats of the colon shown in Figure 60. The diagram has then been reduced to the actual size of the specimen. This diagrammatic representation of the actual specimen will, therefore, serve as a model of the actual condition present, for comparison with a theoretically constructed wall around the lumen as observed roentgenographically.

At first thought the motor phenomenon of the colon appears to be a simple process, but an analysis of the various findings observed roentgenographically and an attempt to explain these findings in terms of motor functions reveal that the contractions of the various muscle elements in the wall of the colon constitute a complicated process. The mere act of constructing the colonic wall around the lumen of the gut (as observed in the roentgenogram) reveals that there is not sufficient space within the sulci produced by the segmental rings for all of the coats of the colon to be present. Figures 118-123 are tracings of several colons, showing the type and contour of various segmental rings which we have observed. Around the contour of the lumen we have diagrammatically constructed the wall of the colon.

These diagrams show clearly that within these sulci there is only sufficient space for a reduplication of the mucosa and muscularis mucosae, together with a core of the submucosa. Whether or not the muscularis propria may be dipped into the base of the fold by a pull through the submucosa as illustrated in Figure 60 is immaterial, since this would be only a passive change produced by forces extraneous to the muscularis propria and not an actual contraction of the muscularis propria itself.

The appearance of the wall of the gut theoretically constructed in this manner is directly comparable to the actual tracing of the wall of the colon specimen (Fig. 117). The folds are of the same type and the same composition. Figures 118-123 are tracings of segmental rings which were selected because their outlines were clearly discernible and could be traced.

without guessing at the margin of the lumen of the gut. These tracings are from roentgenograms made of the colon after administration of a barium enema. One will immediately notice that the segmental folds vary greatly in their form and depth.

- 1 Short fold (Figs 121 and 123)
- 2 Deep fold with narrow tip (Fig 120)
- 3 Fold with bulbous tip (Fig 121)
- 4 Ring with flattened tip and projection both distally and proximally (Fig 122)
- 5 Ring with projection only proximally (Fig 122)
- 6 Ring with projection only distally (Fig 121)
- 7 Ring budding off of base of deeper fold (Fig 118)
- 8 Double fold (Fig 119)

In roentgenograms made of the colon during the passage or, rather, retention of the barium meal one may observe the same type of segmented rings shown in Figures 118-123 and Figure 116-C. There is, however, a definite tendency for the segmental rings to be broadened as shown in Figure 116, A and B. Broad rings of segmental contraction of this type show the possibility but not probability of the other coats of the muscularis propria entering into the formation of the folds.

A localized increase in tone or partial contraction of the muscularis propria we believe is more likely to account for the appearance illustrated in Figure 123, a finding which is not uncommonly found in a local region when the colon is filled with a barium enema. A similar finding is present in the middle of the transverse colon in Figure 116-C.

The effect upon the segmental rings of the extensive waves of contraction (the waves which Case has described) which move forward a large amount of the contents of the colon gives us a great deal of information regarding the nature of the segmental rings. These extensive waves of contraction begin in the ascending colon or in the region of the hepatic flexure. The contraction may extend for variable distances, to the middle of the transverse colon or into the descending colon. From the evidence which we have assembled, the relaxation of the contracted gut is in the reverse direction from which the contraction occurred. For a long time we have desired to study this phenomenon by roentgenocinematography, but as yet have not gotten to it. These waves of contraction are infrequent in occurrence and cannot be accurately anticipated. However, during the making of serial roentgenograms of the colon we have recorded the appearance of the colon in local regions before, during, and after this phenomenon has occurred, and from these records we have obtained much valuable information and are able to state that the following changes may occur in the colon:

- 1 When an extensive contraction of the muscularis propria occurs the segmental rings are not completely obliterated. As soon as the most intense force of the contraction is spent, the segmental rings can be recognized as flattened segments which give a grossly serrated appearance to the margin of the contracted gut (Fig 124 and Fig 116-D). Before we recognized

that these segmental folds remained as definite formations when the colon was contracted by the muscularis propria, we had been greatly puzzled by this gross serration of the lumen of the contracted gut. It is a familiar finding in practically all roentgenograms made of the colon after evacuation of a barium enema.

This phenomenon is shown characteristically in Figure 126, which is a tracing of two roentgenograms from a series of roentgenograms made of the proximal part of the colon while filled with a barium enema. The patient is lying prone in the right oblique position so that there is no confusion or overlapping of the shadows of the colon from the hepatic flexure to near the middle of the transverse colon. The solid line is a tracing of the outline of the colon as shown in Film No 5 of the series. At this time the colon was moderately distended and the segmental rings which divide the first part of the transverse colon into sacculations or haustra are shown distinctly in profile. The outline of the colon is not distorted by longitudinal trisection of the colon by the longitudinal bands.

The interrupted line is a tracing of the outline of the colon as shown in Film No 9 of the series. The outline only of the colon is shown, the intrinsic mucosal markings or pattern not being included. At this time there was an extensive contraction which extended from the cecocolic tract to past the middle of the transverse colon. The shortening of the colon which takes place when this type of contraction occurs is shown distinctly in the shortening of the ascending colon, with depression of the hepatic flexure and deviation of the cecum, and, also, in a shortening of the transverse colon which brings into view segmental folds not seen in Film No 5, and pulls the hepatic flexure anteriorly. For identification we have numbered the segmental folds on both the inferior and superior surfaces of the transverse colon. Superimposition of the two tracings shows that every segmental fold observed in Film No 5 may be identified as a flattened-out, broader fold in Film No 9. The relation of the folds to each other is the same when the colon is partially distended and when it is contracted. This finding shows that the muscle element producing the segmental folds is not the same muscle that produces the more general contraction and the mass movements of the colon.

2. The independence of the segmental folds from contraction of the muscularis propria is further shown by the fact that a long segment of the colon may temporarily contract without disturbing the arrangement of the segmental folds. Figure 127 is a tracing of three roentgenograms from a series of five which were made of the transverse colon while the colon was filled with a barium enema. This series of films was made with an interval of a minute following each roentgenogram and the experiment was made with the definite object of determining what changes occurred in the segmental folds during a short interval of time. We were fortunate in accidentally recording on Film No 2 a mass contraction which occurred and relaxed during the interval of three minutes between the making of Films No 1 and No 4. Film No 2 was probably made at the height of contraction and at this time the proximal part of the colon was contracted and the

without guessing at the margin of the lumen of the gut. These tracings are from roentgenograms made of the colon after administration of a barium enema. One will immediately notice that the segmental folds vary greatly in their form and depth.

- 1 Short fold (Figs 121 and 123)
- 2 Deep fold with narrow tip (Fig 120)
- 3 Fold with bulbous tip (Fig 121)
- 4 Ring with flattened tip and projection both distally and proximally (Fig 122)
- 5 Ring with projection only proximally (Fig 122)
- 6 Ring with projection only distally (Fig 121)
- 7 Ring budding off of base of deeper fold (Fig 118)
- 8 Double fold (Fig 119)

In roentgenograms made of the colon during the passage or, rather, retention of the barium meal one may observe the same type of segmented rings shown in Figures 118-123 and Figure 116-C. There is, however, a definite tendency for the segmental rings to be broadened as shown in Figure 116, A and B. Broad rings of segmental contraction of this type show the possibility but not probability of the other coats of the muscularis propria entering into the formation of the folds.

A localized increase in tone or partial contraction of the muscularis propria we believe is more likely to account for the appearance illustrated in Figure 123, a finding which is not uncommonly found in a local region when the colon is filled with a barium enema. A similar finding is present in the middle of the transverse colon in Figure 116-C.

The effect upon the segmental rings of the extensive waves of contraction (the waves which Case has described) which move forward a large amount of the contents of the colon gives us a great deal of information regarding the nature of the segmental rings. These extensive waves of contraction begin in the ascending colon or in the region of the hepatic flexure. The contraction may extend for variable distances, to the middle of the transverse colon or into the descending colon. From the evidence which we have assembled, the relaxation of the contracted gut is in the reverse direction from which the contraction occurred. For a long time we have desired to study this phenomenon by roentgenocinematography, but as yet have not gotten to it. These waves of contraction are infrequent in occurrence and cannot be accurately anticipated. However, during the making of serial roentgenograms of the colon we have recorded the appearance of the colon in local regions before, during, and after this phenomenon has occurred, and from these records we have obtained much valuable information and are able to state that the following changes may occur in the colon:

- 1 When an extensive contraction of the muscularis propria occurs the segmental rings are not completely obliterated. As soon as the most intense force of the contraction is spent, the segmental rings can be recognized as flattened segments which give a grossly serrated appearance to the margin of the contracted gut (Fig 124 and Fig 116-D). Before we recognized

The segmental folds 1, 3, 4, 5, and 6 show a definite variation in form and 1 and 4 show a marked variation in depth. Fold 2 disappears and is replaced by two folds in a different location (*D* and *E*). At *A*, *A'*, *B*, and *C* there are shallow folds which are not constant and are differently situated in the several roentgenograms.

It is our opinion that these folds act functionally to break up into variable segments the fecal contents of the colon so that the mucosa is brought into contact with different, varying parts of the fecal material. We do not believe that they exert any function in moving the contents of the colon from one region to another.

THIRD FUNDAMENTAL FINDING

(Pliability of the mucosa to peristalsis)

The third fundamental finding is the pliability of the mucosa to peristalsis. This finding is comparable with the waves of the sea as they are interrupted by floating objects, particularly by flat cakes of ice (Fig. 68)—hard, malignant or non-malignant areas, like flat cakes of ice, interfere with the gastro-intestinal peristalsis. This finding is the most delicate of the four and it requires serial roentgenography for its application to early lesions. Use of this finding necessitates the presence of peristaltic contractions which are repeated at sufficiently frequent intervals so that roentgenographic records may be made which will show whether peristaltic contractions pass through a certain section of the gut in a normal manner, or whether they are obstructed by an area of infiltration which has rendered the wall of the gut non-pliable. Reversely considered, the presence of normal peristaltic contractions is of equal importance in that it rules out the presence of infiltration sufficiently deep to interfere with the contracting muscle.

Esophagus.—Under ordinary conditions of examination, particularly with the patient in the erect posture, peristaltic contractions of the esophagus are infrequent and not prominent. Examination of the patient in the recumbent position, with the hips elevated, will usually elicit peristalsis in the esophagus, as the barium bolus must then be forced up an inclined plane. Likewise, the presence of a partial obstruction will often call forth an abnormal number of peristaltic contractions.

Figure 130 shows an unusual finding in the esophagus, which is a physiological reaction to an inconstant spasm in the region of the cardia. The peristaltic contractions, as is usual, are inconstant in depth and arrangement. The slightly dilated esophagus shows the impressions of the adjacent organs so distinctly that the pliability of the wall of the esophagus as shown in the progress of the peristaltic contractions is a valuable aid in ruling out the presence of a newgrowth. This was highly essential in this case because the clinical history was indicative of a newgrowth, that is, difficulty in swallowing and a loss of 60 pounds weight in eight months.

Figure 72 shows the opposite application of this finding. There is an extremely small carcinoma involving the posterior wall of the esophagus, and the growth is not sufficiently large to produce the usual characteristic de-

distal part of the transverse colon was markedly dilated. During this time the patient did not evacuate any of the barium enema. The solid line is a tracing of the colon outline in Film No 1, the dotted line is a tracing of Film No 2, and the broken line is a tracing of Film No 4. In the stage of contraction (dotted line) the imprint in the outline of the lumen of the flattened segmental folds is clearly shown. The most interesting finding, however, is the fact that the number and distribution of the segmental folds is absolutely identical in Films No 1 and No 4. This shows most clearly that a temporary extensive contraction of the muscularis propria may take place without obliteration of the segmental folds, and that following relaxation of the contraction and with the same distension of the gut the segmental folds will have identically the same form and distribution.

3 During a period of contraction of a long segment of the colon the contour of the gut does not remain constant, although the gross outline retains the same general form. Figure 128 is a tracing of two consecutive films from the same series, as was illustrated in Figure 126. A time interval of approximately 30 seconds elapsed between the making of these consecutive films. In this interval of time no change has taken place in the gross form of the outline of the colon, the indentations due to the segmental folds remaining present and changing only slightly in form. There are, however, many slight variations in the finer details of the outline. These changes may be due to varying degrees of tension in the muscularis propria.

4 At the actively contracting end of a long contraction causing a mass movement (Fig. 125, 1) the mucosa and segmental folds are thrown forward ahead of the contraction wave, the appearance being similar to the bending of tall grass as it is swept by a gust of wind. This is entirely similar to the change in appearance of the valvulae conniventes of the small intestine ahead of a broad wave of peristalsis.

From the preceding observations we can logically deduce that the segmental folds of the colon are a reduplication of the mucosa and muscularis mucosae with a core of submucosa, and that they are similar to the sulcus angularis, pyloric valve of the stomach, and the valvulae conniventes of the small intestine. Further, likewise, analogous to these other structures, we believe that the segmental folds of the colon are the product of an active contraction of the one continuous muscle layer included within them, that is, the muscularis mucosae.

That the segmental folds may remain unchanged, even though extensive changes occur in the muscularis propria, has been illustrated in Figure 127. The question naturally arises as to what spontaneous changes do occur in these folds and whether they progress either distally or proximally in the long axis of the colon. As regards the second question, we do not have sufficient evidence as yet to establish whether or not there is any peristaltic action of the segmental folds. The first question is partially answered by a study of Figure 129, which is a group of four tracings of the outline of the distal part of the transverse colon as shown in four of a series of seven films made during a time interval of several minutes.

The segmental folds 1, 3, 4, 5, and 6 show a definite variation in form and 1 and 4 show a marked variation in depth. Fold 2 disappears and is replaced by two folds in a different location (*D* and *E*). At *A*, *A'*, *B*, and *C* there are shallow folds which are not constant and are differently situated in the several roentgenograms.

It is our opinion that these folds act functionally to break up into variable segments the fecal contents of the colon so that the mucosa is brought into contact with different, varying parts of the fecal material. We do not believe that they exert any function in moving the contents of the colon from one region to another.

THIRD FUNDAMENTAL FINDING

(Pliability of the mucosa to peristalsis)

The third fundamental finding is the pliability of the mucosa to peristalsis. This finding is comparable with the waves of the sea as they are interrupted by floating objects, particularly by flat cakes of ice (Fig. 68)—hard, malignant or non-malignant areas, like flat cakes of ice, interfere with the gastro-intestinal peristalsis. This finding is the most delicate of the four and it requires serial roentgenography for its application to early lesions. Use of this finding necessitates the presence of peristaltic contractions which are repeated at sufficiently frequent intervals so that roentgenographic records may be made which will show whether peristaltic contractions pass through a certain section of the gut in a normal manner, or whether they are obstructed by an area of infiltration which has rendered the wall of the gut non-pliable. Reversely considered, the presence of normal peristaltic contractions is of equal importance in that it rules out the presence of infiltration sufficiently deep to interfere with the contracting muscle.

Esophagus.—Under ordinary conditions of examination, particularly with the patient in the erect posture, peristaltic contractions of the esophagus are infrequent and not prominent. Examination of the patient in the recumbent position, with the hips elevated, will usually elicit peristalsis in the esophagus, as the barium bolus must then be forced up an inclined plane. Likewise, the presence of a partial obstruction will often call forth an abnormal number of peristaltic contractions.

Figure 130 shows an unusual finding in the esophagus, which is a physiological reaction to an inconstant spasm in the region of the cardia. The peristaltic contractions, as is usual, are inconstant in depth and arrangement. The slightly dilated esophagus shows the impressions of the adjacent organs so distinctly that the pliability of the wall of the esophagus as shown in the progress of the peristaltic contractions is a valuable aid in ruling out the presence of a new growth. This was highly essential in this case because the clinical history was indicative of a new growth, that is, difficulty in swallowing and a loss of 60 pounds weight in eight months.

Figure 72 shows the opposite application of this finding. There is an extremely small carcinoma involving the posterior wall of the esophagus, and the growth is not sufficiently large to produce the usual characteristic de-

formity of the contour of the esophagus. The non-pliability of the wall in this area, as shown by the fact that the peristaltic contractions do not pass through this region, establishes a positive diagnosis of a lesion infiltrating the wall of the esophagus. The roentgenographic diagnosis of carcinoma was corroborated by esophagoscopy.

Stomach.—The third fundamental roentgenologic finding is of greatest value in study of the stomach. In this organ the peristaltic contractions normally recur in definite and frequently repeated cycles. A series of roentgenograms made of the stomach within a short period of time will record the pliability of the gastric wall. By matching one film over another one can determine accurately the slightest variation in contour of the gastric wall as it reacts to the peristaltic contractions. Serial roentgenography in several positions and projections will show definitely whether the various surfaces of the gastric wall are pliable (Fig. 5), or whether the peristaltic contraction is obstructed by an area of infiltration, malignant (Fig. 131) or non-malignant (Fig. 132). An old but simple method of demonstrating the pliability of the gastric wall is shown in Figure 133. With this method, two or three exposures are made on the same film while the patient maintains his position and holds his breath. The exposures are made at intervals of from 2 to 4 seconds, and each exposure is one-half or one-third of the normal exposure.

The application of this method to very slight areas of induration is a most delicate procedure and serial roentgenography is essential to detect a lack of pliability in a small section of the gastric wall due to an early carcinoma. This finding is especially valuable in detecting the presence of a diffusely infiltrating cancer which involves the entire lesser curvature of the stomach without producing any gross deformity of its contour. This type of lesion frequently escapes detection because of the lack of characteristic deformity of contour and yet the absence of peristalsis is strongly diagnostic.

Small shallow ulcers of the stomach which involve only the mucosa produce a local rigidity of the gastric wall, but this rigid area is so small that it does not disturb the pliability of the adjacent gastric wall. The ulcer, therefore, changes its position in relation to the peristaltic contractions as shown in Figures 97 and 100.

In the pyloric canal one observes a similar disturbance of contraction due to infiltration of the gastric wall. The relation is somewhat different in this region because the contraction of the pyloric canal is a progressive concentric contraction instead of a progressive peristaltic contraction. The small carcinoma shown in Figure 135 and which involves the lesser curvature side of the pyloric canal, was successfully diagnosed roentgenographically and the positive diagnosis of cancer was based on the constant lack of pliability in a local region of the lesser curvature side of the pyloric canal. A chronic spasm of the pyloric canal, which may produce a similar deformity will always show a change in contour of the lumen of the pyloric canal because the pliability of the wall is not completely lost (Fig. 136).

Fig. 66 The first fundamental finding may be likened to one walking around a tree, examining its bark and noticing whether it is smooth or rough, bulged as by a growth, or barked as by an ulcer

Fig. 67 The second fundamental finding is well illustrated by a sandwich, that is, a double slice of bread is likened to the double layer of mucosa and the filling to the submucosa

Fig. 68 The third fundamental finding is comparable with the waves of the sea as they are interrupted by floating objects particularly by flat cakes of ice

Fig. 69 The fourth fundamental finding is comparable with the ruts in an old dirt road in the country partly filled with water and skimmed with ice, a simile not too familiar to the younger generation

formity of the contour of the esophagus. The non-pliability of the wall in this area, as shown by the fact that the peristaltic contractions do not pass through this region, establishes a positive diagnosis of a lesion infiltrating the wall of the esophagus. The roentgenographic diagnosis of carcinoma was corroborated by esophagoscopy.

Stomach.—The third fundamental roentgenologic finding is of greatest value in study of the stomach. In this organ the peristaltic contractions normally recur in definite and frequently repeated cycles. A series of roentgenograms made of the stomach within a short period of time will record the pliability of the gastric wall. By matching one film over another one can determine accurately the slightest variation in contour of the gastric wall as it reacts to the peristaltic contractions. Serial roentgenography in several positions and projections will show definitely whether the various surfaces of the gastric wall are pliable (Fig. 5), or whether the peristaltic contraction is obstructed by an area of infiltration, malignant (Fig. 131) or non-malignant (Fig. 132). An old but simple method of demonstrating the pliability of the gastric wall is shown in Figure 133. With this method, two or three exposures are made on the same film while the patient maintains his position and holds his breath. The exposures are made at intervals of from 2 to 4 seconds, and each exposure is one-half or one-third of the normal exposure.

The application of this method to very slight areas of induration is a most delicate procedure and serial roentgenography is essential to detect a lack of pliability in a small section of the gastric wall due to an early carcinoma. This finding is especially valuable in detecting the presence of a diffusely infiltrating cancer which involves the entire lesser curvature of the stomach without producing any gross deformity of its contour. This type of lesion frequently escapes detection because of the lack of characteristic deformity of contour, and yet the absence of peristalsis is strongly diagnostic.

Small shallow ulcers of the stomach which involve only the mucosa produce a local rigidity of the gastric wall, but this rigid area is so small that it does not disturb the pliability of the adjacent gastric wall. The ulcer, therefore, changes its position in relation to the peristaltic contractions as shown in Figures 97 and 100.

In the pyloric canal one observes a similar disturbance of contraction due to infiltration of the gastric wall. The relation is somewhat different in this region because the contraction of the pyloric canal is a progressive concentric contraction instead of a progressive peristaltic contraction. The small carcinoma shown in Figure 135 and which involves the lesser curvature side of the pyloric canal, was successfully diagnosed roentgenographically and the positive diagnosis of cancer was based on the constant lack of pliability in a local region of the lesser curvature side of the pyloric canal. A chronic spasm of the pyloric canal, which may produce a similar deformity will always show a change in contour of the lumen of the pyloric canal because the pliability of the wall is not completely lost (Fig. 136).

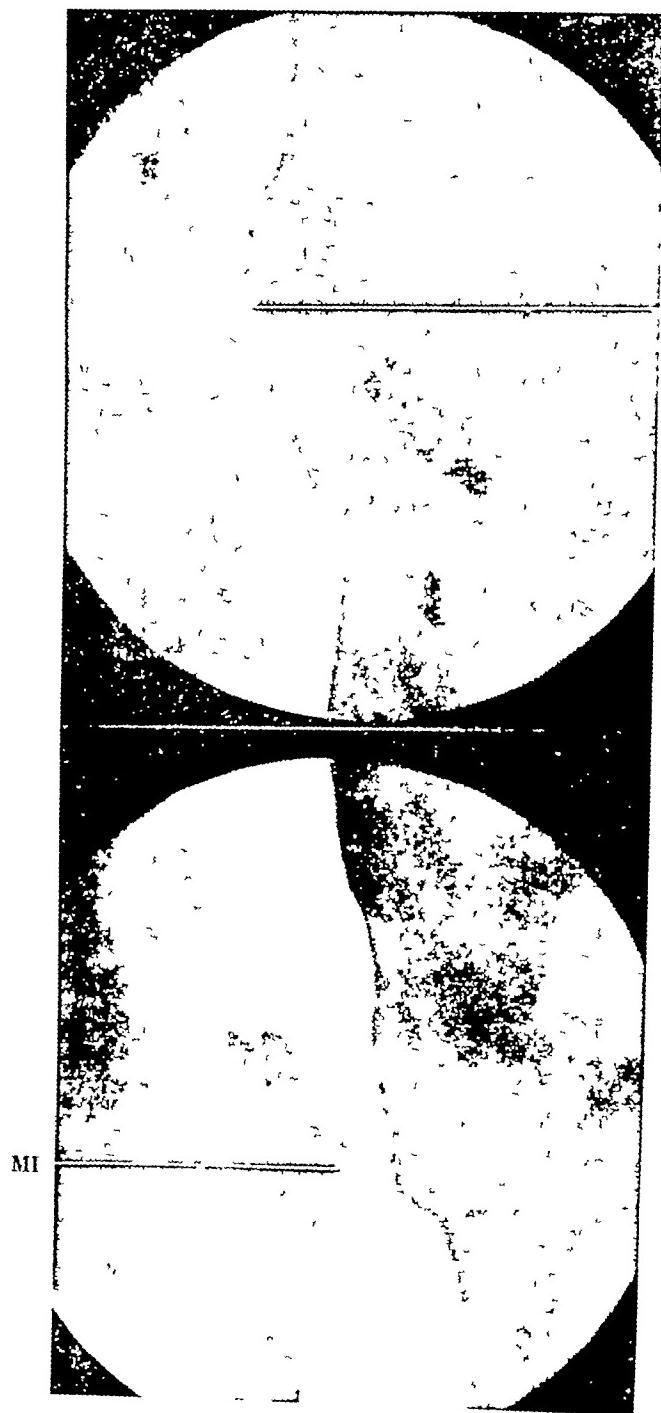

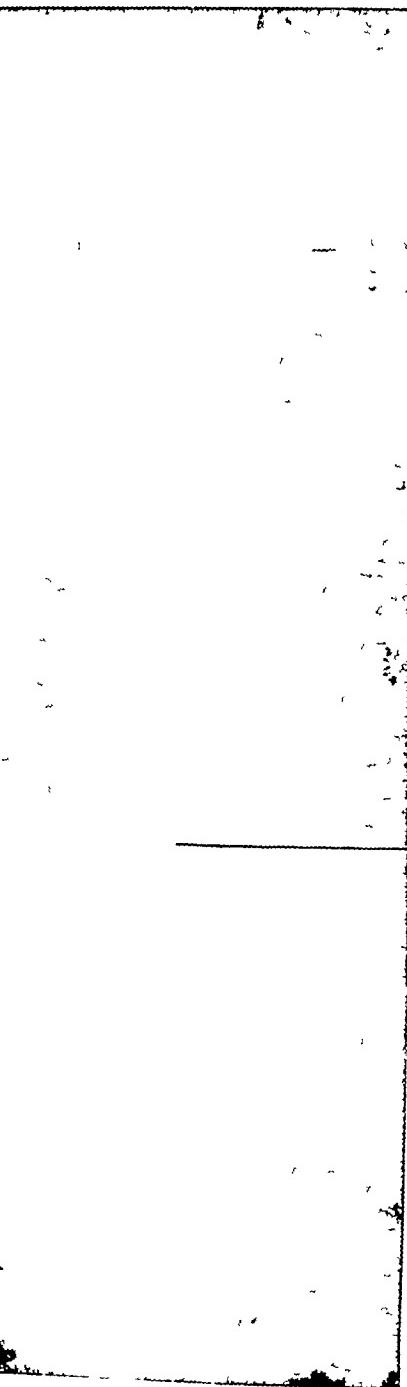

Fig 72 Roentgenograms made of the esophagus in the anteroposterior and right and left oblique directions show a small area of malignant induration (MI) of the mucosa which involves only part of the circumference of the esophagus. The malignant induration projects into the lumen and displaces the barium, giving an alteration from the normal contour. This illustrates the first fundamental finding which enables to detect a small pathologic lesion. The non-pliability of the wall of the esophagus in this area—third fundamental finding—was shown by the fact that the peristaltic contractions did not pass through this region.

Fig. 70

Fig. 71

Roentgenograms made in the postero-anterior direction (Fig. 70), and the lateral direction (Fig. 71), show the alteration in contour of the esophagus produced by a large diverticulum (*D*), which protrudes outside of the normal line of the lumen of the esophagus. The manner in which the neck (*N*) of the diverticulum arises from the posterior side of the cervical vertebra is shown in Figure 71. The esophagus is displaced forward and to the right by the body of the seventh cervical vertebra.

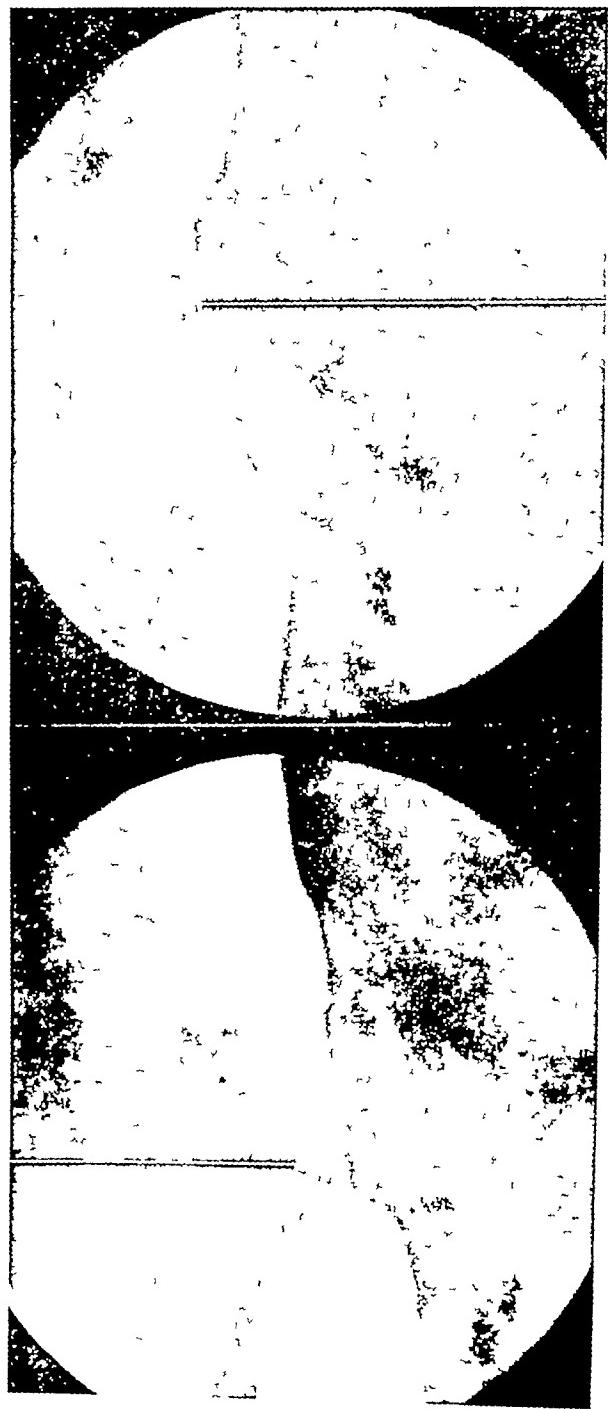

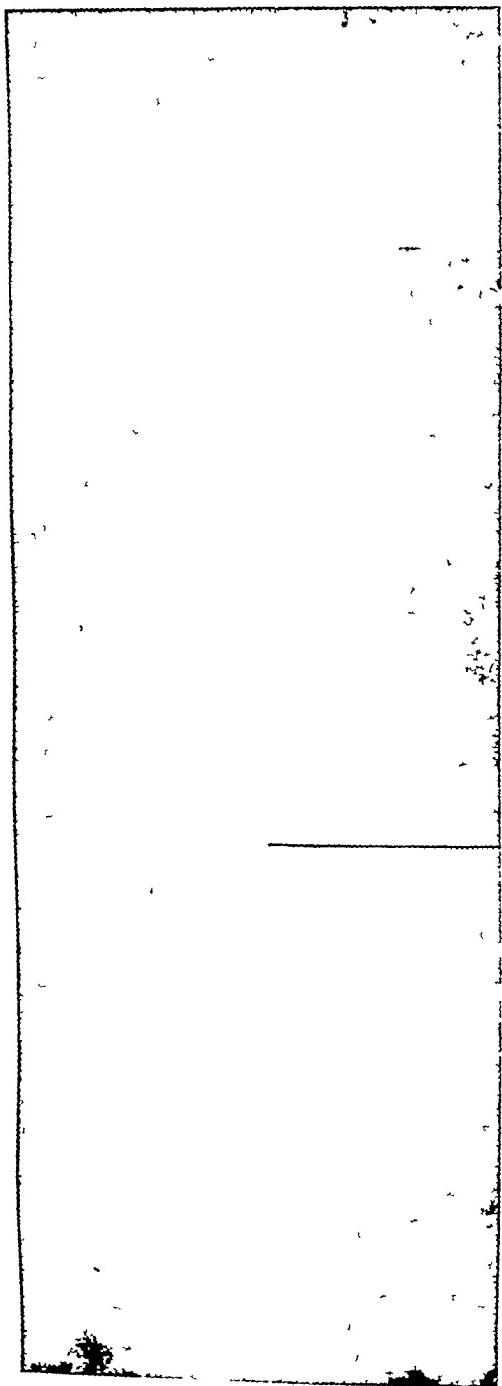

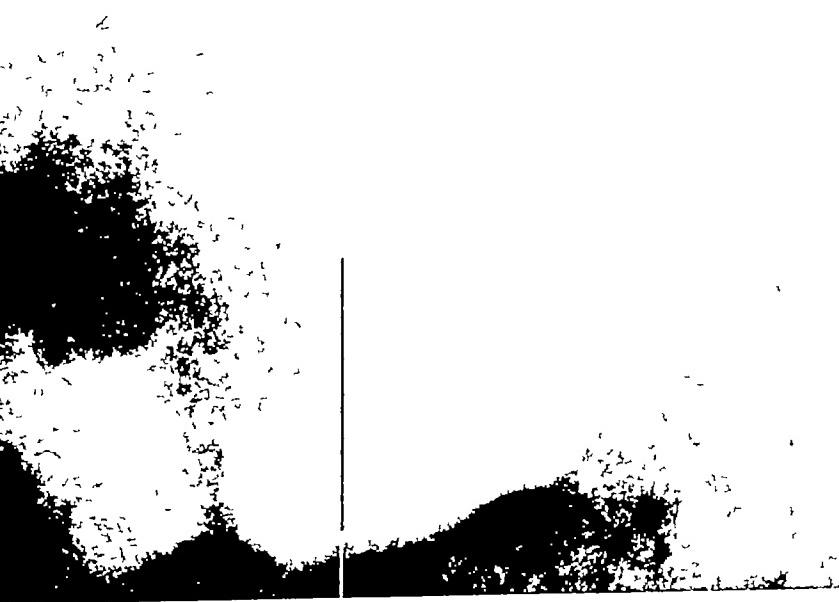

Fig 72 Roentgenograms made of the esophagus in the anteroposterior and right and left oblique directions show a small area of malignant induration (*MI*) of the mucosa which involves only part of the circumference of the esophagus. The malignant induration projects into the lumen and displaces the barium, thus giving an alteration from the normal contour. This illustrates the first fundamental finding which enables one to detect a small pathologic lesion. The non-pliability of the wall of the esophagus in this area—third fundamental finding—was shown by the fact that the peristaltic contractions did not pass through this region.

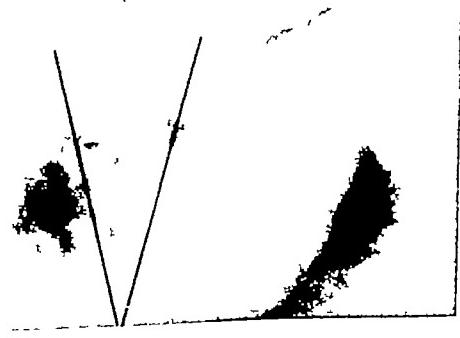

Fig 73

Fig. 73 Roentgenogram in which a growth is observed to project from the greater curvature of the antrum into its lumen. The surface of the central portion of this growth has been destroyed, resulting in an ulcer (U). This figure illustrates the manner in which the induration (I) around a malignant ulcer projects into the lumen of the stomach. This is particularly well shown in Figure 75 which is a photomicrograph of a longitudinal section of the surgical specimen of this same case.

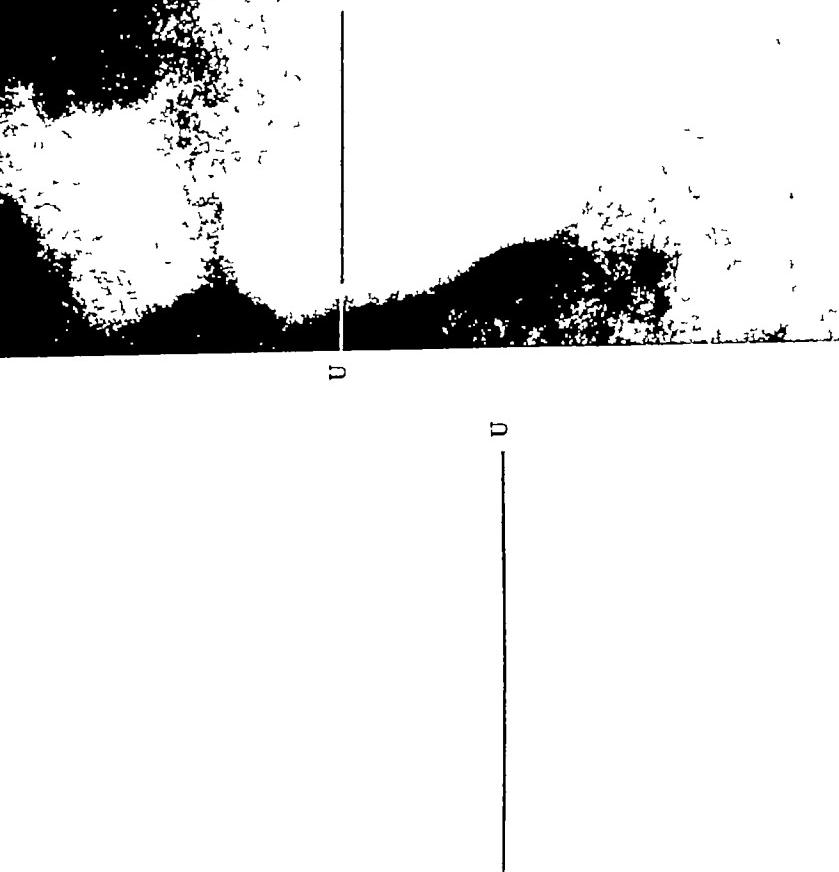

Fig. 74

Fig. 74. Roentgenogram which shows a benign ulcer (*U*) on the lesser curvature side of the antrum. The barium in the crater protrudes beyond the contour of the adjacent gastric wall. Figure 76 is a photograph of a longitudinal section of a similar ulcer.

Fig. 98

Fig. 99

Fig. 100

Figs 97-100 are four of a series of roentgenograms which show a small mucosal ulcer in the region of the sulcus angularis. There is not sufficient induration around the ulcer to interfere with peristalsis and as a result the crater of the ulcer rides with the wave. In Fig 97 the crater is in the distal surface of the peristaltic wave at the sulcus. In the succeeding figures the peristaltic wave has moved pyloruswards and the crater is successively at the tip of the wave (Fig 98), in the proximal surface of the wave (Fig 99), and proximal to the wave (Fig 100).

Fig. 96 Sulci angulares of several cases and of different stages of the same case 1, 2, 3 4, 5, 6—types of sulci observed in different cases 7, 8, 9—the sulcus of the same case at different stages of the cycle *A*—diastole *B*—systole *C*—the pyloric canal closed

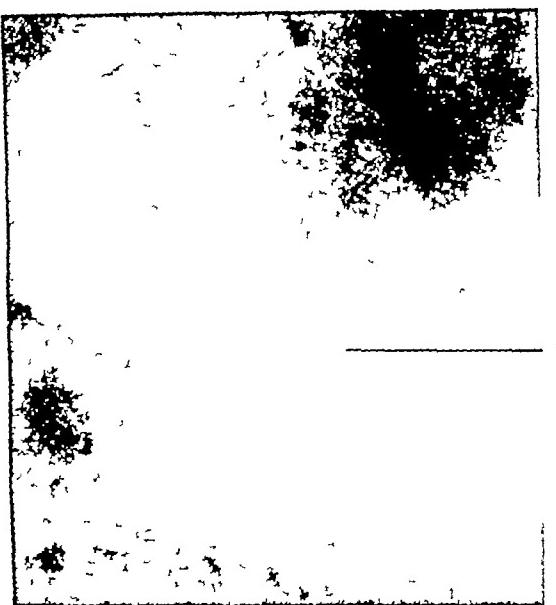

Fig 103 Roentgenogram which shows a small shallow ulcer (*U*) involving the proximal surface of the lesser curvature side of the pyloric valve. The induration around the crater has thickened the lesser curvature side of the valve

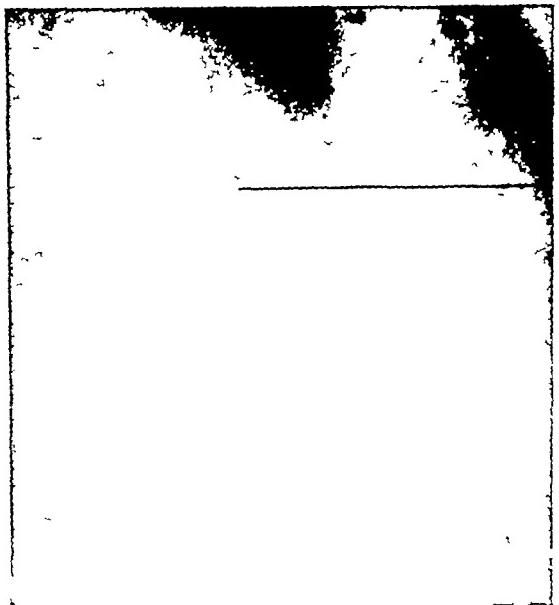

Fig 104 Roentgenogram which shows an ulcer (*U*) in the middle of the pyloric valve. The induration extends into the wall of both the stomach and cap so that the lesser curvature side of the valve is obliterated and there is flattening of the contour of the adjacent parts of the stomach and cap. The residual deformity which was present after this ulcer was healed is shown in Figure 107

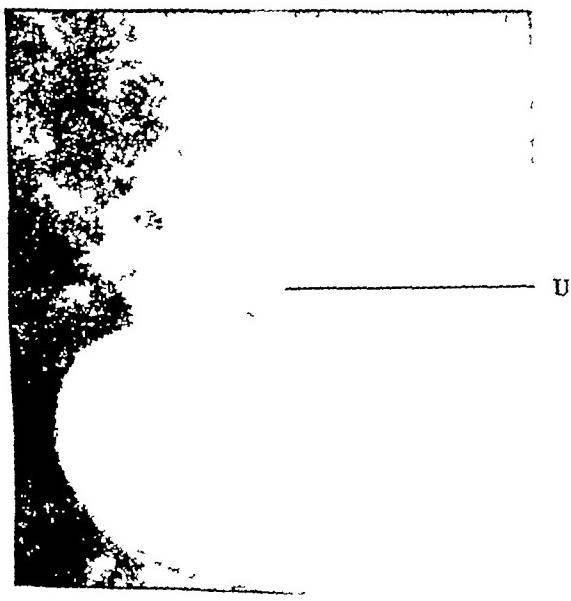

Fig 105 Roentgenogram which shows a deep ulcer (*U*) in the pyloric valve. The induration completely encircles the stomach and cap in the region of the valve

Fig 106 Roentgenogram which shows the manner in which induration around an ulcer (*U*) of the antrum may extend across the pyloric valve and produce a flattening of the contour of one side of the valve and the adjacent part of the cap

Fig. 102 Roentgenogram which shows an ulcer in the region of the sulcus angulans which is sufficiently deep to involve the muscularis propria. The crater and the surrounding area of infiltration have obliterated the sulcus angulans.

Fig. 101 Roentgenogram which shows a small submucosal ulcer in the sulcus angulans. The induration around the ulcer has increased the width of the proximal surface of the sulcus angulans.

Fig 111 Roentgenogram which shows an annular carcinoma of the antrum which has developed adjacent to the proximal side of the pyloric valve. The growth does not extend into the wall of the cap. At the base of the cap there is a small indentation where the valve protrudes slightly into the cap

Fig 112 Roentgenogram which shows an extensive carcinoma simplex involving practically all of the stomach except the portion adjacent to the pyloric valve

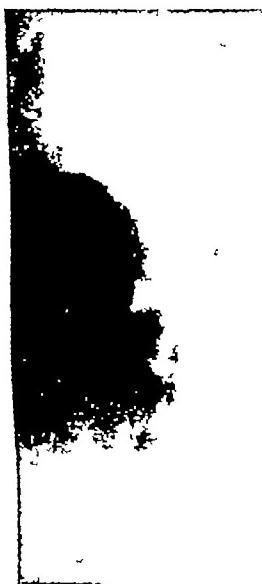

Fig 113

Fig 114

Figs 113 and 114 are roentgenograms made in the prone and erect postures which show a bulky adenocarcinoma involving the antrum of the stomach. The tumor extends close to the pyloric valve but does not involve it or extend into the wall of the cap

Fig 107

Fig 108

Figs 107 and 108 are roentgenograms which show the flattening of the lesser curvature side of the pyloric valve and adjacent parts of the stomach and cap which remains after healing of a deep ulcer of the pyloric valve. Fig 107 is the same case as shown in Figure 104 after an interval of 48 days.

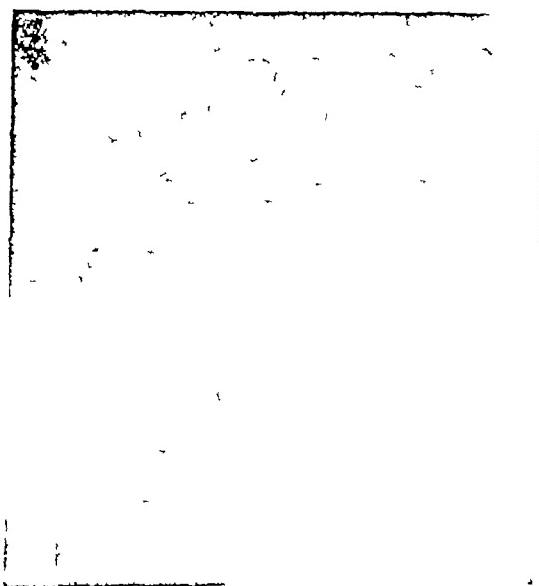

Fig 109 Roentgenogram which shows a funnel-shaped carcinoma of the antrum which extends to the pyloric valve. The contour of the cap side of the valve is normal and the lumen of the valve is centric to the lumen of the cap and the lumen of the constricted antrum

Fig 110 Roentgenogram which shows an annular carcinoma of the pyloric canal. The growth does not extend into the wall of the cap

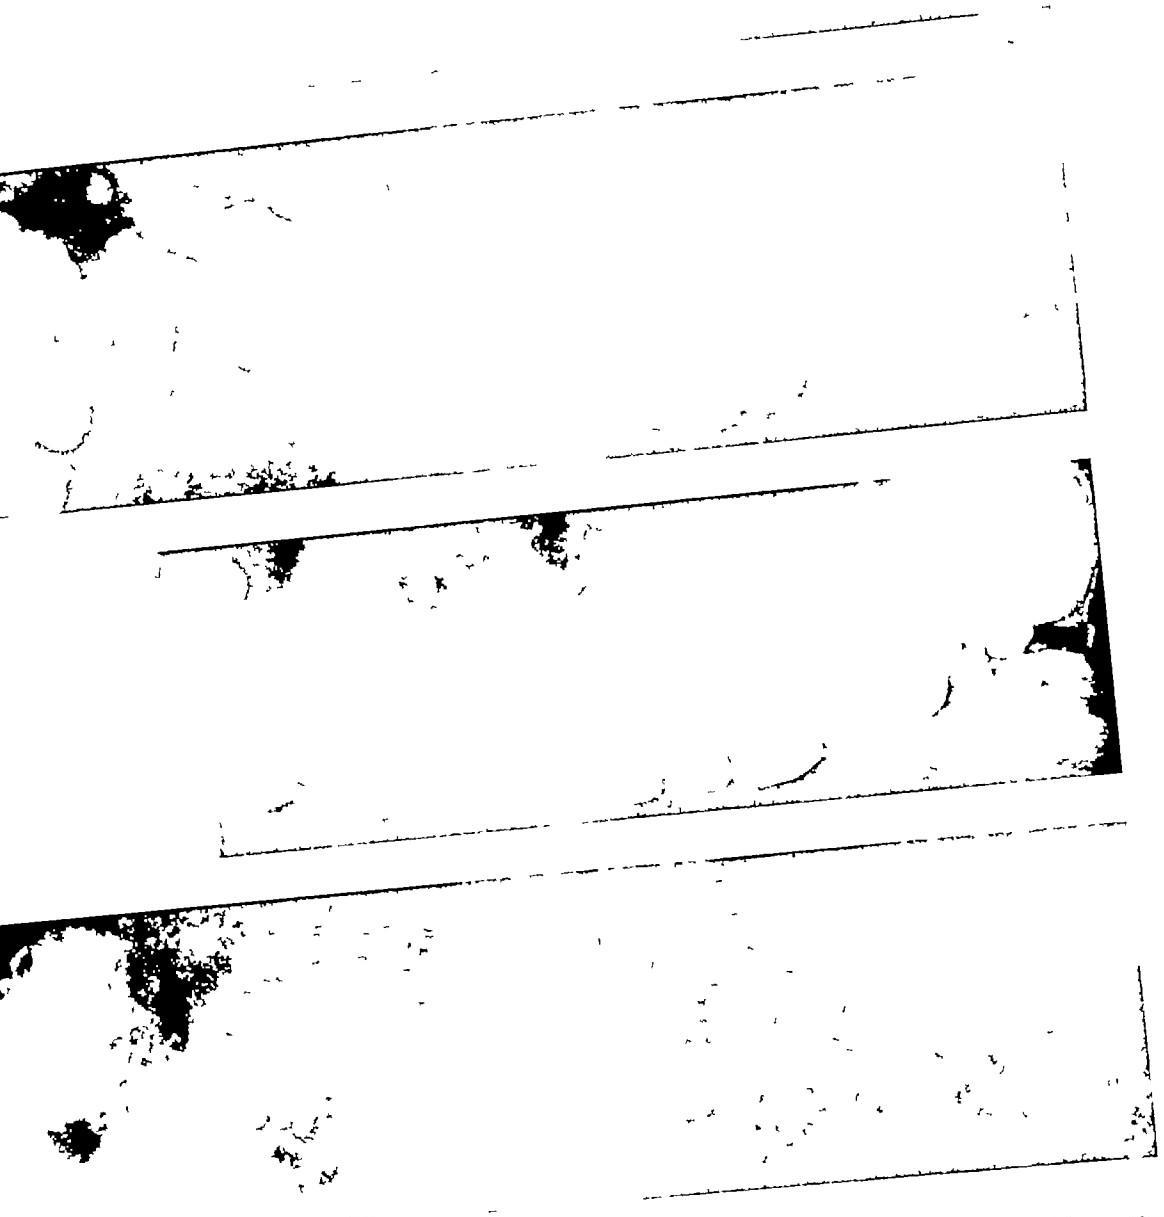

Fig 116 Roentgenograms which show the roentgenographic appearance of the segmental folds in the transverse colon *A* and *B*-24 hours after a barium meal *C*-the colon distended with a barium enema *D*-the contracted colon after evacuation of a barium enema

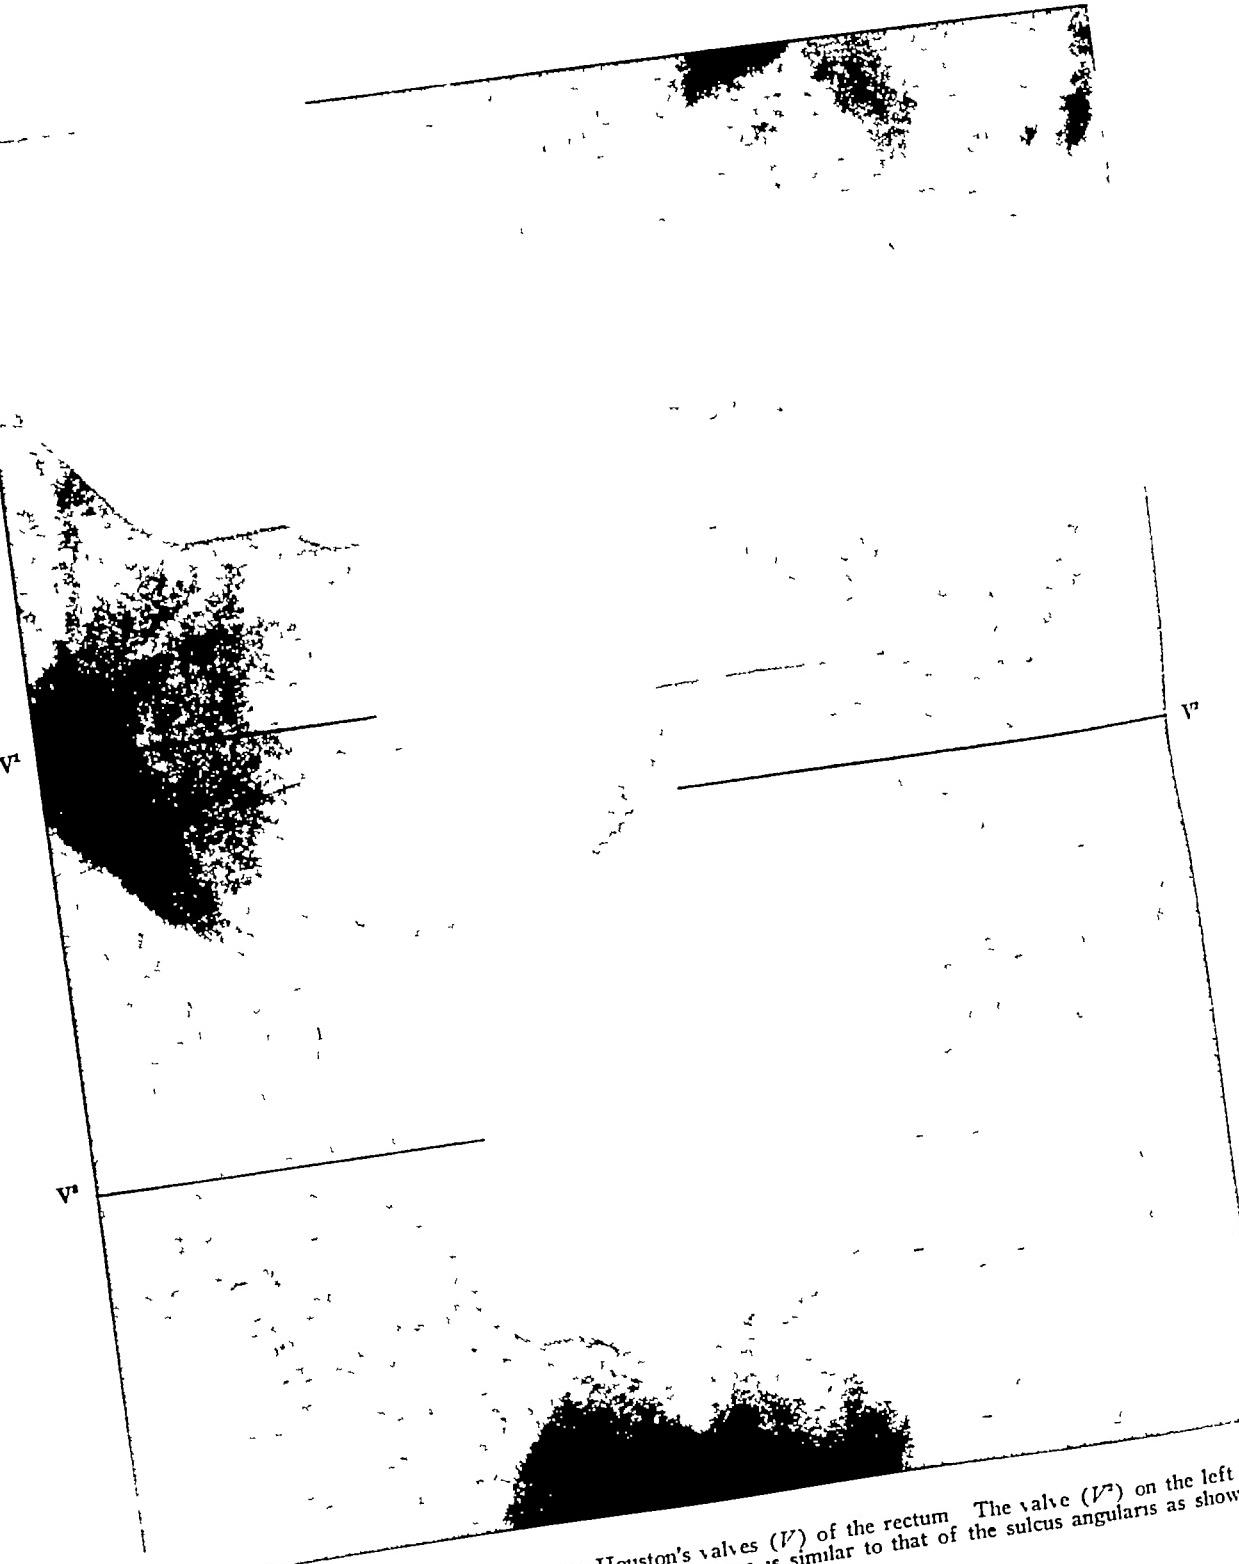

Fig 115 Roentgenogram which shows Houston's valves (V) of the rectum. Note that its appearance is similar to that of the sulcus angularis as shown in Figure 96.

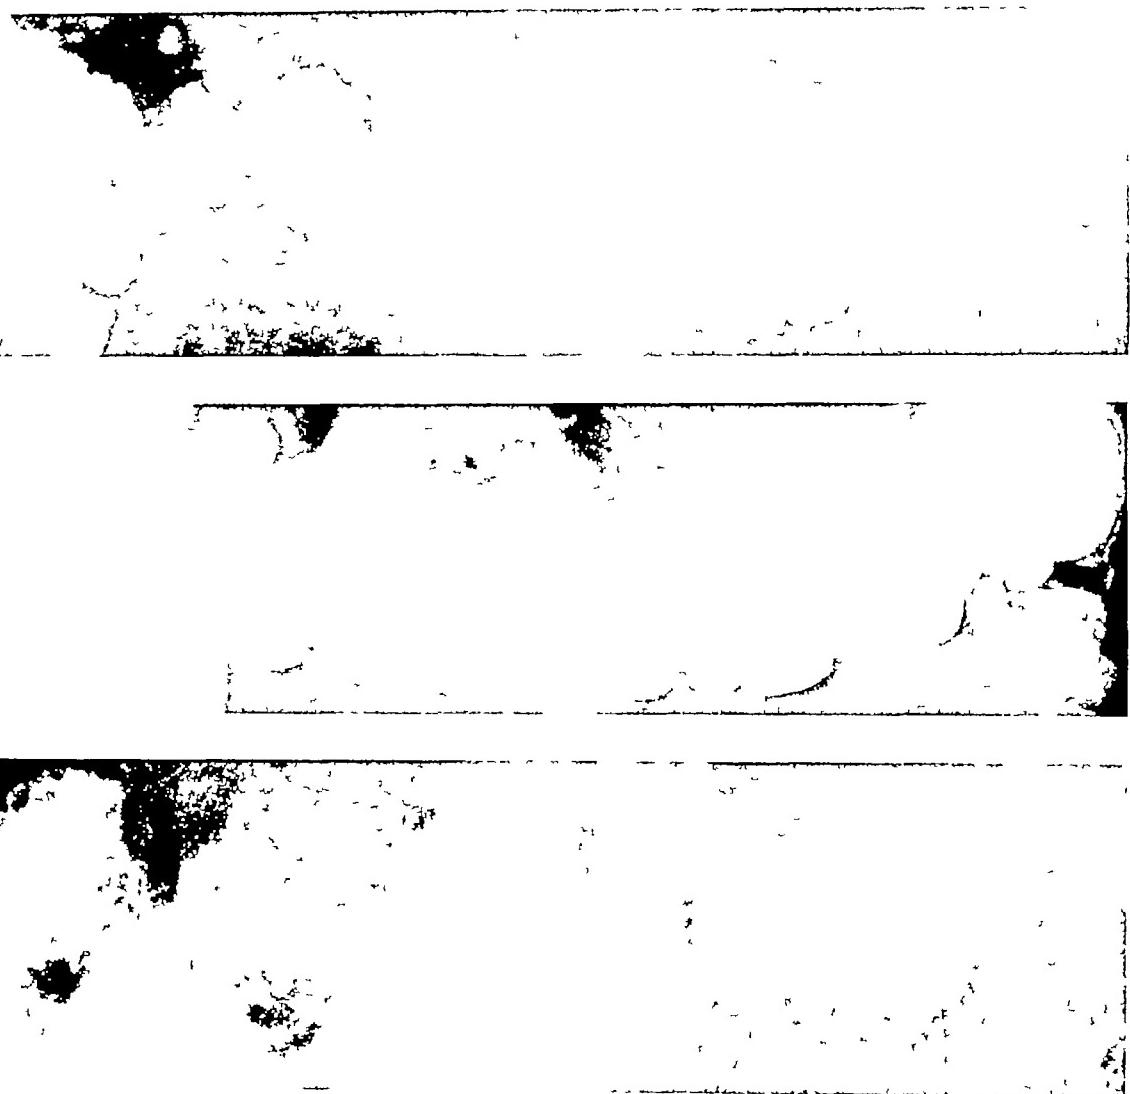

Fig 116 Roentgenograms which show the roentgenographic appearance of the segmental folds in the transverse colon *A* and *B*-24 hours after a barium meal *C*-the colon distended with a barium enema *D*-the contracted colon after evacuation of a barium enema

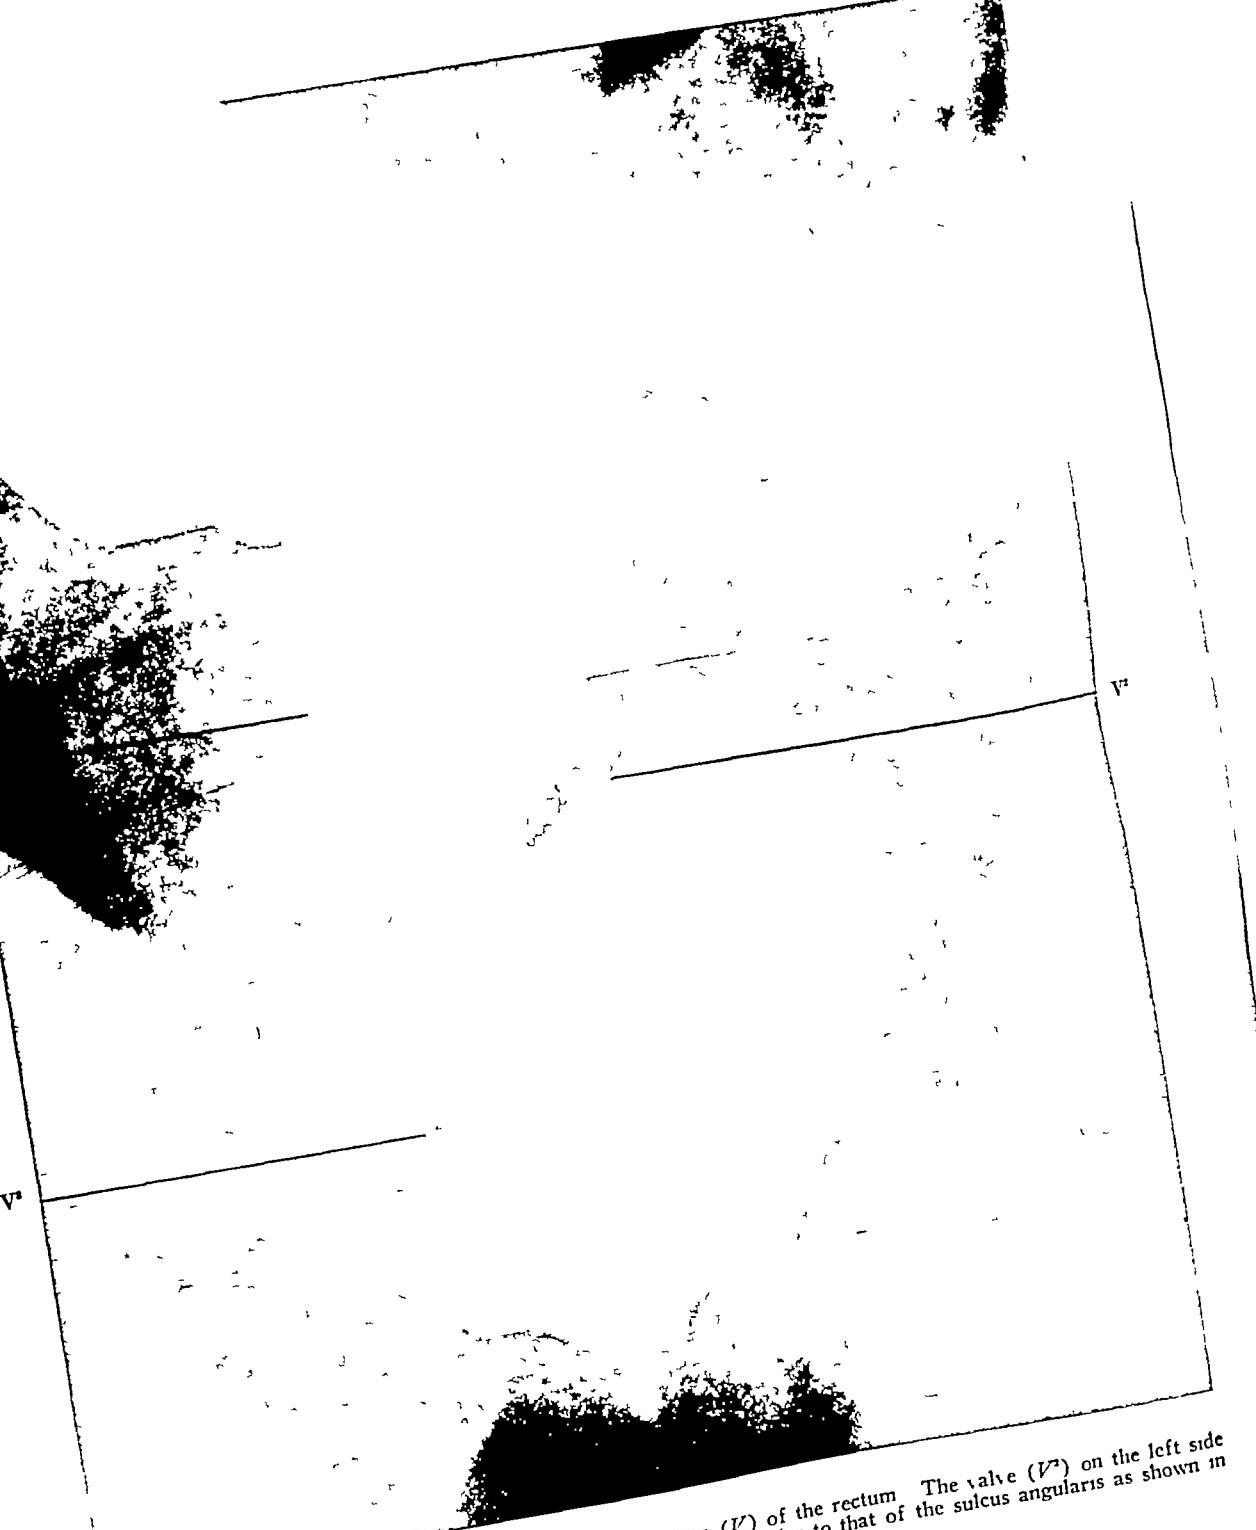

Fig 115 Roentgenogram which shows Houston's valves (V) of the rectum. The valve (V') on the left side of the rectum is viewed on edge. Note that its appearance is similar to that of the sulcus angularis as shown in Figure 96

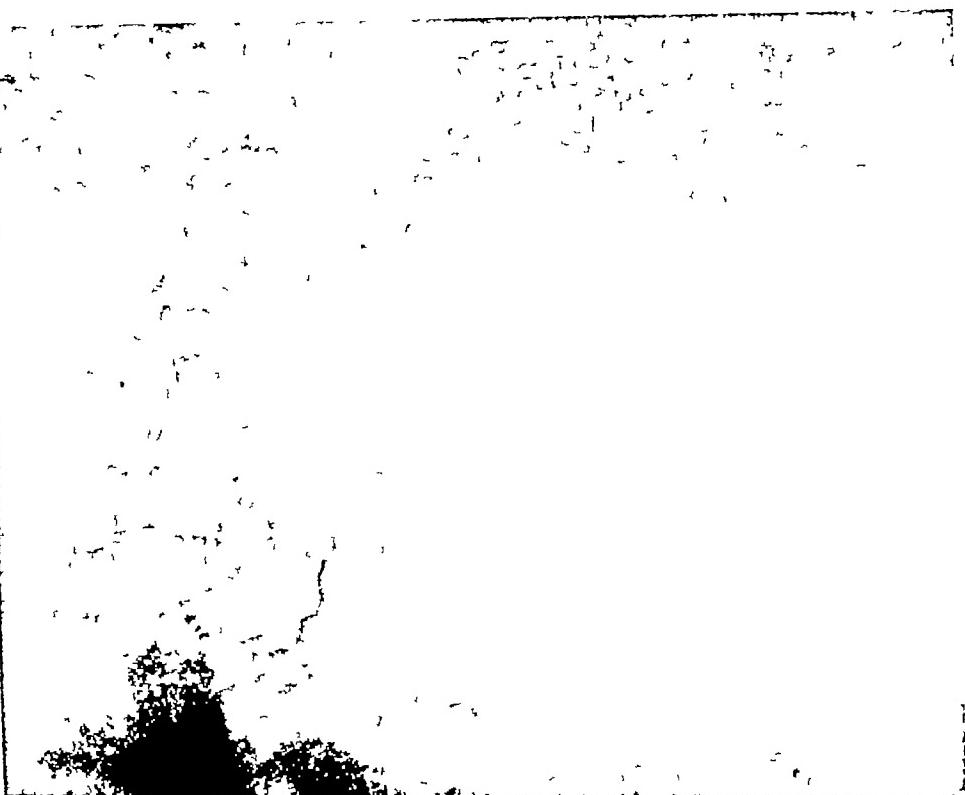

Fig. 124 Roentgenogram made after evacuation of a barium enema shows the grossly serrated contour of the lumen of the contracted colon. The gross serrations are due to the segmental folds which have been flattened out and broadened by contraction of the outer muscle wall (musculi proprii).

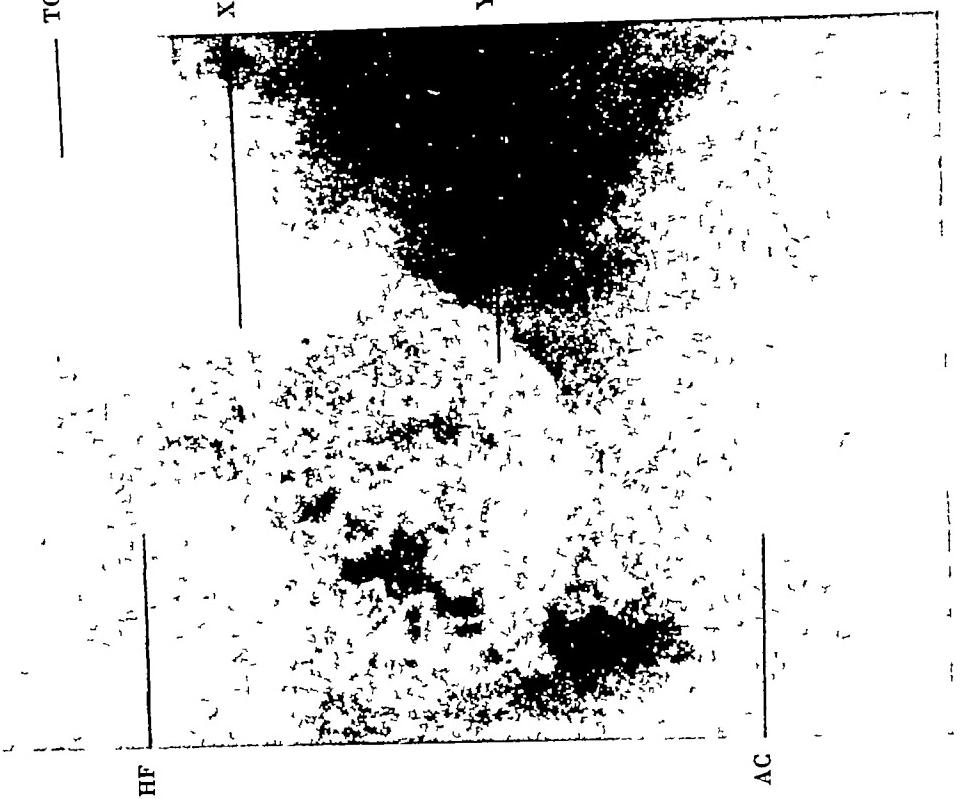

Fig. 125 Roentgenogram made of the colon during the progressive formation of a long contraction causing a mass movement. At the actively contracting end (X) the mucosal and segmental folds are thrown forward ahead of the wave of contraction, the appearance being similar to the bending of tall grass as it is swept by a gust of wind. In the area of most intense contraction (Y) the mucosa is folded longitudinally. AC—ascending colon; HF—hepatic flexure; TC—transverse colon

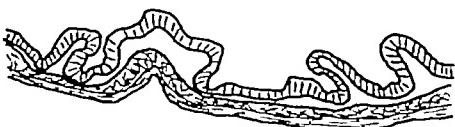

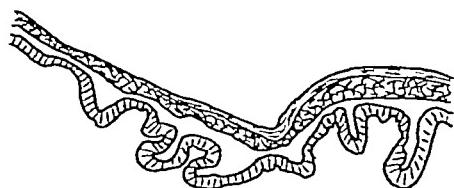

Fig 117

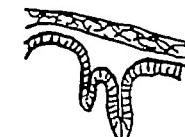

Fig 118

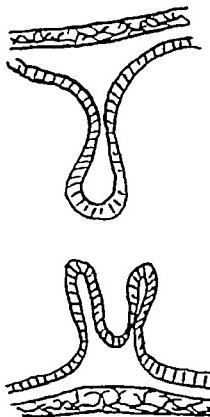

Fig 119

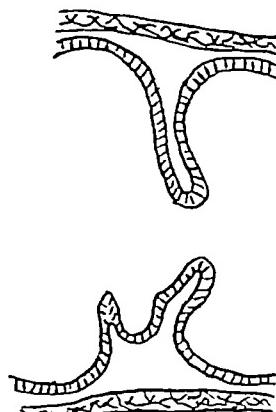

Fig 120

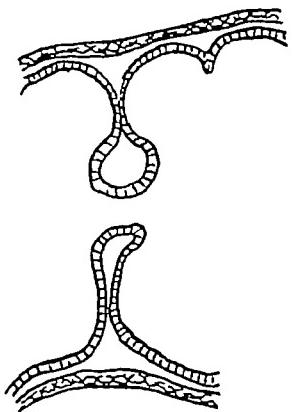

Fig 121

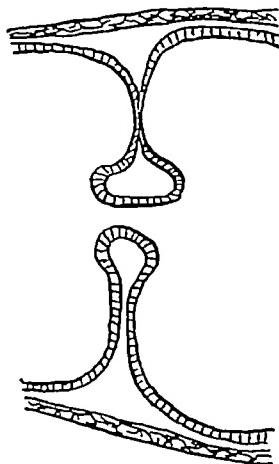

Fig 122

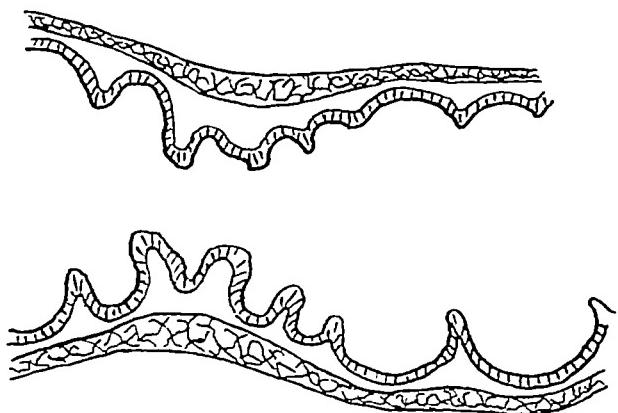

Fig 123

Fig 117 is a tracing of the outline of the coats of the colon specimen as cut longitudinally and shown in Figure 60. The tracing has been reduced to the actual size of the specimen. Using this as a model, in Figures 118-123 we have diagrammatically drawn the wall of the colon around the segmental folds as shown in the roentgenograms.

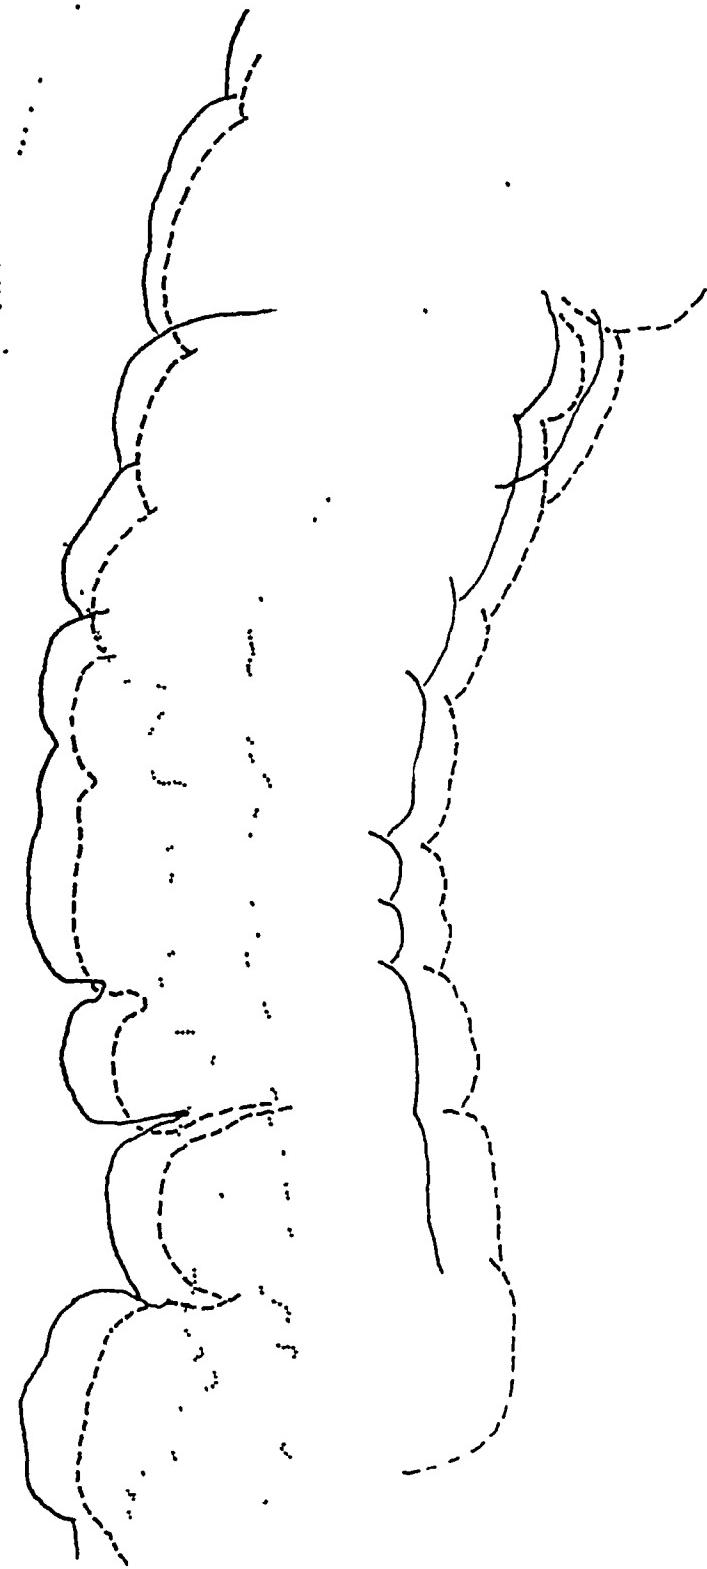

Fig 127. Tracing of the lumen of the transverse colon as shown in three roentgenograms from a series of five which were made while the colon was filled with a barium enema. The solid line is Film 1 of the series, the dotted line Film 2, and the broken line Film 4. There was a time interval of one minute between the making of Films 1 and 2, and an interval of two minutes between Films 2 and 4. Film 2 (dotted line) shows a mass contraction which occurred and relaxed during the interval of three minutes between the making of Films 1 and 4.

In the stage of contraction (dotted line) the imprint of the flattened segmental folds is clearly shown in the outline of the lumen. The most interesting finding, however, is the fact that the number and distribution of the segmental folds are absolutely identical in Films 1 and 4. This shows most clearly that a temporary extensive contraction of the muscularis propria may take place without obliteration of the segmental folds, and that following relaxation of the contraction and with the same distention of the gut the segmental folds will have identically the same form and distribution.

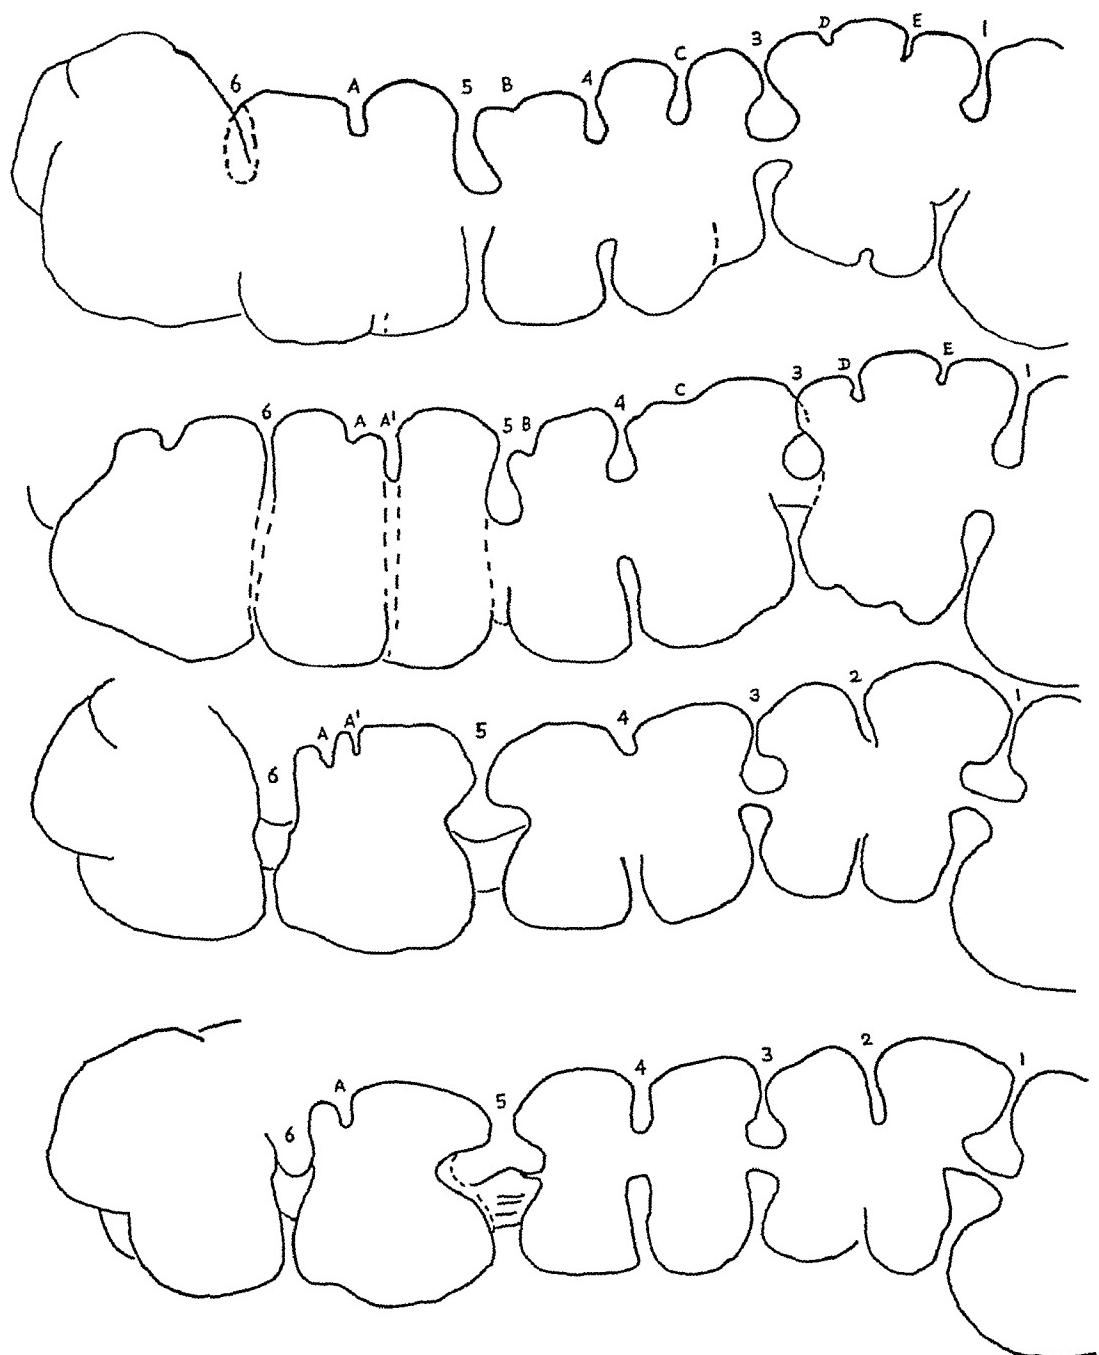

Fig. 129 Tracing of the barium outline of the lumen of the distal part of the transverse colon as shown in four roentgenograms made during a time interval of several minutes. The segmental folds 1, 3, 4, 5, and 6 show a definite variation in form, and folds 1 and 4 show a marked variation in depth. Fold 2 disappears and is replaced by two folds in a different location (D and E). At A, A', B and C there are shallow folds which are not constant and are differently situated in the several films.

Tracing of the lumen of the colon as shown in two consecutive roentgenograms from the same series illustrated in Figure 126. A time interval of approximately three seconds elapsed between the making of these two consecutive films. In this interval of time there is no change in the gross form of the outline of the colon, the indentations due to the segmental folds remaining present and unchanged. There are, however, many slight variations in the finer details of the outline. These changes may be due to varying degrees of tonus in the muscularis propria.

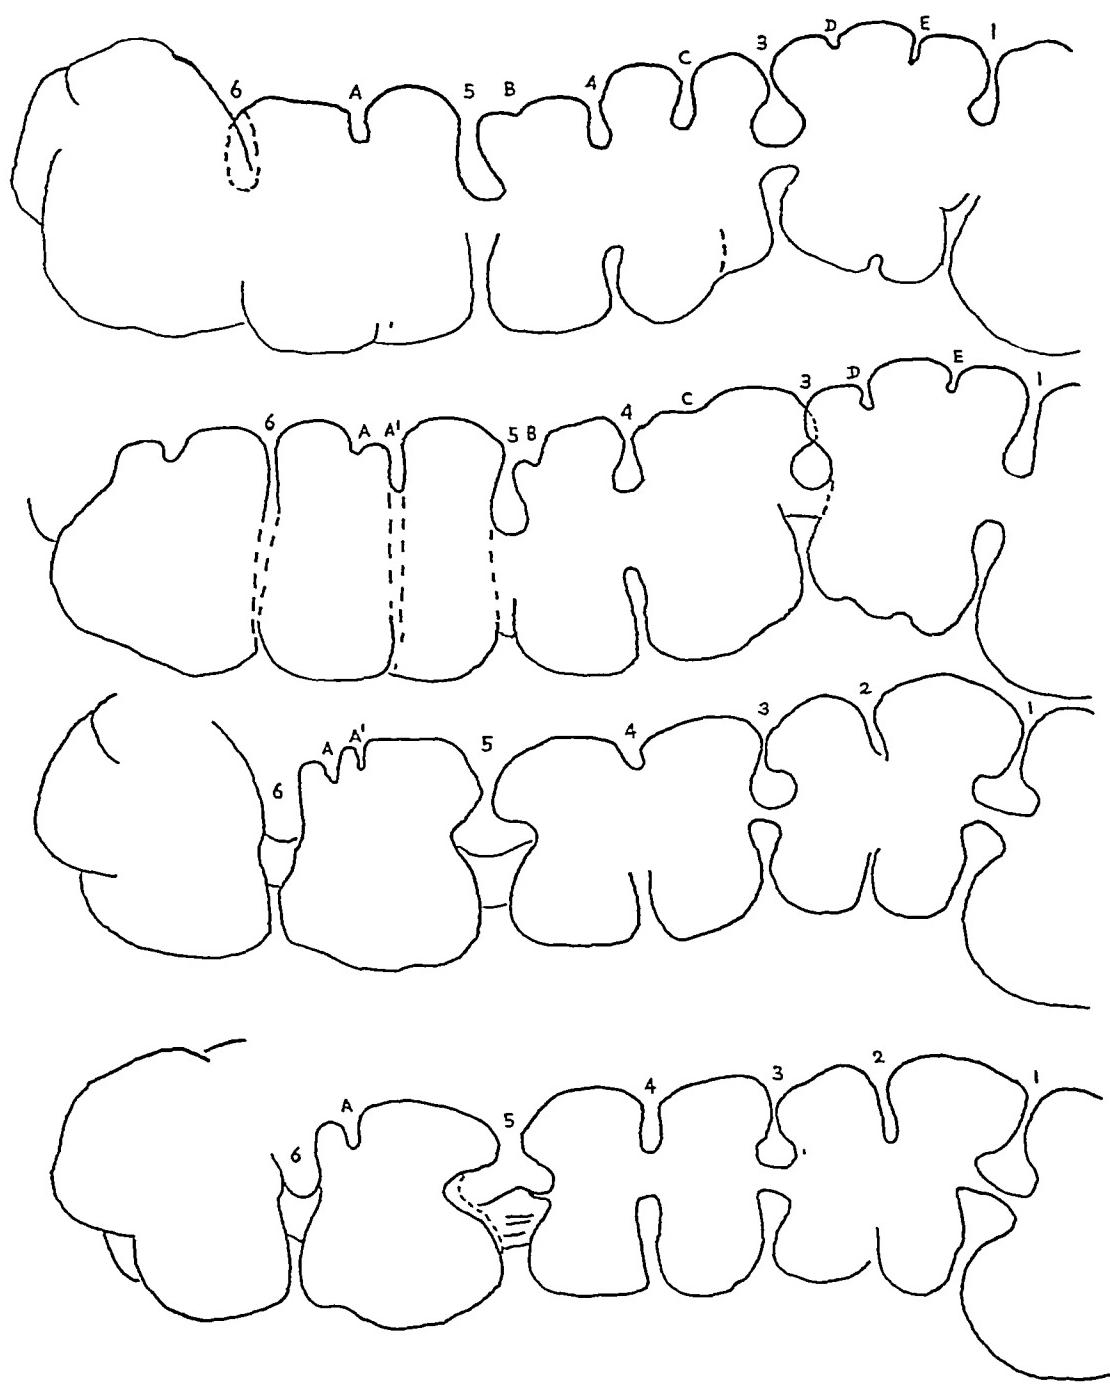

Fig 129 Tracing of the barium outline of the lumen of the distal part of the transverse colon as shown in four roentgenograms made during a time interval of several minutes. The segmental folds 1, 3, 4, 5, and 6 show a definite variation in form, and folds 1 and 4 show a marked variation in depth. Fold 2 disappears and is replaced by two folds in a different location (D and E). At 4, A¹, B and C there are shallow folds which are not constant and are differently situated in the several films.

Fig. 130. Roentgenograms made in the oblique direction with the patient in the recumbent (*A* and *B*) and erect (*C* and *D*) postures show unusually active and vigorous peristalsis of the esophagus secondary to a spasm of the esophagus at the level of the diaphragm. The absence of malignant infiltration is shown by the pliability of the wall to the peristaltic contractions. Diagnosis confirmed by esophagoscopy.

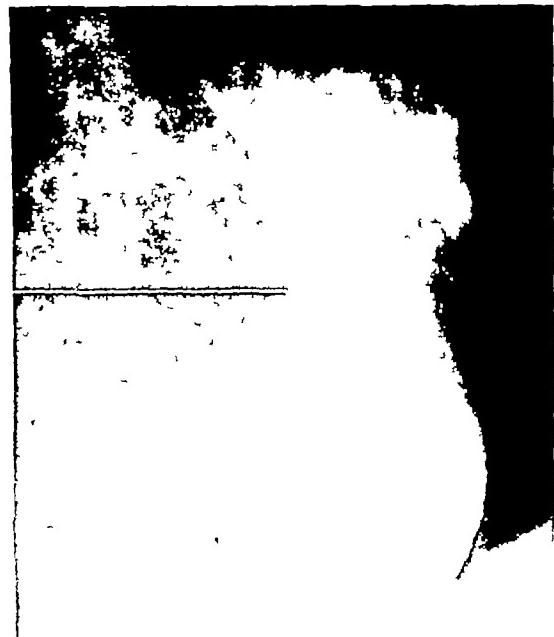

Fig 131 Two of a series of roentgenograms which show obstruction of the peristaltic contractions by an area of malignant infiltration in the upper part of the corpus of the stomach. There is an ulcerated area (*U*) in the surface of the new growth

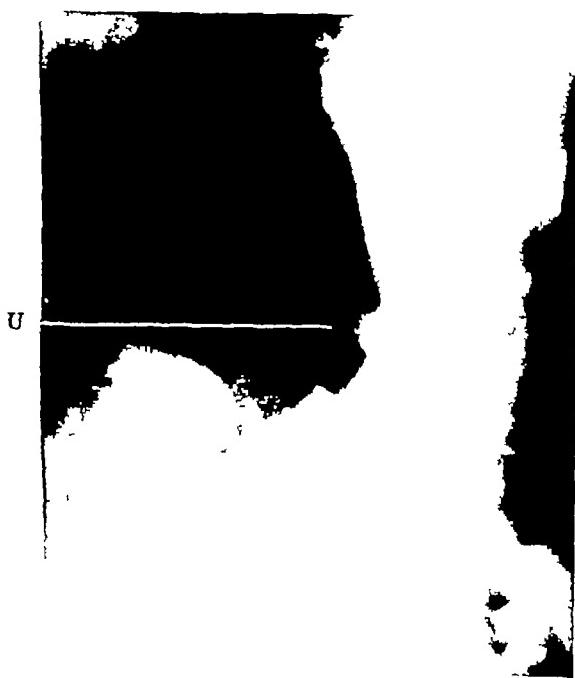

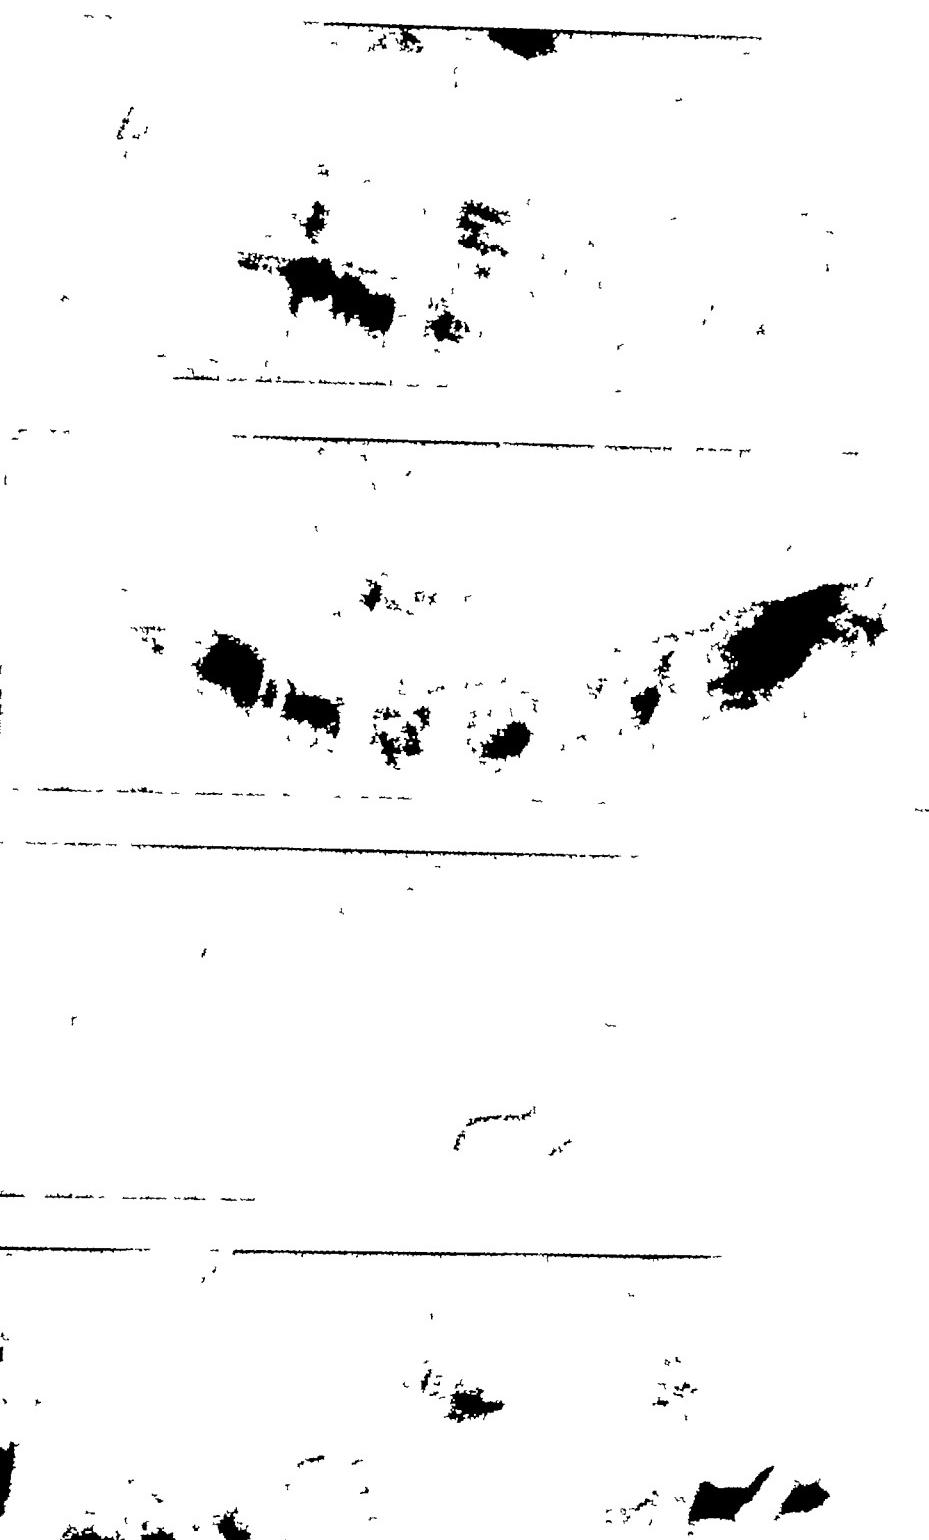

Fig 132 Two of a series of roentgenograms which show obstruction of the peristaltic contractions by an area of non-malignant induration around a benign ulcer (*U*) on the lesser curvature side of the corpus of the stomach

Fig. 130 Roentgenograms made in the oblique direction with the patient in the recumbent (*A* and *B*) and erect (*C* and *D*) postures show unusually active and vigorous peristalsis of the esophagus secondary to a spasm of the diaphragm at the level of the diastrum. The absence of malignant infiltration is shown by the pliability of the wall to the peristaltic contractions. Diagnosis confirmed by esophagoscopy.

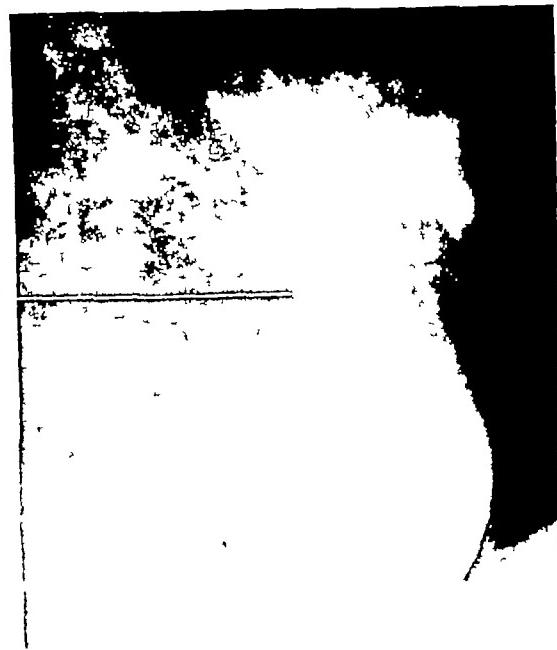

Fig. 131 Two of a series of roentgenograms which show obstruction of the peristaltic contractions by an area of malignant infiltration in the upper part of the corpus of the stomach. There is an ulcerated area (U) in the surface of the new growth

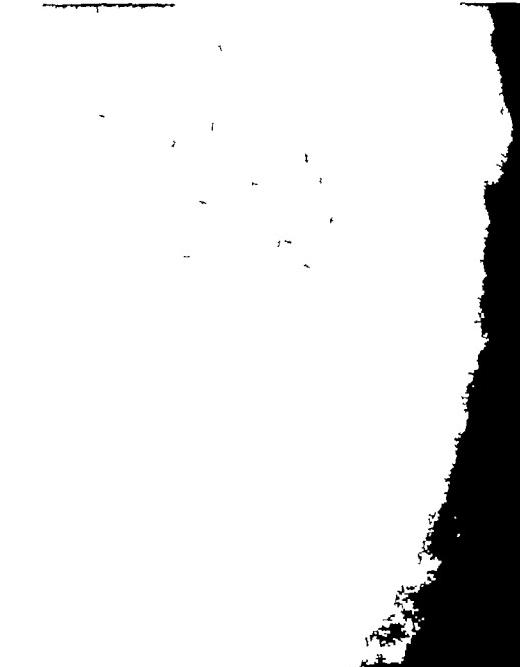

Fig. 132 Two of a series of roentgenograms which show obstruction of the peristaltic contractions by an area of non-malignant induration around a benign ulcer (U) on the lesser curvature side of the corpus of the stomach

Fig. 133 Roentgenogram which was made with three exposures in rapid succession. Each exposure was one-third the duration of the normal exposure. This is a simple method of determining whether or not the gastric wall is pliable to the peristaltic contractions

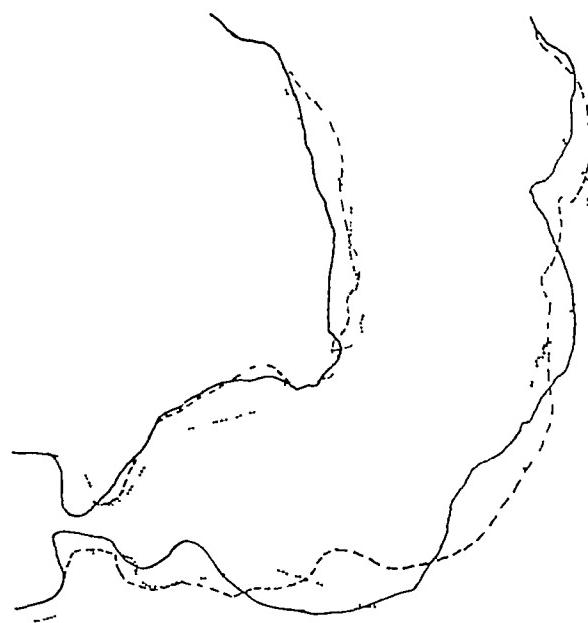

Fig. 134 Roentgenograms of three phases of the gastric cycle which show an extremely small area of lack of peristalsis on the lesser curvature due to an early carcinoma. The area in the diagram in which all three lines coincide indicates the area of lack of peristalsis. This finding might be due to either the scar of an ulcer or an early malignancy.

Fig. 135. A series of roentgenograms which show a very early carcinoma (C) involving the lesser curvature side of the pyloric canal. In this local region there is an absence of the concentric contraction and ex-tracts from its limited degree of expansion in a normal manner. This is the case which Ewing sta-

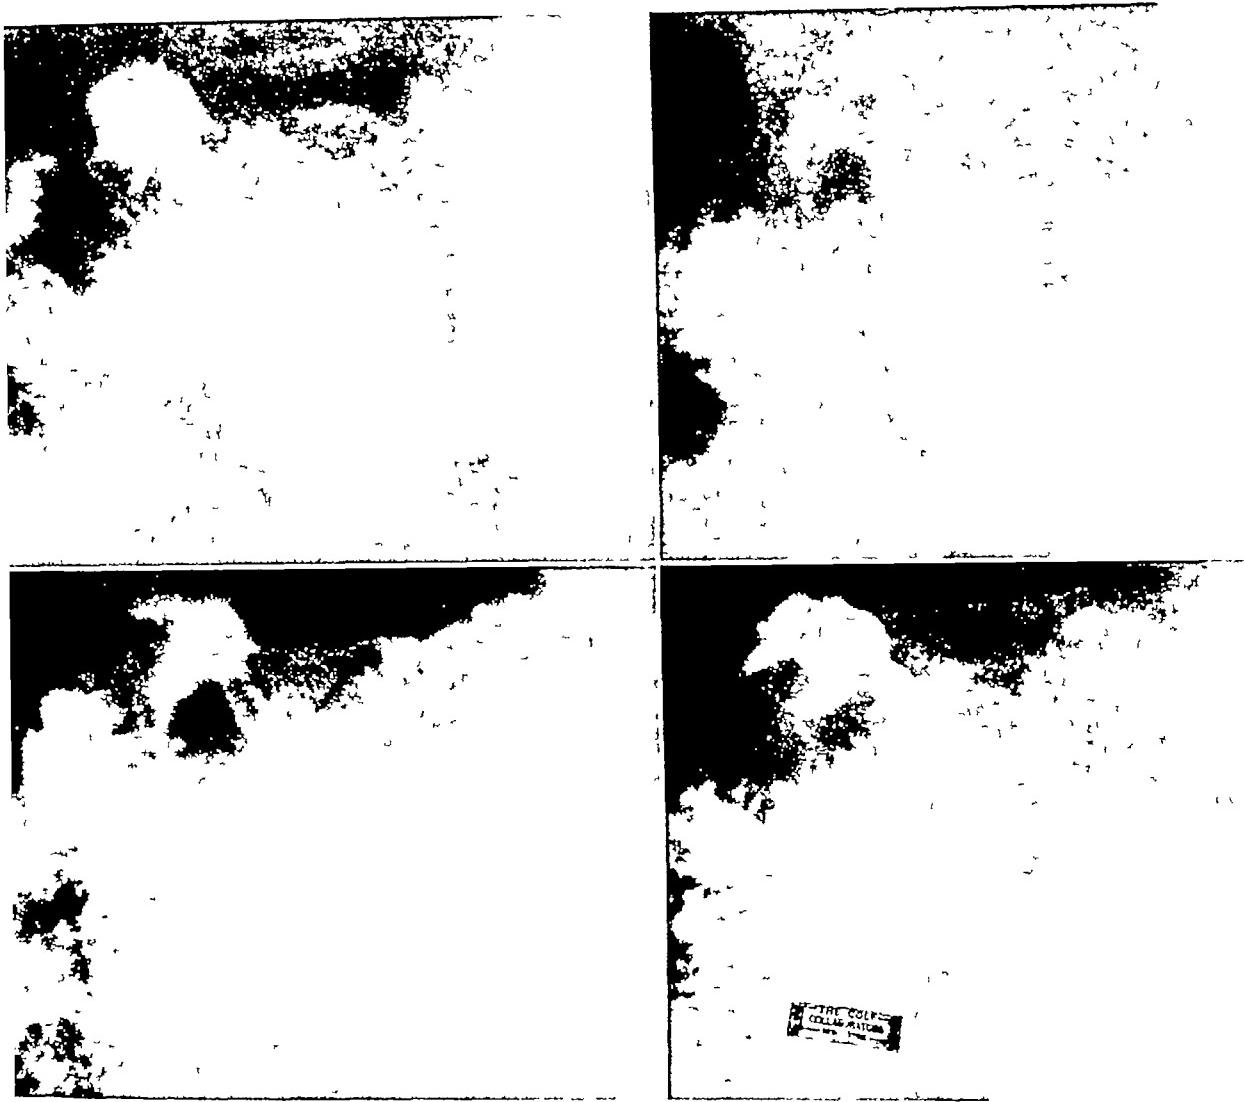

Fig 136 Four of a series of roentgenograms made in the prone oblique posture which show a chronic spasm of the pyloric canal. This lesion is differentiated from malignant infiltration by the fact that the concentric contraction and expansion of the pyloric canal are not entirely destroyed, and by the presence of the normal longitudinal mucosal folds.

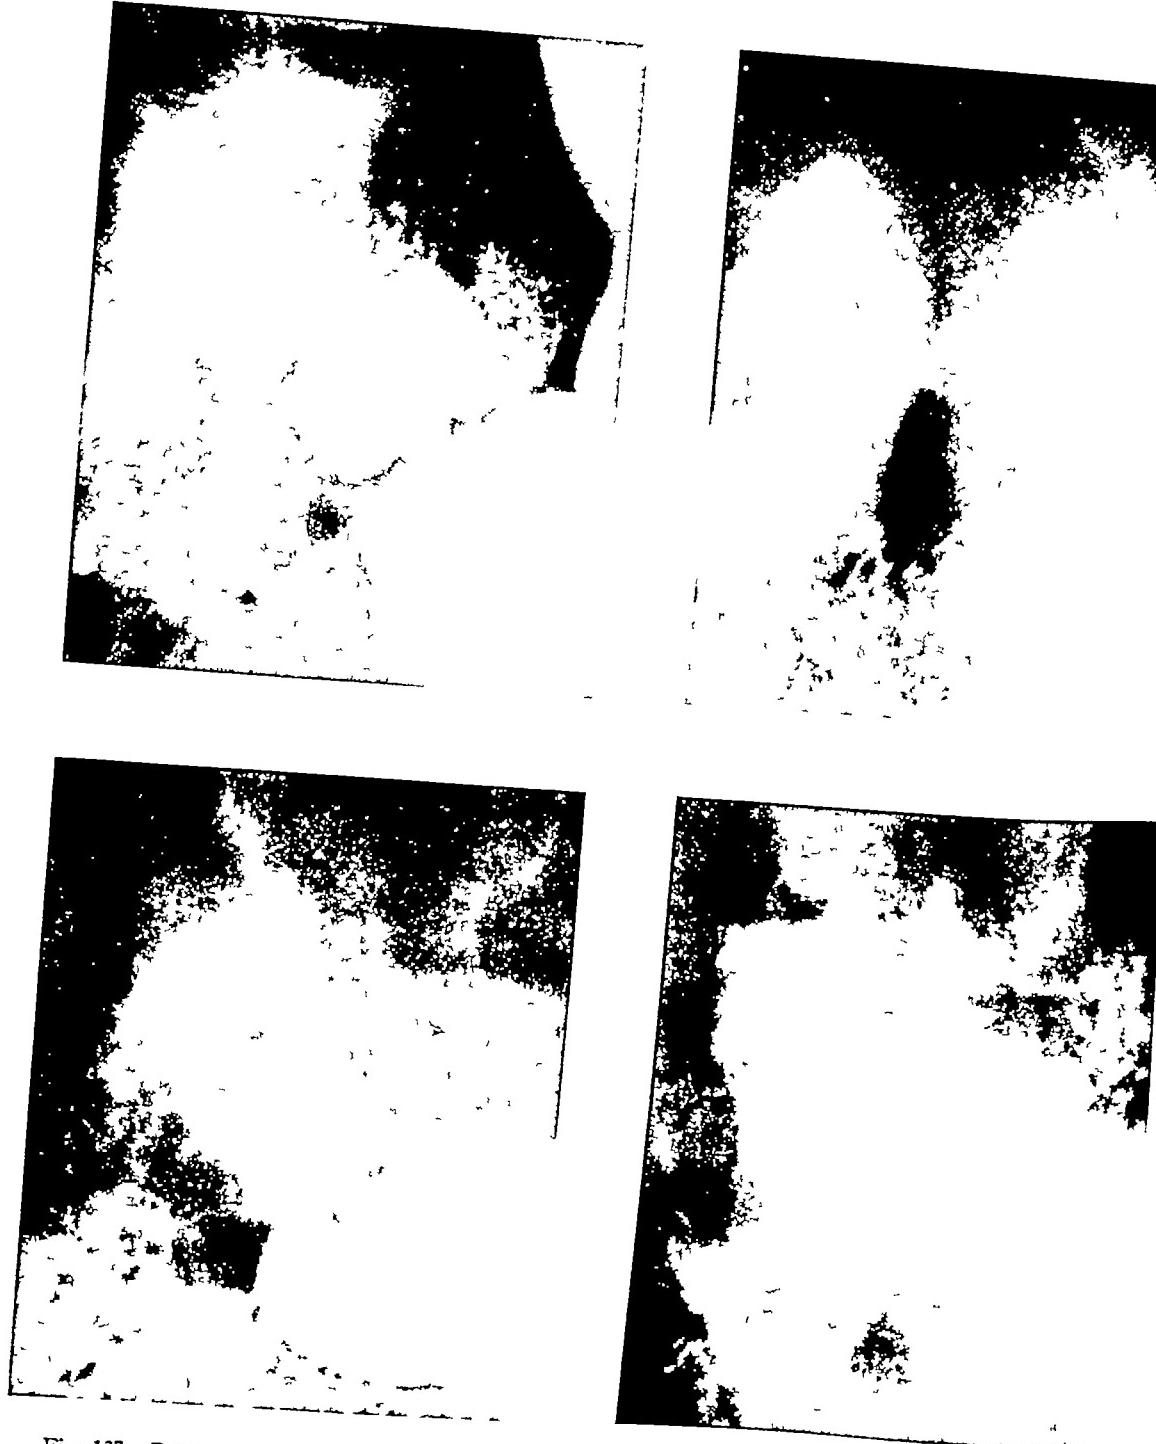

Fig. 137 Roentgenograms of four cases which show the cap being evacuated by a broad wave of peristalsis. The wave begins about the middle of the cap and carries the chyme from the top of the cap rapidly into the descending duodenum

The case illustrated in Figure 135 entered the Fifth Avenue Hospital, New York, with a previous X-ray examination and a positive diagnosis by some other roentgenologist of gastric ulcer. A series of films were made, and the case was up for conference. The clinical history, course of the disease, and physical examination indicated gastric ulcer. This case proved to be of such great significance that we are inserting here a copy of our entire roentgenological report, *verbatim*.

A serial roentgen examination made of the gastro-intestinal tract immediately and six hours after the ingestion of a barium meal shows the size, shape, and position of the stomach and the emptying time of the stomach.

Stomach—Type orthotonic, deformed. Peristalsis three- and four-cycle type, obstructed at the pyloric end of the lesser curvature. Systole and diastole shown very distinctly. Pars pylorica there is an area of induration on the lesser curvature about the size of an English walnut which involves only the lesser curvature, the greater curvature being pliable. This is constant throughout the entire series of roentgenograms. Prepyloric fold not shown. Sphincter slightly eccentric in position.

Cap—Symmetrical in contour and not deformed.

At two hours the stomach is about three-fourths empty.

At six hours there is only a trace of the meal in the stomach and the head of the column is in the cecum.

Diagnosis—There is an area of induration on the lesser curvature of the pyloric end of the stomach about the size of an English walnut which involves only the lesser curvature, the greater curvature being pliable. This is constant throughout the entire series of plates. This does not have all the characteristics of malignancy, but considering its size, location, and the age of the man I believe that the weight of evidence is in favor of its being malignant, and, considering that we always make a negative or positive diagnosis of malignancy, I should feel compelled to make a positive diagnosis of this being malignant.

I believe that one is justified in making a negative diagnosis of ulcer of the cap and postpyloric ulcer. I find no evidence of gallstones or a dilated or pathological gall bladder, but one is not justified in making a negative diagnosis of this condition solely on the roentgenological findings.

The patient was operated on and the specimen was photographed and taken to Dr Ewing within two or three hours after its removal without its having been fixed or cut. After examining the freshly removed gross specimen and having cut it and palpated the surfaces, Ewing expressed the opinion that it was a normal stomach and that I had probably had the man's stomach removed when there was no lesion present. He added—largely to make me feel better—that the microscopic examination might possibly reveal something different. Two days later he called me up on the telephone with great enthusiasm and said that the lesion was malignant, and that he had waited for forty years to see a gastric carcinoma in as early a stage as this. A few days later he sent me the following communication:

DEPARTMENT OF PATHOLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE

Report on Gastric Carcinoma

The material received consists of the pyloric portion of the stomach 11 cm long and 15 cm in diameter at its widest part. Surrounding the pyloric orifice

of 6 cm there is a slight tumefaction of the mucosa, which on the surface is slightly nodular in diameter, where the mucosa is fixed to the muscularis and slightly eroded. The whole area is soft and lacks the usual induration of carcinoma. On section of the eroded area it is found that the mucosa or the thick opaque layer is 3 or 4 mm deep and is fused with the muscularis. This condition extends over a zone 4 cm wide. The serosa is normal, but the surrounding fat tissue is slightly adherent. After fixation in formalin the entire involved area, 6 cm, becomes boardlike, while the rest of the stomach remains elastic. The remaining mucosa shows a marked granular surface, indicating advanced atrophic gastritis. Just beyond the involved area, is a small polypoid projection 4 mm wide, 2 mm deep, which is the seat of the carcinoma.

Microscopic Examination.—The stomach is the seat of an infiltrating adenocarcinoma, which extends through the entire wall, splitting up the muscle fibers over a wide area, reaching the peritoneum and involving the blood vessels and nerve trunks. The main structure is simple tubular glands of various sizes, but there are numerous areas diffusely infiltrated by single tumor cells. There are numerous new lymph follicles. The ulceration is very superficial. The process arises in the tubular glands of an atrophic gastritis and these glands show various stages of transformation from simple atrophy to carcinoma.

Sections taken from the stomach wall, 11 cm from the pylorus, show well marked chronic interstitial gastritis with much overgrowth of lymphoid tissue and considerable fibrosis.

Sections taken 7 cm from the pylorus on the edge of the boardy area show diffuse infiltration of submucosa by cancer cells. This infiltration, although very scanty, accounts for the induration and restricted mobility observed in this segment. The mucosa in this zone shows very marked chronic interstitial gastritis with numerous groups of markedly atypical glands which show many stages toward, but do not reach, adenocarcinoma. These glands show how the original tumor began. It is interesting to note that these changes are identical with the ones found on the edges of old ulcers and are commonly interpreted as cancerous transformation of the ulcer.

Epicritical.—This case represents one of the earliest gastric cancers that I have seen, and one of the earliest that was ever encountered. It is particularly important in that it shows the development of carcinoma on diffuse chronic interstitial gastritis. The superficial erosion is characteristic of a large group of pyloric cancers which seem to develop in the same manner. The very wide infiltration of the submucosa also explains why in many of these cases the infiltration becomes almost universal throughout the stomach, but ulceration is very limited.

[Signed] JAMES EWING, M.D.

Cap.—The cap is evacuated by a broad peristaltic wave which begins about the middle of the cap (Fig. 137) and carries the chyme rapidly from the top of the cap into the descending duodenum and frequently through into the distal part of the duodenum or the upper part of the mesenteric small intestine. During and immediately following the partial emptying of the cap the craters of small ulcers of the cap are often rendered visible, although they had been concealed when the cap was full. The characteristic appearance of this broad wave of peristalsis is destroyed by cicatricial deformity of the cap.

Small Intestine.—The passage of chyme through the small intestine is ac-

complished by broad waves of peristalsis similar to the broad wave which empties the cap and carries chyme into the duodenum. The usual roentgenologic examination records only the fact that the barium meal passes in a normal or abnormal manner through the small intestine. In any roentgenogram made of the small intestine filled with barium, many of these broad waves of contraction may be observed. In cases in which one suspects a lesion in a local region of the small intestine it is very simple to determine by means of serial roentgenography whether or not the wall of the gut is pliable. Fortunately, organic lesions of the small intestine are quite rare and routinely one does not study the small intestine roentgenographically as closely as is really necessary to detect lesions which are not obstructive.

Colon.—Peristalsis in the colon is present as the long waves of contraction, which start from a definite ring of tonic contraction and progressively extend over a long section of the colon and cause mass movements of the contents of the colon. During the passage of the barium meal these extensive contractions are infrequent in occurrence and their detection is more a matter of accident than intent. When the colon is filled with a barium enema, mass movement is likely to occur quite frequently, particularly if the colon is still under the influence of a stimulating cathartic such as castor oil. Progress of the contraction is extremely rapid. The ability of the wall of the colon to contract establishes the absence of infiltration of the muscularis propria.

THE NATIONAL INSTITUTE OF HEALTH¹

By HON JOSEPH E. RANSDELL, WASHINGTON, D. C.,
Former Senator from the State of Louisiana

RADIOLOGY is the youngest of the sciences devoted to the study of physical man, being scarcely more than a third of a century old. Its accomplishments have been marvelous, and there is general belief that the surface of its potentialities for preventing and curing the diseases of human beings has been barely scratched.

While neither a doctor nor a scientist, I have been intensely interested in health problems for twenty-five years, and as Executive Director of the Conference Board of the National Institute of Health I am devoting all my energies to the Institute—the Nation's research center in matters relating to public health.

The bill creating the Institute was first introduced in the Senate on July 1, 1926, but it met with discouraging indifference on the part of most of my colleagues and failed of passage. Believing that persistence is the only cure for such a malady, I again introduced the bill on Dec 9, 1927. It fared a little better on this occasion, and passed the Senate, but was caught in a jam in the House and was killed by the termination of the session. In May, 1928, it was presented to Congress for the third time, and finally, on May 21, 1930, two years to the day after its third introduction, it received the approval of our legislative branch of government. President Hoover wrote the final chapter of this long story by signing the bill on the 26th of that month, and the National Institute of Health became a glorious reality.

During the four years of persistent effort following my first introduction of this measure many men of vision and love of their fellows assisted materially in making it un-

derstood by Congress and the country. This is especially true of the doctors, chemists, dentists, and other scientists who worked actively for the passage of the bill and secured resolutions indorsing it from their great national associations, thereby focusing the attention of Congress upon it. While a few Members of both Houses saw the exceptional merits of the measure and became crusaders under its banner, it was not until Senators and Representatives generally began to hear the voices of their constituents appealing for it that they gave it their support.

It is impossible to name all advocates of the bill, but I can not refrain from mentioning President Hoover, former President Coolidge, Secretary of the Treasury Andrew W. Mellon, and Francis P. Garvan, President of the Chemical Foundation (Inc.). These four great Americans saw with clear eyes the possibilities of the National Institute of Health for preventing and curing disease with its awful train of suffering and colossal economic losses to the world. Without their powerful help this dream of mine could never have come true. They and many others—especially doctors, chemists, and dentists—gave their whole-hearted support to the measure, and I wish to express my lasting appreciation to them.

I can not say too much of the splendid co-operation of the Chemical Foundation, through its wise and generous President, Mr. Garvan, who is so favorably known to radiologists. He gave unceasing and effective aid to the bill in its legislative journey of four years through Congress, and made the first gift to the Institute of \$100,000. I sincerely hope his example will shine brightly and be the guide for many Americans.

Societies such as yours are offered in

¹Presented before the Radiological Society of North America at the Seventeenth Annual Meeting at St. Louis, Nov. 30-Dec. 4, 1931.

ideal opportunity to co-operate with others in close union with the National Institute of Health under the terms of the act creating it It stands ready to receive your aid in its search for solution of many unconquered diseases, which are still a curse to civilization The Public Health Service, of which the National Institute of Health is a part, points to its wonderful record of the past and invites you to partake of the sacrifices and the glory which are the lot of scientific research workers in the cause of health I trust you will join hands with this splendid agency and assist in giving to the world some measure of the true happiness which comes from good health

While research activities in science have resulted in commendable reduction of mortality and alleviation of suffering we have not kept pace with the times in matters of public health conservation It is a sad commentary on the agencies dealing with health that influenza and pneumonia are as deadly to-day as they were a hundred years ago, that cancer and heart affections are claiming greater tolls in lives each year, and that the population of our institutions for the mentally deficient is increasing at an alarming rate Dr Charles W Mayo, in a recent speech before the Annual Clinical Congress of the American College of Surgeons, said "The world has moved ahead so fast as regards material civilization that man has almost for the moment got behind in his power of adaptation Every other hospital bed in the United States is for mentally afflicted, insane, idiotic, feeble-minded, or senile persons"

It is only fair to say, however, that our lagging in the matter of health research has not been due to the inefficient mentality of our scientists, but to the woeful lack of facilities and the discouraging insufficiency of funds to stimulate recruits in science The crying need of the American scientist engaged in a study of health problems is a

great laboratory fully equipped to cope with every disease where he can carry on his work in close co-operation with other students of the laws of life, and with every possible facility at his disposal

Provision was made for supplying that need by my bill creating the National Institute of Health, which contains three distinct features

First It creates the Institute in the United States Public Health Service, under the administrative direction and control of the Surgeon General, for the special purpose of scientific research to ascertain the cause, prevention, and cure of diseases affecting human beings It does not establish any new bureaus or commissions but utilizes existing Government machinery, provides for enlargement of the former Hygienic Laboratory, which came into existence in 1901 by congressional action, and appropriates \$750,000 for the erection of additional buildings

Second It authorizes the Secretary of the Treasury to accept gifts for study, investigation, and research in problems relating to the health of man and matters pertaining thereto, with the provision that if gifts in the sum of half a million dollars or more are made, the name of the donor shall be perpetuated in a suitable way This feature of the act is most unusual and important No precedent can be recalled of donations from philanthropists to enable the Federal Government to maintain institutions for the purpose of research, with possibly two exceptions—the Smithsonian Institution and the Library of Congress The Smithsonian was founded on the gift of \$550,000 by James Smithson to disseminate knowledge among men It stands as a monument to his name and its achievements are known throughout the world The authorization granted to the Library of Congress to accept funds for special purposes has resulted in gifts to it exceeding \$2,600,000

Third It proposes the establishment and maintenance in the Institute, out of funds donated for that purpose, of a system of fellowships in scientific research to encourage and aid men and women of marked proficiency to combat the diseases that menace human health. This provision of the act is regarded as its outstanding feature, for these fellowships offer an opportunity to those specially qualified to serve their fellow-men in the most useful of all ways. While it is contemplated that the bulk of research work will be carried on in the Institute laboratories in Washington, it is not so limited. Under the terms of the act these fellows can be assigned to institutions in any part of the globe, wherever the research problem may be undertaken most advantageously.

This Institute marks the beginning of a new chapter in the history of medicine of a most far-reaching influence in the relief of human suffering. The act creating the Institute is a veritable declaration of war against all the physical forces detrimental to health on a greater scale than ever before attempted. It centers in the Nation's capital all the country's medical and scientific resources for combating disease and creates in Washington a clearing house of health for all the world.

Under a commander-in-chief—the Surgeon General of the United States Public Health Service, with the director of the Institute as his first lieutenant in active charge—will be marshaled the Nation's army of experts in the sciences of medicine, surgery, psychiatry, dentistry, chemistry, physics, radiology, biology, bacteriology, pharmacology, pharmacy, and allied professions in a concentrated drive to prevent disease by ascertaining its cause and applying preventive measures in advance of its outbreak.

In the national capital has been founded an institution devoted solely to study, investigation, and research in problems relating

to the health of man, where every available facility will be provided to aid and encourage scientists to combat sickness and solve the many remaining mysteries of disease, and where all knowledge and every advance in the promotion of human health will be pooled and correlated.

The plan of the Institute is to make of it an immense co-operative scientific organization, in which leading experts in every branch of science connected with plant and animal life will be brought together and given opportunity to work in unison for the purpose of discovering all the laws of life. Harmonious co-operation—one for all and all for one—is the watchword of the Institute.

In this Institute will be carried on new researches in cancer on a greater scale than ever before attempted, new investigations into the cause and cure of infantile paralysis and heart diseases, new studies of the common cold, influenza, and pneumonia, here will be made new discoveries, new and better methods of cure and treatment will be found to replace those now in use, and new and greater safeguards of health in general will be devised.

Although truly remarkable advances have been made in the war for health by individual scientists, by private and governmental institutions, no agency has ever been founded on earth for combating disease on so comprehensive and co-operative a scale as the National Institute of Health. While it is impossible to predict its eventual benefits to humanity, they are certain to be very great.

Genuine co-operation in science is necessary if the best possible results are to be obtained. Dr Treat Johnson, of Yale, said "Nothing can be done, no attack can be made on any (health) problem, except through the principle of co-operation. No one to-day can cover any single field in

science individually and make progress. He must work in co-operation with others.

Until this Institute was created there was no place in which radiologists could meet their brother workers in other branches of science in order to formulate better means of preventing and eradicating disease. Dr. Julius Siegitz of the University of Chicago, deplored the lack of peace-time co-operation among scientists in the field of health, pointing out that in time of national danger from war a great mobilization of scientists takes place in order to bring into existence destructive forces with which to fight the battles of men. In 1923 he said: "There is no institution in which the chemists of the United States can come together with the medical scientists to inaugurate a general attack upon the forces that kill. . . Let there be another war, and no doubt the chemists will be mobilized again, but they will be mobilized to kill."

The National Institute of Health furnishes the means by which can best be put into practice the 'principle of co-operation' described by Johnson as being so essential to the success of the research expert. It is the agency which Siegitz had in mind—an institution where radiologists and chemists can work in friendly union with every other branch of science to solve health problems giving the benefit of their vast store of knowledge in alleviating pain and preventing sickness.

This act provides radiology with the opportunity to render a priceless service to humanity. The Institute enables it to bring into close co-operative effort with other sciences its research activities in a field that includes one of the most difficult and desultory of all unconquered diseases—cancer. Radiologists are devoting much time and effort to the study of this dread malady, which is causing untold suffering and death. While the span of life has been materially lengthened and the death rate in many diseases steadily reduced, cancer has

not responded to scientific treatment and its mortality rate has increased to alarming proportions. In 1850 approximately 32 people per hundred thousand died with cancer. In 1910 the figure had risen to 73, and in 1929 the fatalities from cancer had reached the appalling total of 115 per hundred thousand. In this great altruistic agency, which our Government has provided, you can bring into play, in connection with other sciences, all your skill and research ability to blot out this and other diseases.

Dr. Joseph Colt Bloodgood, one of America's ablest physicians and strongest believers in the merits of your science, who has devoted his great intellect to fighting cancer, and who is with us to-night, recently said: "No specialty in medical science and practice has developed more rapidly than radiology, both in its diagnostic and therapeutic aspects. . . Radiology is not one of the greatest specialties in medicine. We owe a great debt of gratitude to the pioneers, many of whom have lost their lives because of their ignorance of how to protect themselves from irritation of X-ray and radium. . ." May I add that in my opinion no science is destined to play during the next half century a greater part than radiology in the world-wide battle with disease.

The Institute stands surely in need of added facilities with which to carry on its noble work. Only recently Surg. Gen. Hugh S. Cumming, of the United States Public Health Service, said: ". . . Probably the greatest immediate need of the National Institute of Health is the completion of its physical development, especially additional buildings to house a division of physics, where studies, especially of light and ventilation, as they affect the general health of the people, and of the use of X-ray and radium in the treatment of disease, can be undertaken; and a division of physiology, the work of which is intimately concerned with every division of the Institute. Other work which it is desired to take up as soon as

Third It proposes the establishment and maintenance in the Institute, out of funds donated for that purpose, of a system of fellowships in scientific research to encourage and aid men and women of marked proficiency to combat the diseases that menace human health. This provision of the act is regarded as its outstanding feature, for these fellowships offer an opportunity to those specially qualified to serve their fellow-men in the most useful of all ways. While it is contemplated that the bulk of research work will be carried on in the Institute laboratories in Washington, it is not so limited. Under the terms of the act these fellows can be assigned to institutions in any part of the globe, wherever the research problem may be undertaken most advantageously.

This Institute marks the beginning of a new chapter in the history of medicine of a most far-reaching influence in the relief of human suffering. The act creating the Institute is a veritable declaration of war against all the physical forces detrimental to health on a greater scale than ever before attempted. It centers in the Nation's capital all the country's medical and scientific resources for combating disease and creates in Washington a clearing house of health for all the world.

Under a commander-in-chief—the Surgeon General of the United States Public Health Service, with the director of the Institute as his first lieutenant in active charge—will be marshaled the Nation's army of experts in the sciences of medicine, surgery, psychiatry, dentistry, chemistry, physics, radiology, biology, bacteriology, pharmacology, pharmacy, and allied professions in a concentrated drive to prevent disease by ascertaining its cause and applying preventive measures in advance of its outbreak.

In the national capital has been founded an institution devoted solely to study, investigation, and research in problems relating

to the health of man, where every available facility will be provided to aid and encourage scientists to combat sickness and solve the many remaining mysteries of disease, and where all knowledge and every advance in the promotion of human health will be pooled and correlated.

The plan of the Institute is to make of it an immense co-operative scientific organization, in which leading experts in every branch of science connected with plant and animal life will be brought together and given opportunity to work in unison for the purpose of discovering all the laws of life. Harmonious co-operation—one for all and all for one—is the watchword of the Institute.

In this Institute will be carried on new researches in cancer on a greater scale than ever before attempted, new investigations into the cause and cure of infantile paralysis and heart diseases, new studies of the common cold, influenza, and pneumonia, here will be made new discoveries, new and better methods of cure and treatment will be found to replace those now in use, and new and greater safeguards of health in general will be devised.

Although truly remarkable advances have been made in the war for health by individual scientists, by private and governmental institutions, no agency has ever been founded on earth for combating disease on so comprehensive and co-operative a scale as the National Institute of Health. While it is impossible to predict its eventual benefits to humanity, they are certain to be very great.

Genuine co-operation in science is necessary if the best possible results are to be obtained. Dr Treat Johnson, of Yale, said "Nothing can be done, no attack can be made on any (health) problem, except through the principle of co-operation. No one to-day can cover any single field in

belongs to the people and is responsible to them Their problems are its problems It provides for continuity Research work should not be taken up and dropped at the whim of some capricious benefactor or changing board of directors It requires years of continuous application to a definite plan which Government conditions supply Again, the checks and control of Government financial methods assure us that money allotted to this work, whether from private donations or appropriations by Congress, will be carefully accounted for and put to good use

The past record of the Public Health Service indicates that it is the agency *par excellence* to lead in this great public-health movement and that Congress acted wisely in confiding to it the entire management and direction of the National Institute of Health The service now has a large corps of trained personnel engaged in scientific investigations in many parts of the country, which can be most effectively used as a nucleus for developing the necessary organization to undertake the proposed researches in the Institute

Not only does the Public Health Service have in its ranks many experienced and scientific workers but it also has laboratory and other equipment that is being used to great advantage in research work I can not say too much about the work of the United States Public Health Service, which for many years has aided the States in times of epidemic, has made exhaustive studies in health conditions, and, in general, has been a most important factor in reducing mortality in this country

In conclusion, let me appeal to you and to all radiologists to devote your vigorous young intellects to the alleviation of human suffering Your science can be of invaluable assistance to the National Institute of Health in making of it a truly great research institution, thereby fulfilling its noble destiny Good health is the most precious of earthly blessings Nothing can take its place With it, one can enjoy life amid great hardships Without it, vast wealth can not bring happiness To attain this great blessing we should strive so earnestly that when our earthly careers are about to close each and every one can say in the language of the immortal Pasteur, "I have done what I could "

Would Investigate Effects of Radium Find on Evolution—Do the great deposits of radium ore recently discovered in northern Canada have any effects in speeding up the rate of evolution of the plants and animals in their neighborhood?

This question has been raised by Prof W C Broadfoot, of the University of Alberta, who calls attention to the now well-

known ability of X-rays to speed up evolutionary change, first demonstrated to the scientific world by Prof H J Muller, of the University of Texas The effects of radiations from radium and other radio-active substances have also been the subject of numerous experiments, and of observations on living organisms in regions of high natural radioactivity in the earth—*Science Service*

funds and facilities are available are studies of arthritis, focal infections and their relation to chronic degenerative diseases, degenerative diseases of the arterial system, the common cold, puerperal fever, life cycles of bacteria, etc."

The 1931 report of the Twentieth Century Fund (Inc.), entitled "American Foundations and Their Fields," states "Judged by the amount of money donated in 1930 (by 21 leading American foundations, exclusive of private benefactions) the field of medicine and public health is the most popular, a total of \$18,627,222 in grants to it having been reported in the returns. More than one-third (35.5 per cent) of all funds given away by the foundations canvassed has gone into this field."

Of this liberal sum, \$8,396,932, or 45.1 per cent, was paid in support of educational activities, \$8,401,825, or 45.2 per cent, in support of social action, and only \$1,828,-458, or 9.7 per cent, in support of research.

This is very striking, and shows that while American philanthropists, as represented by the report quoted above, were quite generous last year in support of medicine and public health in a general way, less than 10 per cent of these sums were given to pure research, without which it is impossible to ascertain the cause and cure of disease. It is unfortunate that so little was donated last year by these 21 foundations to health research, but I have no doubt that individual benefactions for that purpose were considerable.

Recently an article appeared in "Nation's Business," entitled, "My Money after I Die—by a Man who has Some." The author expressed an earnest desire to so dispose of his large wealth as to promote human happiness and make it continuously useful. Beyond question, suffering, sickness, and death will last until the end of time, and there is no surer way to make money continuously useful in promoting health and happiness

than by liberally endowing the National Institute of Health.

Although the name and some of the facilities are new, the National Institute of Health has been a going concern for over 30 years, and has 155 persons hard at work every day on some phase of health investigation. It has been of tremendous aid to research in the world, and it is impossible to enumerate here even briefly the total of its accomplishments and contributions to science, yet a few points can be noted in connection with past and present work.

From the Institute have come Dr Goldberger's monumental work in the discovery of the cause and prevention of pellagra, Dr Francis's work on tularemia, Dr Spencer's work on spotted fever and his discovery of a protective vaccine, the discoveries of Dr Dyer, Dr Rumerich, and Dr Badger of an Eastern form of spotted fever, which may prove to be one of the most important public health problems, Prof Voegtlín's fundamental work in the metabolism of normal and cancer cells, and Prof Hudson's contributions to work on the chemical structure of sugars.

At the present time, under the guidance of its director, Dr G. W. McCoy, studies are in progress at the Institute relating to nutrition, cancer, typhus-spotted fever, tularemia, infantile paralysis, undulant fever, spinal meningitis, ginger paralysis, standardization of certain drugs, fundamental researches on sugar, and many other problems. Lastly, through its work in the control and standardization of biologic products, the Institute has rendered a very great service to the people of the United States in safeguarding the numerous serums and vaccines placed on the market, and a number of the biological standards worked out at the Institute have been adopted by many foreign countries.

The advantages of having such an institution in the Government are apparent. It

belongs to the people and is responsible to them Their problems are its problems It provides for continuity Research work should not be taken up and dropped at the whim of some capricious benefactor or changing board of directors It requires years of continuous application to a definite plan which Government conditions supply Again, the checks and control of Government financial methods assure us that money allotted to this work, whether from private donations or appropriations by Congress, will be carefully accounted for and put to good use

The past record of the Public Health Service indicates that it is the agency *par excellence* to lead in this great public-health movement and that Congress acted wisely in confiding to it the entire management and direction of the National Institute of Health The service now has a large corps of trained personnel engaged in scientific investigations in many parts of the country, which can be most effectively used as a nucleus for developing the necessary organization to undertake the proposed researches in the Institute

Not only does the Public Health Service have in its ranks many experienced and scientific workers but it also has laboratory and other equipment that is being used to great advantage in research work I can not say too much about the work of the United States Public Health Service, which for many years has aided the States in times of epidemic, has made exhaustive studies in health conditions, and, in general, has been a most important factor in reducing mortality in this country

In conclusion, let me appeal to you and to all radiologists to devote your vigorous young intellects to the alleviation of human suffering Your science can be of invaluable assistance to the National Institute of Health in making of it a truly great research institution, thereby fulfilling its noble destiny Good health is the most precious of earthly blessings Nothing can take its place With it, one can enjoy life amid great hardships Without it, vast wealth can not bring happiness To attain this great blessing we should strive so earnestly that when our earthly careers are about to close each and every one can say in the language of the immortal Pasteur, "I have done what I could "

TEACHING OF RADIOLOGY TO UNDERGRADUATE STUDENTS¹

By HENRY K. PANCOAST, M.D., PHILADELPHIA

From the Radiological Clinic of the Medical School of the University of Pennsylvania and the University Hospital, Philadelphia

RADIOLOGY occupies rather a unique position as a subject for teaching to undergraduate medical students. It is a new medical specialty. Its diagnostic and therapeutic applications have grown at a tremendous rate and have become unusually widespread. While it is more or less intimately concerned in every branch of medicine, its development has been left largely in the hands of a comparatively few medical men, assisted in a great measure by physicists and manufacturers of equipment. Its development and its position as a specialty have been taken largely for granted by the greater part of the medical profession. Comparatively few students or recent graduates expect to take it up as a specialty or even to practise it directly in a smaller way, although it must serve all of them. For these reasons, little earnest thought has been given to radiology from the standpoint of undergraduate teaching, aside from the desire and pride on the part of radiologists to further the interests of their specialty. The latter attitude is but natural, for, as Barclay² states, "when a teacher is placed in charge of a special department, it must be his aim and object to further its interests."

REASONS FOR TEACHING UNDER-GRADUATES RADIOLOGY

While radiologic specialists are constantly urging their claims for teaching privileges, the question frequently arises no doubt in the minds of medical faculties as to why any extended instruction in radiology to undergraduates is necessary. This can be an-

swered by numerous reasons, which, because of their multiplicity and complexity, require enumeration.

1. The intern and the comparatively inexperienced young physician should know something about a means of diagnosis and treatment which either must call on frequently for assistance. Perhaps this appeals to me more than it does to some of the younger generation because my student, intern and early medical experience was gained in the first years of roentgen diagnosis and treatment, when there was no teaching of any kind on the subject. Impressions of roentgenograms and the reasons for therapeutic actions and their effects were as vague as they possibly could be on any subject pertaining to medicine. When, as an intern, I was shown the roentgenogram of a chest, no mental impression whatever was made of the patient's condition because of an utter lack of knowledge of anatomy and pathology as they might be expressed by roentgenographic shadows and appearances. The intern of the present day, however, realizes something of the value of roentgenologic studies because he has been taught something about the subject. He has some understanding of normal and pathologic appearances when they are demonstrated to him. He even learns to interpret abnormalities for himself.

2. To-day one seldom sees a clinical journal that does not contain important references to roentgen diagnosis or therapy. Must the intern or the young physician skip over these references without a proper understanding of them?

3. Roentgen diagnosis now is applicable to every branch or specialty in medicine. In surgery every fracture and dislocation must

¹Read before the Annual Congress on Medical Education, Medical Licensure and Hospitals, Chicago, Feb. 16, 1932. Reprinted by permission from the *Journal of the American Medical Association*, March 19, 1932, NCVIII, 938.

²A. E. Barclay, *The Dangers of Specialization in Medicine* (the thirteenth Sylvanus Thompson Memorial Lecture) *British Jour. Radiol.*, February 1931 IV 60-82.

xamined, not only because of the aid to the surgeon and patient but also of almost a legal requirement. The genogram is the most satisfactory and means of diagnosing and studying diseases and tumors in most instances by all surgical gastro-intestinal lesions diagnosed or confirmed by roentgeno-study. The detection or confirmation large number of urologic conditions depends on roentgenologic assistance, often by intravenous or retrograde urography. Diseases of the gall bladder, intrathoracic lesions, many intrathoracic conditions and a host of others require study by method. In connection with internal medicine the radiologist has to search for of infection in the teeth and sinuses practically all intrathoracic conditions receive more or less roentgenologic study. The digestive tract and the gall bladder constitute a wide field for investigation. In addition, there are bone, joint, soft tissue and many other conditions for which examinations frequently must be made. The pediatrician frequently calls for assistance in examinations of the sinuses, mastoids, larynx, chest, and bones. The orthopedist could be lost without roentgenologic aid. The bronchoscopist could do but little without it. The laryngologist requires it constantly, and the neurologist very frequently uses radiology as practically a specialty among his specialties.

6 The student should be taught the value and in many instances the absolute necessity for, roentgenologic diagnosis as well as limitations, for he is soon to become an intern. As such, he is in many instances likely to request roentgen examinations, until, perhaps, the radiologist has reason to distrust his judgment and insists on a higher authority.

7 The student of to-day should be taught to depend on roentgenologic aid at the expense of other and older diagnostic meth-

ods. He must learn to realize that such studies are expensive procedures for patients and institutions and should not be employed unnecessarily. On one occasion, an intern requested studies on a single patient in a ward which would have cost the institution over seventy dollars had they been carried out. A large part of this general examination was found to be entirely unnecessary.

6 There is a tremendous amount of mediocre roentgenologic work being done to-day by untrained and inexperienced men, and much of it is practically valueless and even misleading. The student and, later, the intern should be taught to realize this, so that when they enter into practice they may be able to judge what is dependable and what is not. Nevertheless, one should not be too hasty in judgment of diagnostic ability on the basis of the appearance of roentgenograms, for they may have been made under unusual and difficult circumstances beyond control if poor, or, on the other hand, some men can produce excellent technical results without having the ability of correct interpretation.

7 To establish the fitness of the young practitioner for such judgment and understanding as have been specified requires that instruction of some kind should have been instituted during his student days, whereby he could have gained some knowledge of normal roentgenographic appearances, their variations within normal limits, and the modifications produced by pathologic processes. By the time of his graduation and the beginning of his internship he should be able to understand the principles of interpretation of living pathologic conditions in roentgenologic terms. The internship would then be the time for him to gain what is needed in the way of experience.

8 Roentgenology is largely but not entirely in the hands of the medical profession to-day. Whether it will eventually fall more and more into the hands of commer-

cial enterprises outside of institutions depends almost entirely on the proper teaching of the younger members of the profession of the interrelation of radiology with the other branches or specialties of medicine. There is a growing tendency, apparently the world over, in the direction of commercialism, even with the vicious habit of fee-splitting. Lack of oversight in this particular line of work only serves to encourage similar proclivities in others. Haenisch,³ of Hamburg, in a recent memorial address, when commenting on the misfortunes arising from the rapid expansion of radiology when it lacked the co-operation of other specialties, made the following statement:

"The harm, however, which resulted from a too rapid expansion of the art and the consequent faulty, insufficiently prepared training was not the worst. This could, if the will were present, be minimized or even eliminated. Much more disastrous was the fact that the incompetent and dishonest elements grasped this specialty. These, in some instances, were unscrupulous physicians who were guided merely by the expected pecuniary advantages and who, unhampered by clinical and roentgenological knowledge and experience, 'sold X-ray pictures,' paying the referring physician rebates or commissions.

In other instances laymen, with or without connivance of dishonest physicians, saw in the purchase of X-ray apparatus a get-rich-quick scheme at the expense of innocent patients."

These practices are all too common, and their elimination must be a co-operative process, and the warning and the education cannot come too early.

9 Radiation therapy has a large share of importance in the treatment of neoplastic disease and many other pathologic conditions. To-day, operative surgery, electro-thermic procedures, and the use of roentgen

rays and radium are the only approved methods of dealing with cancer, which is one of the most important conditions with which we have to deal in these modern medical times, because it is second in mortality rate among adult diseases. The greatest efforts are being made by interested medical bodies to teach the public and, still more important, the medical profession, the importance of early diagnosis and proper treatment. It is generally agreed by these bodies that the proper time to begin this instruction is in the undergraduate medical schools. The teaching is preferably to be carried out by cancer clinic groups, but in lieu of this it must emanate largely from the surgical, medical, and radiologic groups. Many of the unethical and unscientific methods of treating cancer could not flourish to the extent to which they do to-day did they not receive encouragement from men who have not been properly taught. Irradiation is a part of the therapeutic armamentarium of the dermatologist, and the student should be able to understand why it is used on the basis of biologic effects.

10 The dangers from excessive X-ray exposure should be understood, especially as they may be experienced in roentgenography and fluoroscopy for various purposes. Radiologists are frequently embarrassed by the lack of knowledge of these dangers on the part of the medical profession in general.

METHODS OF TEACHING

The reasons so far enumerated would seem to constitute ample justification for instruction in radiology during the undergraduate and intern periods. The latter is an ideal opportunity, but this aspect of the teaching problem will not be considered here. Fortunately, intern instruction is prescribed by medical boards in many States. My only suggestion in this connection is an insistence that the groundwork should begin during

³G F Haenisch, Roentgenology as a Specialty (the Caldwell Lecture), Am Jour Roentgenol and Rad Ther December, 1931, XXVI, 821-833

the undergraduate period. The next arguments are over the time, the place, and the method. Barclay states "It is quite true that the overburdening and consequent extension of the medical curriculum is due to the increase in specialization. The student of to-day has a far greater load of learning to cram into his head than he had a few years back, far more than he can ever hope to remember." The method of general didactic class instruction in radiology as carried out in most institutions in the past has been a failure in many respects. It has certainly not accomplished the desired results, and the only service it fulfils is to give the class as a whole some idea of the scope of radiology, and this is not sufficient compensation for the time and effort. Didactic teaching by lectures to hitherto untaught students means in part the showing of series after series of roentgenograms or lantern slides representing pathologic conditions which the student sees with little or no understanding of their import. Even were he shown the normal first, he cannot correlate that appearance with the structures of the human body represented because he has never been taught to do so. The futility is realized when the teacher reads examination papers or asks even the most practical questions at the end of the period. A few exceptional students may have grasped the subject, but the large majority have not. Didactic lectures are better adapted to graduate students who have received sufficient groundwork in the subject to enable them to absorb and assimilate that kind of instruction. Didactic teaching of radiology had its inception largely in the fact that no text-books were procurable on the subject, whereas this method has gradually declined in other specialties as suitable collateral text-books have become available.

Human psychology requires that the reasons for certain results must be explained if these results are to be understood and are to make any permanent impressions on mem-

ory. Hence, if the student knows why and how roentgenographic and fluoroscopic appearances are brought about or biologic effects are produced, his mind will be more receptive in the way of interpretation of shadows of the body structures and the indications for treatment by irradiation and the results obtained thereby. Therefore, in teaching radiology it is necessary to preface the practical aspect of the subject by a short course of instruction in physics. This must be didactic, but it should be made as elementary as possible and, at the same time, interesting. It should have been taught as a pre-medical subject, but this seems seldom to have been done, or, at least, not in a manner capable of impressing the students in a way a teacher of radiology would desire. The most appropriate time for it, or, at least, to review the necessary part of the subject of physics, if it must be included in the undergraduate medical curriculum, would seem to be during the first year. Then there is more time for it and it can precede any practical teaching. Surely the medical practitioner should know something about the physics pertaining to X-rays and radium and the physical problems involved in their application. It need be but a small percentage of what the radiologist must know and even make use of every day. The physician should be able to talk intelligently with his patients about what he orders for them, if nothing more. How many physicians know just why irradiation is used in cancer or the difference between radium and its emanation or the similarity in effects of roentgen rays and radium? The utter lack of knowledge by physicians of the most elementary facts concerning radiology is often ludicrous and, at times, even embarrassing to the radiologist. Their utter ignorance of nomenclature is all too apparent to editors of journals. The teaching of all the physics a student requires should take but a few hours.

In the teaching of radiology all selfish motives of the radiologist should be ex-

cial enterprises outside of institutions depends almost entirely on the proper teaching of the younger members of the profession of the interrelation of radiology with the other branches or specialties of medicine. There is a growing tendency, apparently the world over, in the direction of commercialism, even with the vicious habit of fee-splitting. Lack of oversight in this particular line of work only serves to encourage similar proclivities in others. Haenisch,³ of Hamburg, in a recent memorial address, when commenting on the misfortunes arising from the rapid expansion of radiology when it lacked the co-operation of other specialties, made the following statement:

"The harm, however, which resulted from a too rapid expansion of the art and the consequent faulty, insufficiently prepared training was not the worst. This could, if the will were present, be minimized or even eliminated. Much more disastrous was the fact that the incompetent and dishonest elements grasped this specialty. These, in some instances, were unscrupulous physicians who were guided merely by the expected pecuniary advantages and who, unhampered by clinical and roentgenological knowledge and experience, 'sold X-ray pictures,' paying the referring physician rebates or commissions.

In other instances laymen, with or without connivance of dishonest physicians, saw in the purchase of X-ray apparatus a get-rich-quick scheme at the expense of innocent patients."

These practices are all too common, and their elimination must be a co-operative process, and the warning and the education cannot come too early.

9 Radiation therapy has a large share of importance in the treatment of neoplastic disease and many other pathologic conditions. To-day, operative surgery, electro-thermic procedures, and the use of roentgen

rays and radium are the only approved methods of dealing with cancer, which is one of the most important conditions with which we have to deal in these modern medical times, because it is second in mortality rate among adult diseases. the undergraduate period. The next arguments are over the time, the place, and the method. Barclay states "It is quite true that the overburdening and consequent extension of the medical curriculum is due to the increase in specialization. The student of to-day has a far greater load of learning to cram into his head than he had a few years back, far more than he can ever hope to remember." The method of general didactic class instruction in radiology as carried out in most institutions in the past has been a failure in many respects. It has certainly not accomplished the desired results, and the only service it fulfils is to give the class as a whole some idea of the scope of radiology, and this is not sufficient compensation for the time and effort. Didactic teaching by lectures to hitherto untaught students means in part the showing of series after series of roentgenograms or lantern slides representing pathologic conditions which the student sees with little or no understanding of their import. Even were he shown the normal first, he cannot correlate that appearance with the structures of the human body represented because he has never been taught to do so. The futility is realized when the teacher reads examination papers or asks even the most practical questions at the end of the period. A few exceptional students may have grasped the subject, but the large majority have not. Didactic lectures are better adapted to graduate students who have received sufficient groundwork in the subject to enable them to absorb and assimilate that kind of instruction. Didactic teaching of radiology had its inception largely in the fact that no text-books were procurable on the subject, whereas this method has gradually declined in other specialties as suitable collateral text-books have become available.

Human psychology requires that the reasons for certain results must be explained if these results are to be understood and are to make any permanent impressions on mem-

ory. Hence, if the student knows why and how roentgenographic and fluoroscopic appearances are brought about or biologic effects are produced, his mind will be more receptive in the way of interpretation of shadows of the body structures and the indications for treatment by irradiation and the results obtained thereby. Therefore, in teaching radiology it is necessary to preface the practical aspect of the subject by a short course of instruction in physics. This must be didactic, but it should be made as elementary as possible and, at the same time, interesting. It should have been taught as a pre-medical subject, but this seems seldom to have been done, or, at least, not in a manner capable of impressing the students in a way a teacher of radiology would desire. The most appropriate time for it, or, at least, to review the necessary part of the subject of physics, if it must be included in the undergraduate medical curriculum, would seem to be during the first year. Then there is more time for it and it can precede any practical teaching. Surely the medical practitioner should know something about the physics pertaining to X-rays and radium and the physical problems involved in their application. It need be but a small percentage of what the radiologist must know and even make use of every day. The physician should be able to talk intelligently with his patients about what he orders for them, if nothing more. How many physicians know just why irradiation is used in cancer or the difference between radium and its emanation or the similarity in effects of roentgen rays and radium? The utter lack of knowledge by physicians of the most elementary facts concerning radiology is often ludicrous and, at times, even embarrassing to the radiologist. Their utter ignorance of nomenclature is all too apparent to editors of journals. The teaching of all the physics a student requires should take but a few hours.

In the teaching of radiology, all selfish motives of the radiologist should be ex-

cluded and he should formulate his plans in such a manner that the instruction may aid that of other subjects rather than take time away from them Barclay says "In teaching the radiological aspect of anatomy and physiology to men I find that nearly all of them have forgotten these subjects to an astonishing extent Surely there must be something radically wrong that this should be the case I believe the trouble lies in the fact that these have become specialist subjects, taught by specialists, in departments that are separated from those in which the practice of medicine goes on" If this is true, as I believe it to be, at least to a considerable extent, is it not possible that the teaching of radiology might serve as a liaison between the clinical and the pre-clinical branches? As a matter of fact, such a purpose would seem to be a direct outcome of many proposed modern methods of teaching radiology

When the internist presents a didactic or clinical lecture to his students, the latter have been prepared in anatomy, physiology, pathology, *materia medica*, applied therapeutics, and physical diagnosis for a better understanding of the clinical subject under discussion This progression of teaching has been worked out through long years of experience Somewhat similar methods of progression would seem to be applicable to the teaching of radiology Instead of a curriculum which prescribes a course consisting of a series of didactic lectures on the general subject suppose we substitute one in which the roentgenologic aspect of anatomy, physiology and pathology in the living subject is considered in connection with the teaching of those branches and later on, with the diagnosis of living pathology in the clinical branches

One of the greatest misfortunes of the early radiologists was their enforced neglect of the study of the normal When they started their work they were obliged to delve immediately into the abnormal without an

adequate knowledge of what was normal Fortunately this has been realized and has been corrected to a great extent, but not entirely Inadequately trained individuals are often prone to interpret normal variations as evidences of disease because of their lack of knowledge of roentgenologic anatomy, physiology and pathology One of the most flagrant examples of this was the one-time popular peribronchial tuberculosis Unfortunately, too many of us were culpable in this error Unfortunately, the assertions of insufficiently trained radiologists have been accepted by unsuspecting clinicians who did not realize the absolute necessity for a proper anatomic and pathologic knowledge in roentgenographic interpretation As a result, men by the wholesale were kept out or put out of the military services or were granted undeserved compensation because of alleged tuberculosis without any true pathologic basis in roentgenograms The radiologists of the future must be properly trained on the basis of our experiences of the past Why should not the proper form of instruction be given, though on a much smaller scale, of course, to the physicians who must, in the end, be the real judges of the fitness of radiologists when the health of their patients is at stake?

RELATION TO OTHER BRANCHES

Anatomy, one of the first basic branches, is a study of the normal It is not a subject to be "crammed" and all too soon forgotten Whether it is covered during the first year or, better, during the first two years, that is the appropriate time for demonstrations of normal living anatomy as depicted on roentgenograms or by fluoroscope This could be done all at one time but preferably, as each part of the body is taught, the normal roentgenographic appearances could be demonstrated This would include the skeleton, with adult appearances, and also a short demonstration of epiphyseal

development, with an explanation of what the roentgenographic appearances mean at different ages I never knew just what an epiphyseal separation really was until I saw it demonstrated roentgenographically in intern days The relations of the bones at the various joints and in the spine should be described anatomically and then roentgenographically The student seems utterly at sea when shown roentgenograms of sinusitis, mastoiditis, pituitary tumors and the pathologic conditions demonstrated by ventriculograms and encephalograms Surely, when the student is taught the anatomy of the head and brain he could be made to understand the roentgenographic appearances of the paranasal sinuses, mastoid cells, sella turcica, and cerebral ventricles I always considered the latter and the circulation of the cerebrospinal fluid things to be learned and then forgotten until the advent of ventriculography and encephalography Surely, typical normal encephalograms and ventriculograms could be advantageously used for demonstration purposes when these structures are considered anatomically The entire digestive tract could be demonstrated roentgenologically, as the anatomy instruction proceeds The student should be taught just how the radiologist sees it as a muscular tube with potential lumen when empty and with invisible walls, but only as a lumen shadow when filled with opaque contents Later on he will be better able to understand how pathologic conditions will affect this lumen shadow The kidneys, ureters, and bladder can be demonstrated by normal urograms after retrograde or intravenous injections of opaque substances Normal gall-bladder demonstrations will be in order, with a few facts explaining the method of filling by the dye, although this would come more under physiology In connection with the thoracic contents, the heart and vessel shadows should be demonstrated Diaphragmatic excursion and cardiac pulsation should be reserved for section

fluoroscopy Group demonstrations would always be desirable for all this teaching, especially to permit of questions being asked by the students, but, if not feasible, much improvement in the present teaching plan could be made possible even by the usual class demonstrations of the various parts as the anatomic instruction proceeds In all these demonstrations the student will be better able to understand why he sees the shadows of the structures shown if he has just received his preliminary short course in physics Needless to state, these anatomic demonstrations should precede any attempt to teach roentgenographic pathology All this anatomic teaching should be carried out in the medical department

The course in physiology is an important teaching opportunity for roentgenology Many of the important and really practical physiologic facts have been determined by fluoroscopic and roentgenographic observations, especially in connection with the digestive and urinary tracts A number of the older beliefs have been entirely changed, and yet it is surprising how slow physiologists have been in appropriating this means of gaining knowledge, and it is inconceivable how known and recognized roentgenologic discoveries have failed to appear in textbooks Barclay calls attention to the persistence of the Alexis St Martin observations in modern print when they are manifestly absurd in the light of our present knowledge of gastric motility How many physiologists teach that the stomach cannot empty properly when the individual lies on his left side, that peristalsis is a mixing mechanism in the stomach but largely propulsive in the intestine, that it and general gastric tonicity together are responsible for motility, that the shape and position of the stomach depend on the build of the individual, tonicity and the amount of contents, that there are such conditions as gastric compensation and decompensation, that pyloric spasm is in-

cluded and he should formulate his plans in such a manner that the instruction may aid that of other subjects rather than take time away from them Barclay says "In teaching the radiological aspect of anatomy and physiology to men I find that nearly all of them have forgotten these subjects to an astonishing extent Surely there must be something radically wrong that this should be the case I believe the trouble lies in the fact that these have become specialist subjects, taught by specialists, in departments that are separated from those in which the practice of medicine goes on" If this is true, as I believe it to be, at least to a considerable extent, is it not possible that the teaching of radiology might serve as a liaison between the clinical and the pre-clinical branches? duced by heavy exercise after a meal, mental fatigue and headache, and that most or all of these phenomena can be demonstrated easily by the fluoroscope? Students seldom know the differences in motility of the upper and lower small intestine and of the mass type of peristaltic phenomena of the colon, and yet these are all practical facts. Several men have followed Cannon in this line of investigation, but many have not. During recent studies of the normal swallowing act I have been surprised at the inaccuracies of physiologic statements concerning this mechanism or the lack of them. Barclay⁴ has been struck by similar observations. It is almost inconceivable how the radiologist could have progressed as he has without the help of the physiologist, but it is conceivable that progress could have been more rapid with the physiologist's co-operation in the early days. It is quite easy to demonstrate how coarse foods remain much longer in the stomach than semiliquid suspensions of finer food particles. This is an example of information that would be of value in connection with later clinical teaching. Demonstrations of barium enemas would be most instructive even if made but once to each student. The pulsations of the heart and vessels, the normal movements of the diaphragm domes and the costal movements with respiration would be so spectacular as to be easily remembered by the student. Naturally, all such demonstrations could be witnessed by only small groups of students at a time. The dangers of exposure should be considered carefully as they apply to both observers and subject, and all such demonstrations should be under the direction of the department of radiology.

Pathology is the next branch by which the student should be helped toward an understanding of the practical aspect of roentgenology. Any teaching along this line should follow that of the normal, as already de-

scribed. Pathologic anatomy in conjunction with roentgenology should be taught, first, from the standpoint of the manner in which the disease affects the structure directly and grossly, and, secondly, as it alters function, because roentgenology is essentially a study of pathology in the living subject and thus differs from morbid anatomy as it is usually understood. The student should learn the actual gross and microscopic pathology first and then be taught to apply that knowledge to roentgenographic and even fluoroscopic appearances, just as the trained roentgenologist has to do every time he attempts to interpret evidences of disease in his roentgenograms or by roentgenoscope. The latter didactic course in radiology will serve to show that when two or more pathologic processes present similar or indistinguishable appearances the clinical aspect of the case at hand, that is, history and clinical observations, must be carefully considered in the rendering of a correct interpretation by the process of exclusion. It is probable that, when the student has become familiar with normal roentgenographic appearances, typical roentgenograms of pathologic conditions will serve the pathologist well for demonstration purposes, not only when teaching from gross specimens, but also in general didactic instruction in various pathologic conditions. Needless to say, a normal roentgenogram of the structure should always accompany that of the pathologic condition under discussion, as for example, cancer or ulcer of the stomach, intestinal neoplasms, bone tumors, aneurysms, heart conditions and many other intrathoracic lesions. It would seem almost if not quite as important to teach roentgen appearances in pathology as it is the histologic pictures of the processes. The roentgenograms of the patient should always be on display in the autopsy room, especially when students are present.

PLACE IN CURRICULUM

The question naturally arises as to how

⁴A. E. Barclay. The Normal Mechanism of Swallowing. Proc. Staff Meet., Mayo Clin., Sept. 10, 1930, V, 251-257.
British Jour. Radiol. December 1930, III, 534-546.

all this instruction is to be carried out in connection with the preclinical branches, and especially in a minimum of time in an already overcrowded curriculum. The time factor in the problem may be disposed of first. All the demonstrations mentioned would be of comparatively short duration and form really a part of the teaching of the branch in which they are included. Many of them would lead to a better understanding of the subject at hand, especially from the practical point of view. I believe that the results obtained would amply pay for any extra time consumed.

It would seem preferable for all this pre-clinical as well as subsequent instruction to be under the direction of the professor of radiology, and for the teaching or demonstrations in each branch to be arranged through agreeable co-operation with the professor in each. There could be one fully equipped roentgenologic department in the medical school, with a well trained technician in charge who could handle all demonstrations and also take charge of all experimental work, as in research surgery, physiology, anatomy, pharmacology and other branches requiring it. This technician would not be a teacher. There are two ways in which roentgenologic teaching could be carried out. The first would be directly by a representative of the department of radiology. The radiologic staff in a teaching institution and hospital must, of necessity, in these days, be a large one. There must be a professor at the head and at least one or two associates. The assistants are frequently two-to-three-year fellowship men, who are to become the trained radiologists of the future. They usually have minor faculty appointments. Technicians must look after all the details of purely technical work. One or more of the associates or fellowship men could be appointed to look after all the details of the instruction in the preclinical branches. The other plan would be to place

this instruction in the hands of trained and competent members of the staffs of the branches, but with the department of radiology having a co-operative oversight. A combination of the two plans might be found advantageous. Decentralization of radiology is usually not a successful venture in the long run. It is a duplication of effort and is expensive and is not conducive to the best interests of teaching in general. It leads to a one-track mind, whether applied to anatomy, physiology, or clinical subspecialties, and fails to preserve the active spirit of co-operation so essential to the perfect teaching machine. The trained and experienced general radiologist is in a better position to see how the teaching in connection with all the branches can be best correlated. Clinical radiology is not laboratory work as we usually understand it. The trained radiologist must have a far wider vision than any laboratory chief can possibly have.

In the third year, the student should be taught to correlate his knowledge of anatomy, physiology, and pathology in a clinical application. The instruction should also be in the nature of a review, which intensifies the mental impression that may have been made previously. After such preclinical teaching as has been outlined there should be a striking difference in the student's receptivity to the clinical application of roentgenology compared to that which is possible when the attempt is made to teach him pathologic roentgenology only at this time, and without any preliminary introduction. The third year instruction under the radiologic staff, who can best correlate previous, present and future teaching, should cover a period of from sixteen to eighteen weeks during the last half of the year, with a weekly demonstration lecture. Each one should be elementary and based only on typical pathologic cases or examples. All exceptional and confusing cases should be absolutely ex-

cluded, and as few illustrative ones used as possible. Continuous didactic lectures illustrated by numerous films or slides shown in rapid succession make but little mental impression on the student, who is still very much a novice. An ideal way would be to divide the class into small sections for demonstration purposes, with each member of the staff teaching a small group simultaneously. Few institutions are equipped to do this, however. While actual didactic lectures should be avoided as much as possible, a few of them are necessary, especially in connection with radiation therapy, which is preferably a fourth year subject, however.

In the fourth year, roentgenology and clinical medicine and surgery and the special branches should be still further correlated. The plan we have followed for a number of years has worked out very satisfactorily. A class section of about twenty students spends an hour a week for six to eight weeks in a medical roentgenologic conference in which the director or professor of radiology is the leader and with the medical staff in attendance. Individual cases with which the students are familiar are discussed from the standpoint of history and clinical observations by the medical staff. The roentgenograms are then demonstrated and the roentgenologic deductions presented. The students are requested from time to time to attempt roentgenographic interpretations and are urged to ask questions.

Similar conferences are held weekly on surgical cases, with the surgical staff in attendance. After the roentgenologic deductions have been made, the surgeon in charge of the case in question briefly reviews the operation and gives the operative observations. These conferences last throughout the fourth year, so that each student has from twelve to sixteen hours of instruction.

A similar plan is carried out with the pediatric staff, although student attendance is optional.

In addition to this, clinical medicine and surgery, and even some of the other specialties, should be taught with the use of roentgenologic data from roentgenograms as a part of the clinical picture of each case under discussion. Probably the subject of fractures is universally taught in this manner. The student will have a much better understanding of what the roentgenograms are intended to convey if he has had such preliminary training as has been outlined. In more or less didactic teaching of clinical subjects, roentgenograms of typical cases might well be shown, with normal roentgenograms for comparison, as a part of the clinical picture of each disease.

As has been previously stated, the preferable method of teaching radiation therapy would be through the agency of a cancer clinic group. The student should be taught unbiased views in regard to the indications and limitations of radium, roentgen rays, surgery and electrothermic methods. He then understands the necessity for early diagnosis and is prepared to go out and choose between accepted and unethical and unscientific methods of treatment.

The foregoing recommendations prescribe what would seem to be an ideal method of teaching radiology to undergraduate medical students and its correlation in a practical way with preclinical and clinical specialties. They are not entirely personal views but include also the ideas and even the practices of many teachers of radiology. They are offered for the purpose of general consideration with the hope that they may assist in the betterment of at least a small part of the medical curriculum.

THE TEACHING OF RADIOLOGY TO INTERNS¹

By JAMES T. CASE, M.D., CHICAGO
From the Northwestern University Medical School

THE average physician cannot boast of great familiarity with the conduct or interpretation of roentgen examinations, or of adequate comprehension of the possibilities of diagnostic aid to be obtained from X-ray studies. His contact with X-ray problems consists in the main of emergency cases in which fractures or dislocations are suspected, and occasional reference of cases to X-ray laboratories for a "picture" of the lungs, stomach, or urinary tract. He has not appreciated that, in addition to skeletal diseases and injuries, roentgen studies may be applied with advantage to nearly all visceral disorders, including many diseases of the nervous system. He does not stop to realize that examination with the X-rays is much more complicated than the simple taking of a "picture", that it is really no more a simple laboratory procedure than an ophthalmic examination or a urinary tract examination or a gynecologic study, and that a clinical knowledge of the conditions entering into his problems is a necessary part of the preparation of the radiologist. The "picture" of the stomach turns out to comprise a careful fluoroscopic investigation supplemented by anywhere from three to a dozen or more roentgenograms in various positions and under various circumstances according to the individual case. The "picture" of the lungs proves to be much more involved, the patient requiring fluoroscopic study in the erect position at various angles, with films to record whatever may be questionable or of especial interest, and sometimes it is advisable to make a screen study of the patient in the horizontal, prone, supine or lateral position, and to record the results with the necessary films. All of

which sounds, and in actuality is, much more complicated than the simple word "picture" would imply, and yet to the layman who hears the X-ray study spoken of as a "picture," the physician's use of this term only serves to strengthen his impression that a roentgen examination is nothing more than some sort of glorified photography.

The remedy lies in some measure in the widening of the horizon of the general practitioner in relation to X-ray matters by having the radiologists of the country enter into a campaign of education through staff meetings, county society and other medical meetings. To a certain degree, perhaps as rapidly as possible, this is being carried on at the present time, but the logical and most important step is to carry this education to the young graduates of medical schools while they are in their intern year.

Medical students receive a certain amount of instruction in radiology, mostly in connection with X-ray investigations made in relation to the various patients with whom they come in contact during their clerkships and clinics. In addition, most medical school curriculums now include required didactic courses in roentgenology, usually in the Senior year, and in many there are well trained roentgenologists who carry on excellent systematic courses of lectures and demonstrations to the students during both the Junior and the Senior years. Many schools make it possible for their students during their Senior year to serve a clerkship in the X-ray department. Thus, when the graduate of to-day comes to the hospital as intern he already possesses a good foundation for further elaboration of his knowledge of roentgenology.

Statistical data from 619 hospitals approved for interns indicate that more than

THE TEACHING OF RADIOLOGY TO INTERNS¹

By JAMES T. CASE, M.D., CHICAGO
From the Northwestern University Medical School

THE average physician cannot boast of great familiarity with the conduct or interpretation of roentgen examinations, or of adequate comprehension of the possibilities of diagnostic aid to be obtained from X-ray studies. His contact with X-ray problems consists in the main of emergency cases in which fractures or dislocations are suspected, and occasional reference of cases to X-ray laboratories for a "picture" of the lungs, stomach, or urinary tract. He has not appreciated that, in addition to skeletal diseases and injuries, roentgen studies may be applied with advantage to nearly all visceral disorders, including many diseases of the nervous system. He does not stop to realize that examination with the X-rays is much more complicated than the simple taking of a "picture", that it is really no more a simple laboratory procedure than an ophthalmic examination or a urinary tract examination or a gynecologic study, and that a clinical knowledge of the conditions entering into his problems is a necessary part of the preparation of the radiologist. The "picture" of the stomach turns out to comprise a careful fluoroscopic investigation supplemented by anywhere from three to a dozen or more roentgenograms in various positions and under various circumstances according to the individual case. The "picture" of the lungs proves to be much more involved, the patient requiring fluoroscopic study in the erect position at various angles, with films to record whatever may be questionable or of especial interest, and sometimes it is advisable to make a screen study of the patient in the horizontal, prone, supine or lateral position, and to record the results with the necessary films. All of

which sounds, and in actuality is, much more complicated than the simple word "picture" would imply, and yet to the layman who hears the X-ray study spoken of as a "picture," the physician's use of this term only serves to strengthen his impression that a roentgen examination is nothing more than some sort of glorified photography.

The remedy lies in some measure in the widening of the horizon of the general practitioner in relation to X-ray matters by having the radiologists of the country enter into a campaign of education through staff meetings, county society and other medical meetings. To a certain degree, perhaps as rapidly as possible, this is being carried on at the present time, but the logical and most important step is to carry this education to the young graduates of medical schools while they are in their intern year.

Medical students receive a certain amount of instruction in radiology, mostly in connection with X-ray investigations made in relation to the various patients with whom they come in contact during their clerkships and clinics. In addition, most medical school curriculums now include required didactic courses in roentgenology, usually in the Senior year, and in many there are well trained roentgenologists who carry on excellent systematic courses of lectures and demonstrations to the students during both the Junior and the Senior years. Many schools make it possible for their students during their Senior year to serve a clerkship in the X-ray department. Thus, when the graduate of to-day comes to the hospital as intern he already possesses a good foundation for further elaboration of his knowledge of roentgenology.

Statistical data from 619 hospitals approved for interns indicate that more than

80 per cent offer instruction in X-ray work. In some, provision is made for the rotation of the interns to include a brief service in the roentgen department, and in some of the larger hospitals there is a special X-ray internship. In others, occasional lectures are arranged to be given by the members of the staff of the roentgen department so that the interns may have more or less systematic instruction in roentgen diagnostics and therapy. In most hospitals, however, observation leads me to believe that the X-ray instruction given interns is desultory and not under definite check. The idea seems to be that the intern may absorb his knowledge of radiology while making rounds with the attending physicians and surgeons. In small institutions this is perhaps a necessary procedure, but in hospitals where the services of a trained roentgenologist are available it would be well for the interns to get from him also his slant on the meaning of the roentgen examination. The attending staff has a duty and a privilege in collating the roentgen observations with the other clinical and laboratory aspects of each case, whereas the roentgenologist, no matter how familiar he may be with the clinical and laboratory observations in a case, must not read into his roentgenologic interpretation more than can be supported by the X-ray evidence. It is well for him to know as much as possible about each case, the more the better, but he should not put into writing as a part of the X-ray report any statement which cannot be substantiated by the X-ray evidence.

PROGRAM OF INSTRUCTION

It is evidently quite necessary, if interns are to be given X-ray instruction, to formulate a definite program which can be followed out. Let me consider some of the things I believe it essential for an intern to learn about the X-rays. Naturally, the extent to which this ideal can be carried out depends on the size of the hospital.

of secondary radiation, and the physical and biologic laws that apply to them. This may be accomplished by reading text-books, and it may have been done by some of the interns but a systematic review should be made of the subject. Only by appreciating the physical facts will the intern ever learn to take care of himself and his patients during roentgenologic investigations and therapy. He should be taught the necessity of constant protection by lead-rubber aprons and gloves, to conduct roentgen examinations with expedition, to realize that proper filters must be kept in place between the source of the rays and the patient, whether for therapy or for examination, and that that most memorable of laws, the inverse square law, applies to all radiation (including radium and ultra-violet rays). He should learn that the patient becomes a potent source of secondary radiation against which protection must be provided.

2 *The scope of roentgen examinations.* In his daily work the intern learns the general applicability of the roentgen rays to diagnosis, but the refinements of X-ray diagnosis should be systematically brought to his attention by didactic work. There are conditions not encountered in daily work in which the average physician will not think of a roentgen examination, for instance, acute intestinal obstruction, subphrenic abscess, pulmonary and pleural abscesses, perirenal abscess, certain abdominal abscesses, the measurement of the size and the position of certain viscera such as the liver and spleen, and the application of opaque oils and other opaque media to the study of the sinuses and fistulas as well as certain organs into which such opaque oils may be introduced. The localization of foreign bodies is a field in which most physicians do not know (or else have forgotten) the value of the X-rays. Physicians with experience on the front during the War had brought home to

localizing foreign bodies of all kinds, special emphasis being placed on fluoroscopic methods, yet how few seem to remember at this short interval since the War the efficiency and the speed of the fluoroscopic methods of routine use in war hospitals during hostilities. Peace-time studies have added non-opaque foreign bodies in the respiratory tract to the opaque foreign bodies detectable with the roentgen rays. Naturally the intern, even in his student days, became familiar with the scope of the roentgen study of the gastro-intestinal tract, the urinary tract, the lungs and bronchi, the heart and great vessels, and the skeletal injuries and diseases. It is important that in all autopsy and staff conference discussions the roentgen observations should be presented by the radiologic department and carefully correlated with the clinical and autopsy aspects of each case. It is a practice in one hospital, at least, to present at the autopsy room a roentgenogram of the chest, made postmortem, to bring further down to date the X-ray data on the thorax.

3 Fluoroscopic control of the reduction of fractures and dislocations and in the removal of foreign bodies. Some of the larger hospitals are equipped for biplane fluoroscopy for use during the setting of fractures and the reduction of dislocations, but the very accessibility of such apparatus may tend to relax one's vigilance against damage by the X-rays to the patient and staff. Every year new cases are brought to attention in which irreparable damage has resulted to physicians from injudicious fluoroscopy. When special apparatus is not provided for such work, improvisation can be made in the roentgen department or a portable X-ray instrument and a hand fluoroscope may be carried to the operating room, under which circumstances the danger of damage by the X-rays to the staff is greatly increased, to say nothing of danger from possible explosion from unwise choice of anesthetic agent to use under such

circumstances. These precautions are all the more important if it is sought to use the roentgen aid in the extraction of an opaque foreign body. Here again one seems to see very little effort to use the fluoroscopic aid so widely taught in military surgery. Time and again one sees surgeons attempting the removal of superficially located foreign bodies in the good light of the operating room when, by the aid of the fluoroscope and a proper technic of protection against surgical contamination and roentgen damage, the offending substance may be extracted with great saving of time and no danger from the X-rays.

4 Roentgen interpretation. To develop skill in reading roentgenograms and in translating the appearances made manifest by fluoroscopy there must be opportunity for observation of and participation in fluoroscopic and X-ray film examinations, and for sharing in the conference at which the roentgenologist puts together into the written report the X-ray evidence shown by films and screen. To make this of teaching value, it is important that the roentgen department be furnished with a statement of the problem in each case referred for examination. It is not enough to refer the patient merely for an examination of such and such part, the examination desired should be stated, but, most important of all, the problem should be stated clearly. The referring physician had some reason for sending the patient for examination in the roentgen department, what was that reason? A tentative diagnosis would be ideal, but practically it seems impossible to get the co-operation of staff members to that extent. It is possible to insist on knowing the question that was in the referring physician's mind when he wrote the requisition and he should take the time and trouble to state his problem briefly.

5 Roentgen terminology. Terminology is of importance in the instruction of interns. It is difficult to change the habits of

a lifetime and, on the other hand, it is relatively easy to instruct young people just entering their practical experience To a man who has all his life spoken of roentgen examinations as "having a picture taken," and who has been guilty of sending his patients into the X-ray department for an "X-ray picture of the gastro-intestinal tract," an "X-ray picture of the lungs," and of this, that, and the other thing, it is useless to talk about terminology But the younger men are susceptible to persuasion and rule in this matter, especially when reason is used in talking with them There is a certain dignity which belongs to all branches of the medical profession, and it is well to maintain that dignity The surgeon does not speak of making such and such a "gash" or "slash" to "dig out" the appendix, that would be exceedingly undignified He makes such and such an "incision" to "resect" the appendix One does not "dig out" the prostate through a low belly "slash", he "enucleates" the prostatic tumor through a "suprapubic incision" Just so, in roentgen terminology it is possible with a little care to school oneself to dignified language and to speak of "X-ray films," "X-ray examination," and "X-ray study" if one is determined that his tongue cannot negotiate the more cumbersome "roentgenogram" or "roentgen study" One of my dear friends protested that he could not curl his tongue around "roentgenogram," yet within two or three minutes he was talking about a nice case of urethral obstruction in which he performed a "ureteromeatotomy"! Proper terminology aids materially in the collection of fees that are necessary to carry on X-ray work adequately The American Medical Association has published an acceptable list of radiologic terms

6 *Therapy* The field of roentgen therapy is so complicated that it is to be doubted whether more can be done in the way of instruction during the intern year

ment, the selection of cases, the realization that it is possible to make accurate dosage, and the limitations of the method

Circumstances will determine how far such a program can be carried out in the individual hospital In large hospitals, with internships of from eighteen months to two years, it is quite reasonable that a portion of this time be given to the roentgenologic department, each intern spending a while in that department as a participating assistant Such a stay should be for not less than two months, and three would be better The practice of assigning an intern to the X-ray department instead of a place on a rotating service should be condemned, no fellow in the roentgen department should be accepted until after having served his regular internship, and preferably after a few years of general practice Failure to observe this precaution results in unbalanced training, which soon becomes evident in the practical work of the fellow

In some hospitals the interpretation is done at the same time during which the members of the attending staff are making their rounds, so that it is difficult for the interns to participate in the reading of the roentgen examination In such cases it is feasible to arrange a certain hour at the close of the forenoon or at the end of the day for revision of some of the more interesting of the X-ray cases of the day It is also possible for the staff to arrange that the roentgenologist shall give a series of systematic lectures and demonstrations covering the X-ray instruction deemed necessary

Much good will have been accomplished if the intern on leaving the hospital can carry with him a thorough appreciation of the scope and limitations of the roentgen examination in various disease conditions, its value and dangers in the control of fracture and foreign body work, and its place with radium in the treatment of many benign lesions as well as in the management of malignant disease

THE POST-GRADUATE AND GRADUATE TEACHING OF RADIOLOGY¹

By ARTHUR U DESJARDINS, M D, ROCHESTER, MINN
From the Section on Therapeutic Radiology, Mayo Clinic

RADIOLOGY is still a comparatively new branch of medicine, but its rapid development during the last thirty-five years, and especially during the last ten years, is deservedly attracting widespread attention. Moreover, its relations to many other phases of medicine are increasing day by day. In several phases of medical practice, in fact, radiology has already become an indispensable factor. Such evolution has been so rapid that, although many of the better medical schools provide more or less substantial instruction for under-graduates, little effort has yet been made to organize and provide thorough post-graduate or graduate courses. In this respect America has allowed itself to fall behind several European countries. In England, France, and Sweden, for instance, the teaching of radiology is well organized and has been placed on a higher plane than in any school in this country. This deficiency is now crying for correction.

Any consideration of post-graduate and graduate instruction in medical radiology must take into account a number of factors: the present status of the subject as it affects, and is affected by, other phases of medical practice, the existing plane of under-graduate teaching of radiology, the number of qualified teachers available, and the objects which an ideal system of instruction should seek to attain. It must be obvious that, without an ideal to strive for or a definite objective to attain, it would be difficult or impossible to construct a plan that could be expected to yield the desired result. In other words, the first essential is to know

what is the desired result and to keep it clearly in mind. The main object of post-graduate instruction in radiology, it seems to me, should be to develop full-fledged specialists in this branch of medicine, masters of the subject, thoroughly equipped to practise the specialty, and worthy of public confidence. This, then, should be the ideal toward which we should strive. But before constructing a plan to achieve this result, it is important to inquire into the present status of radiologic practice. In a recent analysis I² have attempted to point out some of the undesirable conditions that characterize such practice at the present time, such as the comparatively low standards that countenance the reference of patients by their attending physicians to so-called laboratories operated on a commercial basis by unqualified laymen, the dependence of many physicians on interpretations of roentgenologic data by non-medical technicians, the treatment of patients by technicians without supervision by medically trained therapeutic radiologists, and the dearth of teachers of academic caliber. These different factors are so closely interrelated that to analyze and set forth precisely the influence of each factor is not a simple task. Nor is such exact distinction necessary. It is quite enough to know that these factors collectively constitute a sort of vicious circle. The one point at which this circle can be most effectively broken is that which relates to post-graduate instruction, because the present lack of such instruction furnishes the best opportunity for constructive action. It is true that the break is rendered difficult by the relative paucity of teachers, but the

¹Read before the Annual Congress on Medical Education, Medical Licensure and Hospitals, Chicago, Feb 16, 1932. Reprinted by permission from the *Journal of the American Medical Association*, March 19, 1932, NCVIII, 933.

²A U Desjardins, The Status of Radiology, Jour Am Med Assn, May 23, 1931, NCVI, 1749-1753.

number of teachers can be increased only by such a break

Besides developing full-fledged specialists, however, the scheme of instruction should also include short courses in the different phases of diagnostic and therapeutic radiology. This would satisfy a widespread demand, would spread the knowledge of advanced methods, and would tend to raise the general level of radiologic practice.

A well-considered scheme of instruction, therefore, should provide

1 Short, strictly post-graduate, courses in different phases of diagnostic and therapeutic radiology for graduate physicians who may merely wish to keep informed on the value of various new methods or to prepare themselves to utilize one or another phase of radiology, and also for radiologists who may want to keep abreast of the newer technical developments and methods.

2 A comprehensive, graduate course of systematic and thorough instruction in every phase of radiology for physicians who desire to qualify as specialists.

The short courses should be open to any graduate physician, regardless of the character of his practice. This suggestion will no doubt be objected to by some, who may feel that to allow any physician to take such courses must result in encouraging physicians in general to conduct roentgenologic procedures or radiotherapy for themselves and in restricting the field of the radiologic specialist. This objection, I am convinced, is not strong. Although it must be conceded that the broad privilege of taking short courses would undoubtedly lead an increasing number of physicians to interest themselves in radiology and perhaps to employ it in their own work, I feel certain that instead of limiting the field of the specialist it would extend it. The more widespread the realization of the usefulness of different phases of radiology, the greater the likelihood that the real value of highly qualified

... specialists will receive the recognition it de-

serves. Certainly, it cannot be said that the short post-graduate courses in ophthalmology have lowered the level of ophthalmologic practice as a whole, on the contrary, they have led an increasing number of physicians to recognize the importance of high grade ophthalmology, and the status of this branch of medicine has risen as the number of qualified specialists has increased. To be sure, it would be fallacious to assume that this achievement has resulted from the provision of short post-graduate courses, the point is that such short courses do not appear to have acted as a deterring factor, and there are reasons for thinking that they have had an opposite effect. Therefore, the fear that short courses of instruction in radiology for graduate physicians may interfere with the general program of placing the post-graduate teaching and practice of radiology on a higher plane seems unwarranted.

Among the subjects in which short courses might well be provided are

Physics of roentgen rays

Physics of radium

The quantitative and qualitative measurement of roentgen rays and radium

Roentgenologic technic

Roentgenologic interpretation

Roentgenologic diagnosis of diseases of bones and joints

Roentgenologic diagnosis of diseases of the respiratory tract

Roentgenologic diagnosis of diseases of the gastro-intestinal tract

Roentgenologic diagnosis of diseases of the urinary tract

Roentgenologic localization of foreign bodies

The newer methods of roentgenologic diagnosis

The biologic principles of radiotherapy

The technic of roentgen therapy

The technic of radium therapy

Physicians taking such courses should be entitled only to a certificate of attendance and should not be required to pass any

examination, unless the number of short courses taken is sufficient to enable them to qualify as specialists. In this event, they should be allowed to take a comprehensive examination, and, if they succeed in passing it, they should be entitled to a certificate and to the title of specialist. The courses should be arranged so as to crowd as much information as possible in the time allowed and should consist of both didactic and laboratory exercises or practical work. The aim of the lectures should be to set forth principles and to explain their application, so that those who take such courses may be able to solve their own problems by analyzing the factors involved and applying fundamental laws. Neither didactic nor practical instruction alone can serve the purpose. Laboratory exercises should be chiefly in the form of demonstrations, because to expect the average short-course student to derive much information from being allowed to fuss and stew in a laboratory for two hours a day for six weeks would be likely to prove a delusion. Often it would only serve to waste the time of the student and of the instructor. In general, a well conducted demonstration would be much more effective. In certain courses, however, in which it is essential for the student to familiarize himself with technical procedures or with the operation of measuring or other instruments, individual practice under the supervision of the instructor is essential.

COMPREHENSIVE GRADUATE COURSE

The comprehensive course leading to a degree such as that of Master of Science in Radiology or Doctor of Radiology should be conceived along the broadest possible lines. It is difficult to see how anything like a thorough course of instruction can be compressed into less than three years. Any attempt to effect undue compression must necessarily result in sacrificing thoroughness and, therefore, quality.

To insure that candidates may be able to take full advantage of the course, they should be subjected to reasonably rigid requirements, as far as antecedent instruction or training is concerned. The privilege of registration should be restricted to graduates of Class A schools and preference in selection should be given, or selection should be limited to those who have had, as part of their pre-medical training, college courses in physics and biology or their equivalent. An internship of at least one year in a Class A hospital should also be required as a preliminary to registration.

The first year of the graduate course should be devoted to anatomy, physiology, and pathology and to the physical aspects of radiology. One-half year of concentrated training in anatomy, physiology, pathologic anatomy (otherwise known as gross pathology), and microscopic pathology would provide the strongest possible foundation for both roentgenologic diagnosis and radiotherapy. A radiologist cannot possibly have too much knowledge of anatomy and pathology. Ability in roentgenologic interpretation depends in about equal measure on knowledge of anatomy and pathology, and these subjects are about equally important for roentgen and radium therapy. To meet the needs of roentgenologic diagnosis, instruction in anatomy should lay particular stress on landmarks and relations of special importance in roentgenology and on the developmental phases of bones. Physiology should be taught chiefly in the form of a review, but special attention should be given to the more significant radiologic considerations.

The second half of the first year should be given over to radiologic physics, instruction in which should include both didactic lectures and laboratory exercises. The lectures or conferences should be as practical as possible and should be planned so as to explain and demonstrate physical principles.

as they apply to different phases of radiology. As much as may be feasible, examples should be selected from material related to that subject, and demonstrations should be arranged in the same way. The object of the laboratory exercises should be to serve as additional demonstration of principles, to explain the construction and operation of apparatus, and to familiarize the student with physical methods and instruments for measuring electrical potential and resistance, the quality and quantity of roentgen rays, and all other measurable factors that enter into the scientific practice of radiology.

The second year should be fully taken up by diagnostic roentgenology. Not only should the students be taught how to interpret roentgenograms, but they should be required to spend a good part of their time in performing, under the guidance and supervision of qualified instructors, the numerous technical procedures incidental to the present-day practice of diagnostic roentgenology. To watch some one else and to do things oneself are two quite different things. The one may be a useful preliminary to the other, but in no way can the former be regarded as a substitute for the latter. One who has not become thoroughly familiar with every step of a procedure by actual experience can never be in a position to direct subordinates intelligently. By every possible means, therefore, students should be induced to regard themselves as working members of the department in which they are receiving instruction and should be made to feel some measure of responsibility for whatever work they may be engaged in. This is the only way by which any one can expect to become really proficient. Roentgenography and roentgenoscopy have become so important that familiarity with every phase of their utilization in the diagnosis of diseases of bones and joints, of the digestive, respiratory and urinary tracts, of

the nervous system, and also for the recognition and localization of foreign bodies, requires a detailed knowledge of many methods and of the variations in technic by means of which maximal information can be elicited under different circumstances. To become proficient in every detail of roentgenologic diagnosis in one year does not allow any time for frivolity. The question is, is one year really sufficient? Certainly, it can be accomplished only by careful planning and correlation and by the utmost economy of time.

Perhaps the foregoing results can best be achieved by arranging for the students to concentrate their attention, for periods of two or three months, on the roentgenologic procedures involved in the diagnosis of lesions affecting each of the groups of structures or organs previously mentioned. However, a fixed schedule is out of the question, because considerable latitude must be allowed in adjusting the details of the scheme of instruction to the circumstances of the institution in which the course is given. Besides instruction and practical training in roentgenography and roentgenoscopy, the students should be taught the photographic and chemical aspects of roentgenography and the methods of protection required for the safe practice of radiology.

Throughout this part of the course it is desirable that contact with clinical medicine and surgery be maintained. In some institutions the diagnostic roentgenologist may be obliged to work with little knowledge of the clinical features of the cases examined. At best, this is to be regarded as an unfortunate necessity, but never should it be looked on as an ideal. On the contrary, the closer the relations between medical or surgical clinicians and the roentgenologist, and the more knowledge the latter may have concerning the cases he examines, the more valuable should be his opinion.

The third year should be given over to

therapeutic radiology, including roentgen rays, radium and, if possible, ultra-violet radiation. The field of radiotherapy, once so restricted, is now rapidly extending, and every radiologist worthy of the name should receive as broad and as thorough training in the therapeutic as in the diagnostic aspect of this branch of medicine. The conspicuous and widespread lack of such training, and of the clinical and pathologic foundations on which it rests, are among the most glaring deficiencies of present-day American medicine. Owing to the general neglect of this phase of the subject, but chiefly because of the lack of qualified instructors, few institutions are now in position to undertake such teaching. If this deficiency is to be corrected, a beginning must be made. For a time it may even be necessary for two or more institutions to pool their facilities and personnel.

Students should be required to take an active part in the examination of patients, in outlining their treatment and in preparing patients for irradiation, as well as in the actual administration of the treatment. I should be quite feasible to arrange the work so that, without any transfer of responsibility from those on whom the professional and legal obligations actually devolve, the students may yet have an appreciable share in all phases of such treatment. Only through some such scheme can they be made to realize the significance of many details, careful consideration of which and attention to which spell the difference between superior and inferior treatment. Too often the medical side of radiotherapy is neglected and the physical aspects are over-emphasized. Both should receive due consideration. Important as it is to know the quantity and quality of radiation most useful in dealing with different pathologic conditions, it is even more important to be able to recognize the disease at different stages, to ascertain the extent of the primary lesion and of secondary foci, to size up the general

state of the patient, and to adjust the treatment accordingly. Needless to say, the instruction in therapeutic radiology must be delegated to instructors of broad medical and radiologic experience. It may be contended that the general clinical, pathologic, dermatologic, surgical, gynecologic and other aspects of radiotherapy should be presented by specialists in the respective branches. But considerable difficulty may be encountered in finding specialists who have had sufficient experience with the radiologic aspects of their subject to qualify them for the task. To mention another example, few pathologists, and only a slightly greater number of practising radiologists, know much about the relative radiosensitivity of different varieties of cells and tissues. To be sure, the subject is still comparatively new, but, unless a start is made, such knowledge as we possess will be slow to diffuse.

On the whole, the most feasible arrangement at the outset will probably be to delegate the general teaching of the subject to the most experienced and the best informed therapeutic radiologist available. He, in turn, should arrange to have those phases of the subject with which he is not sufficiently familiar presented by qualified specialists. The strictly radiologic teaching should be supplemented by lectures on related aspects of clinical medicine, surgery and dermatology. Here again the need of combined didactic and practical teaching must be emphasized. This can be accomplished by means of lectures, but another effective, supplementary method is that of conferences or seminars at which certain of the students present a general review of some phase of the subject, which is then discussed by the instructor and by the other students.

The scope of roentgen therapy is distinctly broader than that of radium therapy, in that a wider variety of cutaneous, inflammatory, and neoplastic diseases are amenable

to treatment with roentgen rays than with radium. It must not be inferred, however, that the former subject should be allowed a greater proportion of time than the latter. An approximately equal period should be allotted to the two subjects. The therapeutic use of radium involves physical, clinical, and often surgical considerations, in which adequate knowledge, experience and judgment cannot be acquired hurriedly.

The program which I have ventured to outline would not be complete without the additional condition that, as part of his training, each graduate student should be required to undertake a piece of research on some phase of diagnostic or therapeutic radiology and to prepare a report or thesis based on such work. It is true that some, who may be brilliant in the practical aspects

of radiology, may not shine as investigators. The value of the research requirement does not lie so much in the actual results obtained as in making the student realize the importance of careful work and in the discipline which may cause him to realize that, even after an extensive course of study, he does not know everything.

I am aware that such a sketchy outline may be unsatisfactory and that some would undoubtedly prefer a more detailed plan. I have deliberately avoided this, however, because the conditions at each institution, and the personnel and facilities available, vary so much that the details of any scheme of instruction must be worked out by those who are familiar with the requirements on the one hand and with the local conditions on the other.

X-rays Most Destructive to Young, Growing Cells—X-rays in sufficient doses are destructive to all kinds of living cells, but they are most so to cells that are physiologically young and active. This is one of the basic physiological facts that underlie radiotherapy. Dr Arthur U Desjardins said in speaking before the American Association for the Advancement of Science. It follows from this principle that tissues that remain "chronically young" respond to X-ray dosages much smaller than those needed for effect on maturer tissues.

The most sensitive of all the cells in the hu-

man body are certain classes of white blood corpuscles, and the glands and other tissue masses where these are found most thickly are also very sensitive to the destructive rays. Dr Desjardins inclines to the opinion that the easy destructibility of these white blood cells is at the bottom of the value of X-ray therapy in certain inflammatory conditions. White blood corpuscles crowd around foci of infection, causing inflammation. The X-rays break them down, releasing the germ-destroying substances they have formed within themselves, and thereby hasten the death of the trouble-causing bacteria.—*Science Service*

A STATISTICAL STUDY OF RADIOLOGIC TEACHING IN THE MEDICAL SCHOOLS OF THE UNITED STATES AND CANADA

By LEON J MENVILLE, M D, F A C R, NEW ORLEANS

A REVIEW of the radiologic literature reveals many interesting articles appertaining to a lack of proper understanding by a certain number of clinicians and surgeons of the limitations of and indications for the roentgen ray and radium in the diagnosis and treatment of disease. It would appear from current reports that this misconception of radiology is widespread, that it is not restricted to the rural districts, but is evident as well in large medical centers.

Years ago, when little was known concerning the roentgen ray and radium, it was to be expected that few physicians, except those specializing in radiology, would have other than a little practical medical knowledge of these agencies. In recent years, the progress of radiology has attracted the attention of the medical world; its scientific achievements fill pages in the medical literature. The result is that this literature offers a splendid opportunity to all its readers to become acquainted with the fundamentals of radiology, so that there should be no excuse for the modern, progressive physician to be ignorant of the limitations of and indications for radiology in its application to medicine.

In spite of the many advantages which organized medicine offers its members, only a certain number avail themselves of this opportunity. Many will continue to grope in the dark as mind-blind physicians, without the faintest conception of just what a radiologist really is. They are unable to differentiate between a radiologist and a physician who manipulates an X-ray apparatus. In fact, many physicians believe that roentgenologic diagnoses are not necessarily the result of skill or a knowledge of

medicine. Their understanding is that the roentgenological examination is purely the result of mechanical apparatus so standardized that anyone familiar with its operation can and does make correct diagnoses. We have all experienced the embarrassment of having to refuse to make certain impossible roentgenologic examinations at the request of a referring physician, and likewise to decline the treatment of certain diseases not amenable to radiation therapy. For instance, a radiologist was requested to measure in inches the length and width of the mitral valve of a patient's heart, and when the referring physician was informed that the radiologist was incapable of performing such an examination, the physician became indignant, saying that he would refer his patient to someone who could. He did, but not to a radiologist—to a physician friend who owned an X-ray machine. In this connection, however, there are many physicians who have acquired a substantial knowledge of the importance of radiology in medicine, and frequently consult with the radiologist in the same manner as with the surgeon and other specialists.

It is not difficult to ascertain the reason for the existence of this general confusion, which, of course, is due to a lack of radiologic education. It must be remembered that many of these physicians attended medical school at a time when little was known about the roentgen ray and radium. The medical curriculum then allocated but very little, if any, time to radiology, consequently early medical graduates who have not kept in touch with the development of this branch have but a vague conception of it. It is unfortunate that such physicians must continue to be deluded by the false

RADIOLOGY

TABLE I—QUESTIONS 1 TO 7, INCLUSIVE

| School and Location (Alphabetical by States) | How many hours of didactic lectures are given in the following classes? | | | | Have you a Department of Radiology? | What title is given to the Head of the Radiological De- partment? | Is the radiological teaching separate, or is it given in the De- partment of Medicine or Surgery? |
|--|--|----------------|------------|----------------------------|--|--|---|

| | Do you believe that more time should be given to radiology in medical schools? | Do you consider radiology of sufficient importance to be recognized on a parity with otolaryngology, dermatology, and ophthalmology? | Remarks |
|--|--|--|--|
| | | | |
| Of what importance is the teaching of radiology considered in your school? | | | |
| Very important in diagnosis, plate reading, and general principles of X-ray therapy, but not to be taught as a technical specialty | Yes | Not equal to them | Gives only first two years of medical course One hour of second semester of Sophomore year given to introductory talk on radiology Twelve hours is given to the reading of X-ray films |
| Considered important | No | Yes, and rather more time is given to it than these specialties | In first semester of Junior year, one hour a week is spent in radiologic conference under the Dept. of Medicine, this centering around radiographic records of patients. We begin X-ray instruction in Anatomy and Physiology. With undergraduates, believe radiology should be stressed for diagnosis and treatment |
| Important Professors of medicine and surgery attend combined clinic (weekly) Ninety per cent of students elect optional courses | Not as a separate course | Yes | |
| The utmost, but is a tool of medicine and surgery | No | No | |
| Very important | Yes | Yes | |
| Of considerable value in diagnosis and is a therapy | Undergraduate no | With otolaryngology and ophthalmology, yes | In elective course, students spend about 60 hours in the department. In addition, conferences are held each week of the 6 weeks' course. Often students spend 12, instead of 6, weeks in the department |
| Of major importance | No | Yes | Six hours each in first 2 years given as radiologic anatomy. Forty-two hours in the fourth year spent in clinics |
| Very necessary and should be a separate department | Yes | Yes | |
| Of very great importance | See remarks | Clinically, yes | Roentgenology utilized in all clinical departments for diagnostic and observation purposes. It has become almost indispensable in clinical teaching and practice |
| Very valuable as diagnostic aid and every student should appreciate it | No | No | While radiologic teaching is given separately, X-ray films and reports are used in the instruction given in the Departments of Medicine and Surgery |
| Important | No | | |
| Essential | Yes | | The teaching is given in a conjoint course offered by several departments in co-operation |
| It is an elective subject | Yes | Yes | Junior and Senior students only at this college. An elective course, lecture, is given for 2 hours a week throughout the quarter and three quarters a year. The radiologist has ward-round students for 6 hours |

| School and Location (Alphabetical by States) | How many hours of didactic lectures are given in the following classes? | | | | Have you a Department of Radiology? | What title is given to the Head of the Radiological De- partment? | Is the radiological teaching separate, or is it given in the De- partment of Medicine or Surgery? |

| Washington University School of Medicine, St Louis, Mo | 0 | 0 | 0 | 0 | Yes | Prof of Radiology | Both |

| Of what importance is the teaching of radiology considered in your school? | Do you believe that more time should be given to radiology in medical schools? | Do you consider radiology of sufficient importance to be recognized on a parity with otolaryngology, dermatology, and ophthalmology? | Remarks | |
|--|--|--|---|--|
| | | | | |
| Of great importance. | No | Yes | Students also receive 12 hours' instruction in the dispensary, examining and interpreting radiograms | |
| Of much importance | Impossible at present | No | | |
| Of great importance. | Yes | Yes | The radiologic instruction in the Junior year is incidental to clinical work by clinicians | |
| Same as for other laboratory work in diagnosis and therapy | Not a great deal more | Not on a parity but as adjunct | | |
| | No | Yes | | |
| | No | Yes | | |
| It is considered of definite importance. | In some, more, in others, not | Yes | | |
| Two hours demonstration weekly for 8 weeks | No | No | | |
| Of the utmost importance | Yes | Yes | | |
| Quite important | No | Depends on personnel of department | In the Senior year 10 hours are given in sections and work in all clinical subjects | |
| | Yes | | In the Junior year 4 hours are given by courtesy of the medical staff. There should be instruction in normal X-ray anatomy during the first and second years | |
| | Yes | Yes | In the Junior year, the work is clinical, in the Senior year, the course is elective. Elective one month's course | |
| Very All students follow every film of every patient assigned to them | Yes | Yes | Also 32 section hours | |
| Highly important | If practicable | Yes | The work in radiology is supplemented by practical work in connection with medicine and surgery | |
| Very important | No | Yes | The professor of radiology offers an elective in X-ray anatomy for Freshmen and Sophomores, scheduled among the anatomy classes. The department participates in the medicine, surgery, etc., courses and offers electives | |
| Its importance begins in the Sophomore year | No | Not before Junior year | Only the first two years of the medical course are given. Physicians and surgeons demonstrate X-ray films to the classes | |
| On equal basis with other subjects according to semester hours | Possibly more than some give | Yes, we are doing just that | In the Junior year, the course consists of lectures, demonstrations, and quizzes | |
| First | Yes, however, do not see how more time can be found | Yes | Here there is little didactic teaching of any subject | |

| School and Location (Alphabetical by States) | How many hours of didactic lectures are given in the following classes? | | | | Have you a Department of Radiology? | What title is given to the Head of the Radiological De partment? | Is the radiologi cal teaching separate or is it given in the De partment of Medicine or Surgery? |

| Of what importance is the teaching of radiology considered in your school? | Do you believe that more time should be given to radiology in medical schools? | Do you consider radiology of sufficient importance to be recognized on a parity with otolaryngology, dermatology, and ophthalmology? | Remarks |
|---|--|--|--|
| It is a minor department | Not here for undergraduate students | Yes | In connection with anatomy, Freshmen see fluoroscopic demonstrations, Juniors, in connection with dispensary work. |
| Great | Only in conjunction with medical and surgical teaching | Yes | |
| Important branch of surgery | Not with present crowded curriculum | No | No special course in radiology, it is given in regular work in surgery |
| Considered an important part of the courses in medicine and surgery by hospital staff and faculty | Not at our school | Not sure it would be considered so | In Senior year, 1 hour a week given to chest and 1 hour to gastro-intestinal. Patient examined under internist, then brought to X-ray department and physical signs and radiographic evidence correlated |
| Great importance | Probably | No | In all clinical departments, considerable attention given radiology, from diagnostic and therapeutic standpoints |
| On an equal basis with physical diagnosis | Yes | Yes | |
| Contributory | No | Not quite | In Freshman year, 2 hours are given in conjunction with anatomy, in Sophomore year, 6 hours in laboratory |
| Important | | Yes | |
| Great importance | Probably not | I think so | Thirty hours of conferences included in medicine, surgery, pediatrics, neurology |
| Of great importance but must be limited in hours to proportionate allotment of total curriculum time | | Radiology is not an isolated specialty | Students follow their ward cases through the X-ray department |
| Of great importance | No | Yes | |
| | | | Gives only the first two years of the medical course |
| A minor, but required of all graduates | No | Yes | |
| Of prime importance | | Yes | |
| Radiology ranks after general medicine, surgery, pediatrics, and gynecology, and rates above special branches | Yes | Yes | All radiologic courses are elective, as tendency at this school is away from required courses |
| Of great importance | No | Not for undergraduate teaching | |
| An elective course here, only students averaging 80 for the first three years are allowed to take it | Hope to make it required | I do | |
| Very little time given because we are only a two-year medical school | Yes | No | |

| School and Location (Alphabetical by States) | How many hours of didactic lectures are given in the following classes? | | | | Have you a Department of Radiology? | What title is given to the Head of the Radiological De partment? | Is the teaching : is it given partment or Si |

medical schools, which have already made substantial advancement in radiologic education

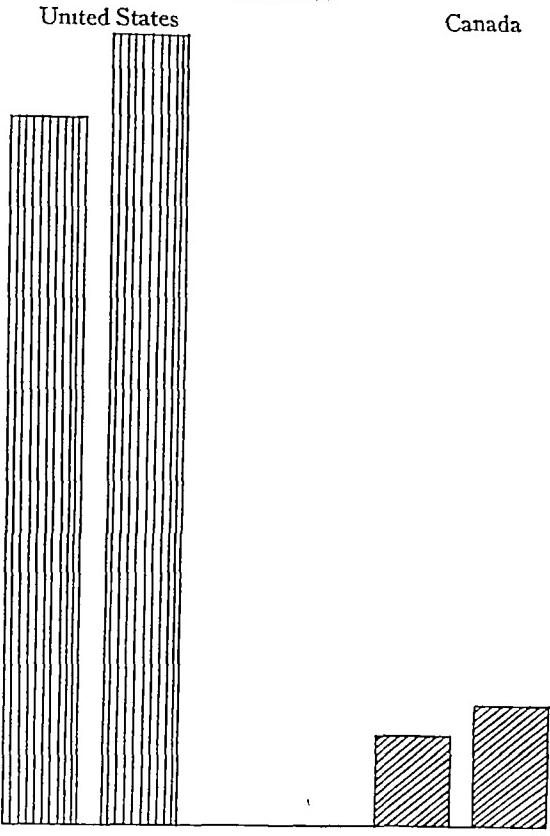

Recent graduates in medicine are well equipped with the medical knowledge and training in technic to practise medicine scientifically. Modern medical schools are usually sufficiently endowed to procure the best medical talent available as teachers, and are adequately equipped with laboratory facilities, all of which contributes to the

education of the modern, scientific, and practical young doctor of to-day. Young doctors appreciate the necessity for years of application and study in order that they may become specialists in any branch of medicine. They are taught how to perform an operation for cataract, and even the enucleation of an eye, yet how many would be brave enough to perform these operations on private patients? They have been taught that such procedures are for the ophthalmologist, who is a specialist with years of

| Yes | 2 | 33.3 |
| No | 4 | 66.6 |

experience in eye diseases. A substantial course in radiology in our medical schools would have a like influence on students as in the instance just mentioned, and few would venture in the realm of radiology without sufficient knowledge and experience.

Radiologists have often wondered if the medical schools of this country are giving sufficient time to the teaching of radiology, so that their graduates will have acquired at least an intelligent and practical understanding of this subject.

While we have known for some time that certain schools were teaching students radiology, few of us knew the amount of time consumed and the different methods used. Very little information is available in this regard. Personally, I have known for some time that certain of our schools were giving a more substantial course in radiology than most of us thought. My attention was first attracted to this when, as a member of my State Board, I was asking questions pertaining to radiology. The answers received from the recent graduates indicated that, on the whole, they had an intelligent understanding of the application of the roentgen ray and radium, so much so, in fact, that I thought that more radiologic questions

should be asked by the various State Boards of Medical Examiners. But before agitating this question, I decided to ascertain the status of radiologic teaching in various medical schools. For this reason the following seven questions were sent each medical school of this country and Canada:

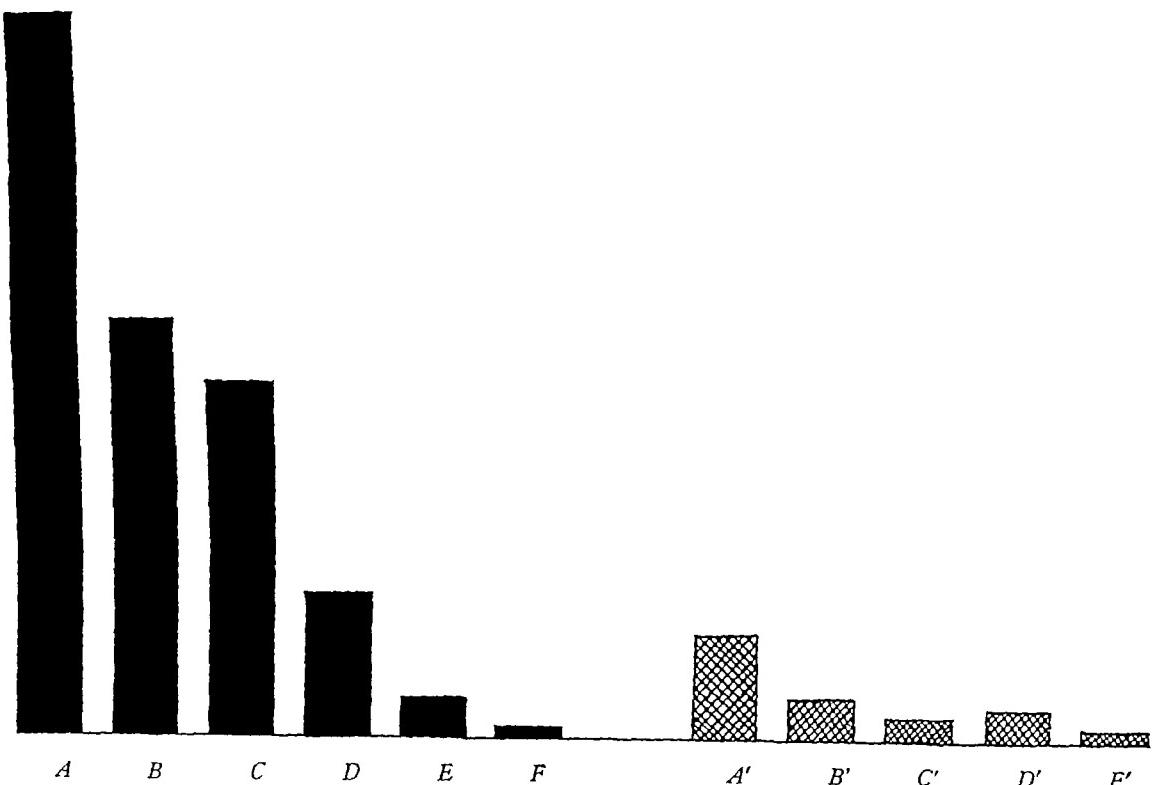

- 1 How many hours of didactic lectures are given in the following classes Freshman, Sophomore, Junior, Senior?
- 2 Have you a Department of Radiology?

- 3 What title is given to the head of the Radiologic Department?
- 4 Is the radiologic teaching separate, or is it given in the Department of Medicine or Surgery?
- 5 Of what importance is the teaching of radiology considered in your school?
- 6 Do you believe that more time should be given to radiology in medical schools?
- 7 Do you consider radiology of sufficient

Canada

A—71 medical schools in U S

B—41 medical schools in U S have a Department of Radiology

C—in 35 medical schools in U S the title of the Head of the Radiological Department is Professor

D—in 14 medical schools in U S the title of the Head of the Radiological Department is Associate Professor

E—in 4 medical schools in U S the title of the Head of the Radiological Department is Assistant Professor

F—in 1 medical school in U S the title of the Head of the Radiological Department is Instructor in Radiology

A'—10 Canadian medical schools

B'—4 Canadian medical schools have a Department of Radiology

C—in 2 Canadian medical schools the title of the Head of the Radiological Department is Professor

D'—in 3 Canadian medical schools the title of the Head of the Radiological Department is Associate Professor

E'—in 1 Canadian medical school the title of the Head of the Radiological Department is Lecturer in Radiology

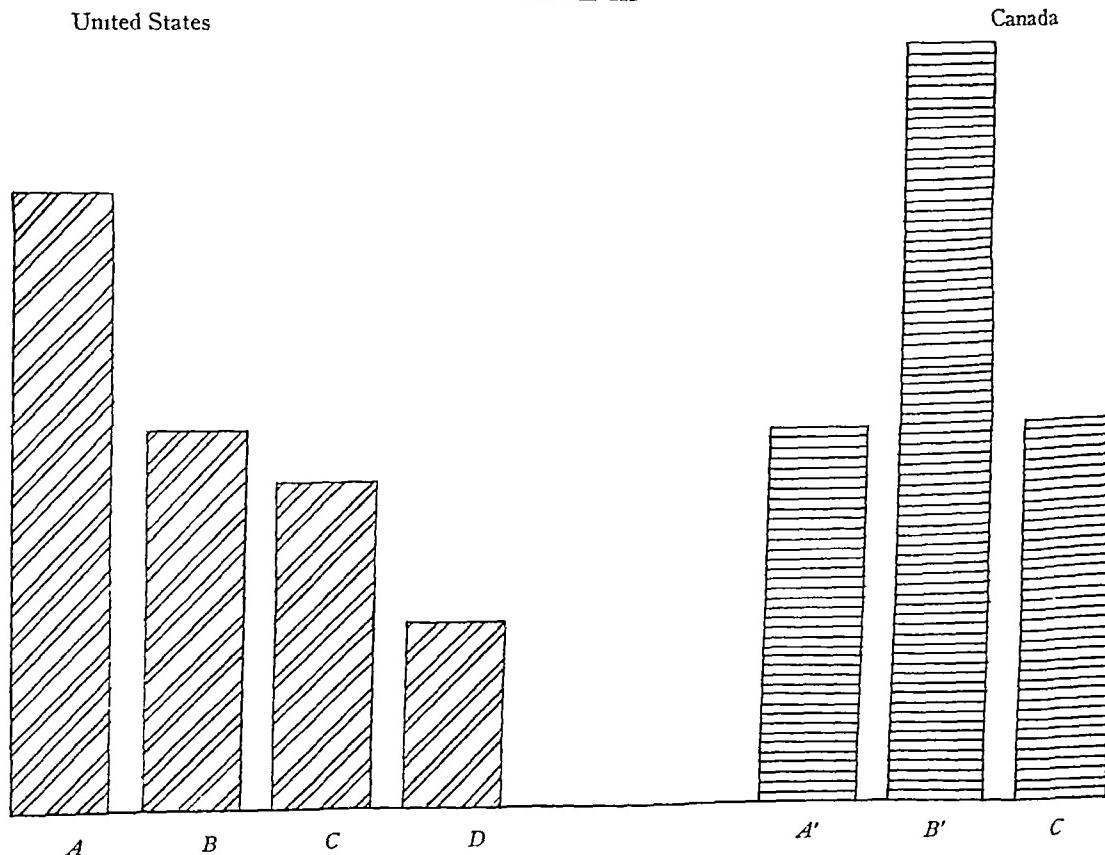

importance to be recognized on a parity with otolaryngology, dermatology, and ophthalmology?

The replies have been tabulated (Tables I-XIII) so that the information may appear in concise form, easy of analysis. Thirteen tables are presented, comprising the essential information derived from the questionnaire.

Table I presents the names of the different medical schools of the United States and Canada and their replies. Table II shows the number of schools which do not give lectures on radiology or clinic demonstrations, etc., the number which did not reply to Question 1, the number in which lectures

are required, the number of hours of radiologic lectures, and the hours per school. Table III presents the number of schools in which clinic and class demonstrations are required, the hours allotted to each, an average of those requiring clinic demonstrations, and the number of hours of elective lectures. Table IV presents the number of schools and hours given to elective clinic demonstrations and to the required courses in lectures and demonstrations, also the number of schools giving elective lectures and clinic demonstrations. Table V lists the number of hours of required and elective lectures, Table VI the number of hours of

GRAPH III

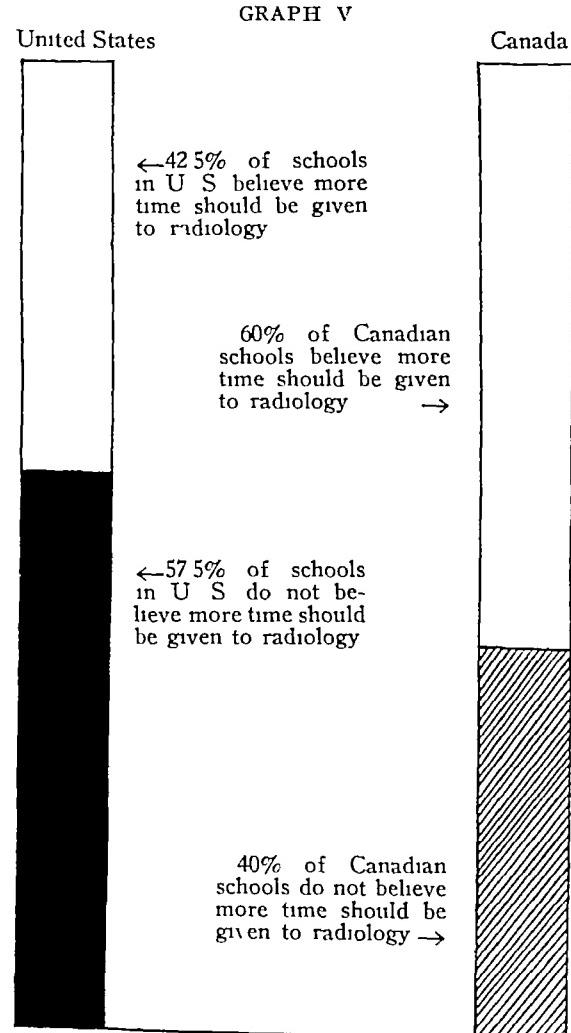

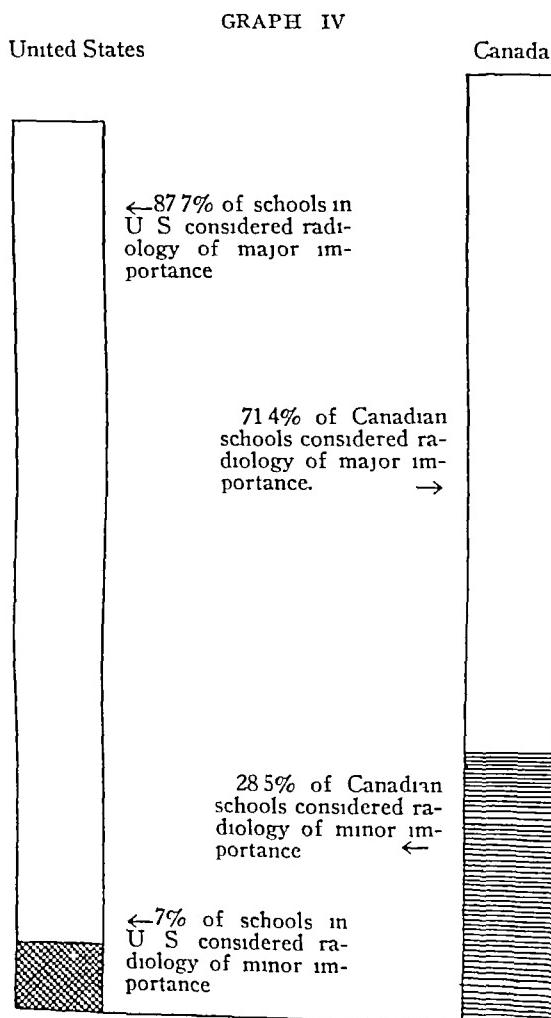

- A—40.6% of schools in U. S. give separate radiological teaching.
B—25% of schools in U. S. teach radiology in the Department of Surgery.
C—21.8% of schools in U. S. teach radiology in the Department of Medicine.
D—12.5% of schools in U. S. teach radiology in the Departments of Medicine and Surgery.
A'—25% of Canadian schools give separate radiological teaching.
B'—50% of Canadian schools teach radiology in the Department of Medicine.
C'—25% of Canadian schools teach radiology in the Departments of Medicine and Surgery.

required and elective class demonstrations Table VII shows the number of hours given in all elective courses, also the number of schools and hours giving required and elective courses Tables VIII-XIII tabulate the replies to Questions 2-7 in percentages Each of the 71 recognized medical schools of the United States and 10 Canadian schools answered the questionnaire They did not, however, answer every question The two-year schools answered only Question 1 Some of the answers to Question 1 are in Table II, the others are in Table VIII (See also Graphs I-VI)

In the Freshman year, six medical schools of this country give 20 hours, or 33 hours per school, to required radiologic lectures,

in the Sophomore year, 10 schools give 95 hours, or 9.5 hours per school, in the Junior year, 40 schools give 877 hours, or 21.9 hours per school, and in the Senior year, 29 schools give 670 hours, or 23.1 hours per school The Canadian schools do not give lectures in radiology in the Freshman year One school gives 30 hours in the Sophomore year, 4 schools give 109 hours, or 27.2 hours per school, in the Junior year, and 4 schools give 89 hours, or 22.2 hours per school, in the Senior year Besides this, two Canadian schools give 25 hours, or 12.5 hours per school, in the fifth year, and one school gives 40 hours in the sixth year The total number of hours given to required radiologic lectures in the medical schools of

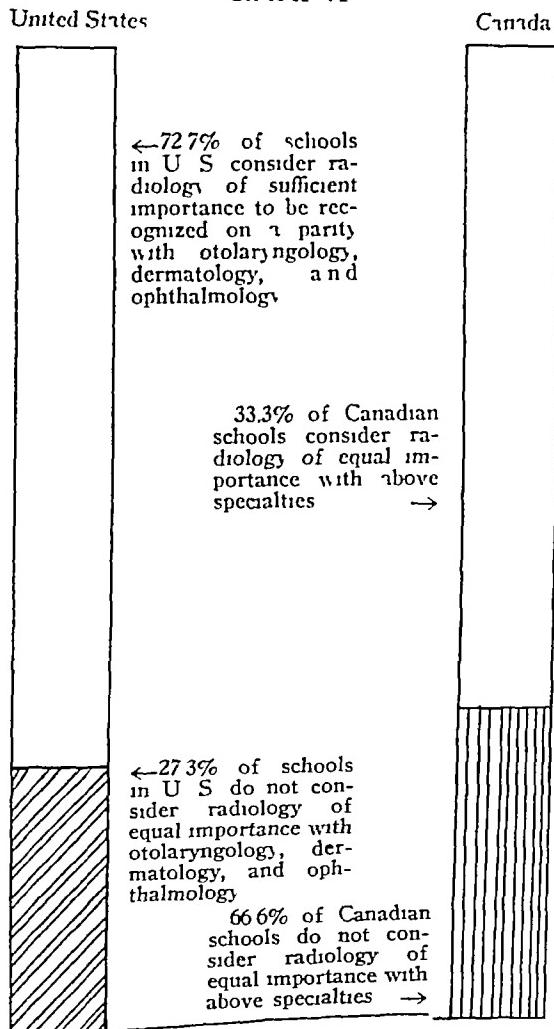

the United States is 1,662, in Canada, 293, which includes the fifth and sixth years. This makes a total for both countries of 1,955 hours (See Graph I.)

Many different answers were received to Question 1. The answers appertaining to didactic lectures have already been tabulated. Those answering that they gave, in addition, required class and clinic demonstrations are found tabulated in Tables III and IV. Table V is a summary of Tables II, III, and IV. In Table V we find that 8 of our schools, or 12.5 per cent, gave required and elective courses in the Freshman year, 11, or 17 per cent, in the Sophomore

year, 43, or 78.1 per cent, in the Junior year, and 44, or 75.8 per cent, in the Senior year. One school in Canada, or 12.5 per cent, gave required and elective courses in the Sophomore year, five schools, or 62.5 per cent, in the Junior year, and four, or 50 per cent, in the Senior year. The courses of required and elective periods in our Freshman year consisted of 22 hours, or 27 hours per school, 95 hours, or 8.6 hours per school, in the Sophomore year, 923 hours, or 21.4 hours per school, in the Junior year, and 971, or 22 hours per school, in the Senior year. In Canada none was given in the Freshman class, 30 hours per school in the Sophomore year, 114 hours, or 22.8 hours per school, in the Junior year, and 89, or 22 hours per school, in the Senior year. The total number of hours given in all elective courses in our medical schools is 227, or 21.8 hours for each school. The total hours devoted to radiologic teaching in schools in the United States is 2,011. In Canadian schools it is 308, a grand total of 2,319.

GRAPH VI

Question 2 (Table VIII) was answered by 66 of our schools. Of these, 41, or 62.1 per cent, stated they have a Department of Radiology, 25, or 37.9 per cent, do not. Of the Canadian schools, 8 answered the question, 4, or 50 per cent, have a Department of Radiology and 4, or 50 per cent, do not. In the United States and Canada, 60.8 per cent of the schools maintain Departments of Radiology and 39.2 per cent do not (See Graph II.)

Question 3 (Table IX) was answered by 54 of the schools in the United States and 6 in Canada. Of medical schools in the United States, 35, or 63.6 per cent, have Professors of Radiology, 14, or 25.4 per cent, Associate Professors, 4, or 7.3 per cent, have Assistant Professors, and 1, or 1.8 per cent, has Instructors. In Canada, 2 schools, or 33.3 per cent, have Professors, 3, or 50 per cent, have Lecturers, and 1 school, or

16.6 per cent, has an Associate in Radiology (See Graph II)

Question 4 (Table X) was answered by 64 American schools and 8 Canadian schools. Of these, 26, or 40.6 per cent, stated that radiology is being taught as a separate branch in the United States, 14, or 21.8 per cent, that it is being taught in the Department of Medicine, 16, or 25 per cent, in the Department of Surgery, and 8, or 12.5 per cent, in both Medicine and Surgery. In Canada, 2, or 25 per cent, teach radiology separately, 4, or 50 per cent, in the Department of Medicine, and 2, or 25 per cent, in both Surgery and Medicine (See Graph III).

Question 5 (Table XI) was answered by 57 American schools and 7 Canadian schools. In the United States, 50, or 87.7 per cent, consider the teaching of radiology as of major, considerable, or great importance, 4, or 7 per cent, consider the teaching of radiology as a minor department or of minor importance, 2, or 3.5 per cent, consider it as elective, and 1, or 1.7 per cent,

as contributory. In Canada, 5, or 71.4 per cent, of the schools consider it as of major importance, and 2, or 28.5 per cent, consider it as of minor importance (See Graph IV).

Question 6 (Table XII) was answered by 54 schools in the United States and 5 in Canada. In the United States, 23, or 42.5 per cent, believe that more time should be given to radiology in medical schools, and 31, or 57.5 per cent, did not so believe. In Canadian schools, 3, or 60 per cent, believe that more time should be given to it, and 2, or 40 per cent, did not so believe (See Graph V).

Question 7 (Table XIII) was answered by 55 American and 6 Canadian schools. In the United States, 40, or 72.7 per cent, thought that radiology is of sufficient importance to be recognized on a parity with otolaryngology, dermatology, and ophthalmology, and 15, or 27.3 per cent, did not so believe. 2, or 33.3 per cent, of the Canadian schools believe it to be so, and 4, or 66.6 per cent, do not agree (See Graph VI).

World-wide Study of Cosmic Rays Begun
—A world-wide campaign for more knowledge about the little-understood cosmic radiation, whose rays are the most penetrating known, was begun when Dr Arthur H. Compton, of the University of Chicago, noted physicist, left for Panama to start the first investigations.

In Panama Dr Compton will climb Mt. Chico to measure the rays with a new instrument. He will then go to Huancayo in Peru, Mt. Cook in New Zealand, Mt. Kosciusko in

Australia, Mauna Loa in Hawaii, and Mt. McKinley in Alaska. Mrs. Compton and a fourteen-year-old son, Arthur Alan, will accompany him on this trip around the world.

When Dr. Compton returns next summer he will hear reports from three other parties, one of which will work in Patagonia and Chile, the second in South Africa, and the third in India, Ceylon, Straits Settlements, and Java. It is expected that tests at altitudes of 20,000 feet and higher will be made. Negotiations are also under way for observations in the polar regions.—*Science Service*

RADIOLOGIC SERVICE IN THE UNITED STATES¹

REPORT BY THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

The work of preparing a list of acceptable "radiologic laboratories and departments of radiology" was assigned to the Council on Medical Education and Hospitals by the House of Delegates at the Minneapolis session in 1928. The "Essentials" were prepared by the Council in collaboration with a large number of specialists in the field of radiology. Suitable questionnaires were prepared in the same manner and were mailed to all the physicians who were known to be engaged in the practice of radiology and roentgenology. The majority of the physicians so engaged returned their questionnaires and they were considered for the list. To assist the Council in preparing the list, the officials of the two leading radiologic societies co-operated with the Council's special committee by appointing qualified radiologists in all parts of the country to act as advisers. These advisers, numbering 198, examined the credentials of applicants from their respective localities, made inspections, and advised which candidates could qualify, according to the "Essentials." The resulting tentative list, together with a detailed report on the survey, was published in the Radiologic Number of *The Journal*, May 23, 1931.

Since various branches of medicine look to the radiologist for important aid in diagnosis and treatment, the careful certification of physicians qualified in radiology should be made to protect the patient and the profession. A powerful influence in the regulation of those qualified is, of course, membership in special radiologic societies. This membership immediately bars the lay practitioner and, to some extent, the physician who has not had adequate training and experience. Membership lists of the special

societies include the names of many whose main interest lies in other specialties.

The Council has understood from the beginning and has advocated the principle that the practice of radiology is the practice of medicine. It has followed this principle in the interpretation of the essentials, in the preparation of its lists and in every opportunity that the Council has had to express itself on this point to the entire medical profession.

EMPHASIS PLACED ON SPECIALISTS

At first the emphasis was on laboratories and departments of radiology and roentgenology. Both the questionnaire and the "Essentials" laid stress on the laboratories, including equipment, personnel, records and publicity. The tentative list referred to laboratories or departments of radiology and roentgenology. But difficulties were found in the listing of laboratories as such, because laboratories change names, they also change directors and ownership, these changes often resulting in an entire change of methods and sometimes a reversal of ethical principles. It became apparent that the determining factor in radiologic service is the specialist who does the work or supervises it. Emphasis therefore, was shifted from the laboratory to the directing radiologist, the main emphasis now being placed on his qualifications.

The "Essentials" have been recently revised to correspond with this new point of view, and the newly revised "Essentials," as adopted by the Council at its meeting in February, 1932, are printed in connection with this article.

HOW THE LIST IS COMPILED

The routine by which all applicants are admitted to the list is as follows:

¹Reprinted by permission from the *Journal of the American Medical Association* March 19 1932 XCVIII

1 A questionnaire is sent to all specialists in the field who, according to information, seem to have the necessary qualifications

2 On receipt of the returned questionnaire, the record and credentials of the applicant are verified in the biographic file of the American Medical Association

3 Each application is submitted to at least three or more advisers, who give their estimate and opinion of the qualifications of the applicant, based on personal knowledge or inspection, or both

4 Membership in special societies is looked up, and the advice of the officers of those societies and the officers of county medical societies, and of councilors, is obtained

In this way the principle is observed that specialists should be judged by specialists. Those who work and associate with specialists have the best opportunity of knowing them. Due attention is also given to the records in the biographic file of the American Medical Association and to the individual's own report on himself and his work.

The first survey covered mainly those radiologists who were conducting laboratories of their own and included, also, those who were connected with hospitals, but did not include others, such as those who teach and supervise radiologic work in medical schools and those working in research institutions and government departments. More recently, the work has been extended to all of these fields. Questionnaires have recently been sent out and applications received from thirty-two of these specialists who were not included in the first survey. There has not been time to give to all the later applications the consideration that is due them, which will explain the omission of some from the list contained in the accompanying pages.

Additions and revisions will be made from time to time, suggestions for changes will be received and consideration of new applications will go on continuously. Co-

operation by the men in the specialty has been excellent and must continue in order that the work may be of optimum value.

PATHOLOGISTS AND CLINICAL PATHOLOGISTS

The list of clinical pathologists which accompanied the list of radiologists in the Radiologic Number for May 23, 1931, is not included in the present issue but is being revised for a later issue of *The Journal*. This will give the necessary time for a thorough revision of that list, including a classification of pathologists and clinical pathologists so as to form a more accurate and a more useful list. Also, the pathologists and clinical pathologists connected with medical colleges, research institutions and government departments will be included, as is being done in the case of the radiologists.

ESSENTIALS FOR ADMISSION TO LIST OF PHYSICIANS SPECIALIZING IN RADIOLOGY

Physicians Eligible

Consideration for admission to the list is open to all regular licensed physicians engaged in radiologic work in accordance with the essentials, whether connected with a hospital or conducting an independent laboratory.

1 Qualifications

(a) The candidate shall be a graduate of a medical school that is approved by the Council on Medical Education and Hospitals and shall be licensed to practise medicine in the State in which his department is located. He shall also have had special training, such as is approved by the Council, in radiology, roentgenology or radium therapy at an acceptable school—preceptorship, hospital or clinic, department of radiology, roentgenology or radium therapy—for a period of at least three years, or, in lieu of such training, shall have had a minimum of five years' experience in the exclusive practice of radiology, roentgenology or radium therapy. He must be a man of good standing in the medical profession, and particularly among those specializing in radiology. He shall be a member of the Ameri-

basis or have definite hours of attendance at the department, such hours to be ample to insure the element of medical consultation in every examination or treatment

(b) The department shall be under the direction of a physician radiologist, roentgenologist or radium therapist, as the circumstances may require. The director shall be responsible for all examinations and treatments. He shall be responsible for all professional assistants and for the efficient maintenance of the department.

Physicians employed by laboratories which are under lay control and direction will not be eligible for consideration for this listing.

(c) Assistants—The director may have a corps of qualified medical and technical assistants responsible to him, and for whom he is responsible, to carry out accurately the various functions of the department.

2 Definitions

Radiology—The branch of medicine which deals with the diagnostic and therapeutic application of radiant energy, including roentgen rays, radium, ultra-violet rays and other spectral radiation.

Department of Radiology—A private laboratory or department of a hospital, clinic or other institution, organized and equipped for the diagnostic and therapeutic application of radiant energy, including roentgen rays, radium, ultra-violet rays and other spectral radiation.

Radiologist—A qualified physician who also has obtained adequate special training and experience in general radiology.

Roentgenology—The phase of radiology which deals with the diagnostic and therapeutic application of roentgen rays only.

Department of Roentgenology—A private laboratory or department of a hospital, clinic or other institution organized and equipped for the diagnostic and therapeutic application of roentgen rays only. A department organized and equipped solely for the diagnostic or therapeutic application of roentgen rays shall be known as a department of diagnostic or therapeutic roentgenology, respectively.

Roentgenologist—A qualified physician who

has had adequate training and experience in the diagnostic and therapeutic application of roentgen rays.

Diagnostic Roentgenologist—A roentgenologist who limits his practice to the diagnostic phase of roentgenology.

Therapeutic Roentgenologist—A roentgenologist who limits his practice to the therapeutic phase of roentgenology.

Radium Specialist—A physician who has had adequate training and experience in the therapeutic use of radium and who specializes in this work.

3 Scope

A department of radiology should be able to render all of the following services:

(a) Roentgenography, simple or stereoscopic, of any part of the body, with medical interpretation of the roentgenographic observations and under satisfactory conditions for the protection of the patient and of the professional and technical personnel.

(b) Roentgenoscopy of any part of the body, in any position, with or without opaque media, with medical interpretation of the roentgenoscopic observations, and under satisfactory conditions for the protection of the patient and the professional and technical personnel.

(c) Roentgenotherapy of all benign and malignant diseases amenable to such treatment with roentgen rays generated at low, moderate or high voltage (long, medium or short wave length), as the conditions may require, and under satisfactory conditions for the protection of the patient and of the professional and technical personnel.

(d) Radium therapy of all benign and malignant diseases amenable to such treatment with an adequate quantity of radium element or emanation, and under satisfactory conditions for the protection of the patient and of the professional and technical personnel.

Ultra-violet therapy, general or local, with satisfactory air-cooled and water-cooled quartz mercury lamps or carbon arc lamps, with suitable quartz and other applicators for irradiation of cavities, sinuses or the superficial lesions under pressure, and under satisfactorily

conditions for the protection of the patient and of the professional or technical personnel This stipulation is not mandatory, but the Council recommends that every department of radiology be equipped for ultra-violet therapy or that the ultra-violet equipment of hospitals be placed in the department of radiology Ultra-violet treatment by the department of physical therapy shall not be countenanced unless such department is under the control and supervision of a medical director who has specialized in radiology

A department of roentgenology should be able to render the services specified under *a*, *b* and *c*

A department of diagnostic roentgenology should be able to render the services specified under *a* and *b*

A department of therapeutic roentgenology should be able to render the services specified under *c*

A department of radium therapy should be able to render the services specified in *d*

4 Housing

The housing should be adequate for the proper functioning of the department of radiology or roentgenology Damp or ill ventilated quarters are unsuitable for such work

5 Equipment

The equipment should be sufficient to carry out properly the technical procedures and activities of the department of radiology, roentgenology or radium therapy

6 Protection

The arrangement of working rooms and conditions, and the construction of all apparatus shall be such as to provide adequate protection, both from electrical shock and from avoidable exposure to roentgen rays or radium, to patients, attendants, and other persons in or near the department The requirements in this respect are based on the recommendations adopted by the International Congress of Radiology, held at Stockholm, Sweden, in July, 1928, and approved by the American Roentgen Ray Society and the Radiological Society of North America

7 Records

Full records of all examinations and treatments made by the department, suitably indexed, are essential Roentgenograms made in the department should have inerasible identification marks which will preclude error as to patients concerned Roentgenograms may be lent to referring physicians but should be returned to the laboratory for filing and future reference Suitable storage facilities should be provided where roentgenograms and other records will be both safe and readily available for reference They shall be kept as long as there is the possibility of their being needed for the benefit of the patients or their physicians

As roentgenography constitutes only a kind of medical examination, on which the roentgenologist's opinion of the patient's condition is partly or wholly based, and as the opinion of the specialist is the essential factor, the Council holds that the introduction of roentgenograms as evidence in medico-legal cases should be discouraged as immaterial and as tending to adulterate the process of justice There is no more reason for the introduction of roentgenograms than for requiring a pathologist to bring to court his microscope and his sections of tissues

8 Reports

The reports of a department of radiology, roentgenology or radium therapy shall be made through the director on stationery or blanks having the name of the director printed thereon Under no circumstances shall roentgenologic diagnoses, interpretations, opinions statements of prognosis, or therapeutic suggestions be offered by the non-medical personnel

9 Library

The department of radiology, roentgenology, or radium therapy should be provided with, or have convenient access to, a library including current scientific books and journals on all the various subjects required in its work

basis or have definite hours of attendance at the department, such hours to be ample to insure the element of medical consultation in every examination or treatment

(b) The department shall be under the direction of a physician radiologist, roentgenologist or radium therapist, as the circumstances may require. The director shall be responsible for all examinations and treatments. He shall be responsible for all professional assistants and for the efficient maintenance of the department.

Physicians employed by laboratories which are under lay control and direction will not be eligible for consideration for this listing.

(c) *Assistants*—The director may have a corps of qualified medical and technical assistants responsible to him, and for whom he is responsible, to carry out accurately the various functions of the department.

2 Definitions

Radiology—The branch of medicine which deals with the diagnostic and therapeutic application of radiant energy, including roentgen rays, radium, ultra-violet rays and other spectral radiation.

Department of Radiology—A private laboratory or department of a hospital, clinic or other institution, organized and equipped for the diagnostic and therapeutic application of radiant energy, including roentgen rays, radium, ultra-violet rays and other spectral radiation.

Radiologist—A qualified physician who also has obtained adequate special training and experience in general radiology.

Roentgenology—The phase of radiology which deals with the diagnostic and therapeutic application of roentgen rays only.

Department of Roentgenology—A private laboratory or department of a hospital, clinic or other institution organized and equipped for the diagnostic and therapeutic application of roentgen rays only. A department organized and equipped solely for the diagnostic or therapeutic application of roentgen rays shall be known as a department of diagnostic or therapeutic roentgenology, respectively.

Roentgenologist—A qualified physician who

has had adequate training and experience in the diagnostic and therapeutic application of roentgen rays.

Diagnostic Roentgenologist—A roentgenologist who limits his practice to the diagnostic phase of roentgenology.

Therapeutic Roentgenologist—A roentgenologist who limits his practice to the therapeutic phase of roentgenology.

Radium Specialist—A physician who has had adequate training and experience in the therapeutic use of radium and who specializes in this work.

3 Scope

A department of radiology should be able to render all of the following services:

(a) Roentgenography, simple or stereoscopic, of any part of the body, with medical interpretation of the roentgenographic observations and under satisfactory conditions for the protection of the patient and of the professional and technical personnel.

(b) Roentgenoscopy of any part of the body, in any position, with or without opaque media, with medical interpretation of the roentgenoscopic observations, and under satisfactory conditions for the protection of the patient and the professional and technical personnel.

(c) Roentgenotherapy of all benign and malignant diseases amenable to such treatment with roentgen rays generated at low, moderate or high voltage (long, medium or short wave length), as the conditions may require, and under satisfactory conditions for the protection of the patient and of the professional and technical personnel.

(d) Radium therapy of all benign and malignant diseases amenable to such treatment with an adequate quantity of radium element or emanation, and under satisfactory conditions for the protection of the patient and of the professional and technical personnel.

Ultra-violet therapy, general or local, with satisfactory air-cooled and water-cooled quartz mercury lamps or carbon arc lamps, with suitable quartz and other applicators for irradiation of cavities, sinuses or the superficial lesions under pressure, and under satisfactory

10 Ethics, Fees and Publicity

Radiology is a special type of medical practice, and the physician practising radiology is subject to the same rules of special training and conduct that govern his fellow specialists in the practice of medicine and surgery. The Principles of Medical Ethics of the American Medical Association shall apply in all cases. The fees charged for radiologic services shall be under the control of the director of the department. All systems of rebates, discounts, special group rates, etc., shall be considered unethical, except that, in cases in which the patient's economic status is the determining factor, the radiologist, like his fellow physician in medicine or surgery, may waive part or all of the fee.

The publicity of a department of radiology, roentgenology or radium therapy should be in professional good taste and limited to statements of fact as to name, address and telephone number, names and titles of the director and other active responsible personnel, field of work covered, office hours, directions for referring patients, and so forth. It should not contain misleading statements or claims of unusual superiority. It should not advocate medical fads nor lay undue stress on the importance of roentgenologic observations. On the letterheads or any other form of publicity, only the names of those rendering regular services to the department should appear as being connected with the department. Advertising matter should be directed only to physicians, either through bulletins or through recognized technical journals, and never to the non-professional public, as, for example, by announcements in popular journals and periodicals, circulars, pamphlets or telephone lists.

11 Admission to the Approved List

Only when the physician is the director or is affiliated with a department of radiology, roentgenology or radium therapy in which the personnel, space, equipment, management, finances and records are such as will insure honest, efficient and accurate work may he expect to be listed. Physicians desiring to be considered for the approved list should apply to the Council on Medical Education and Hos-

pitals of the American Medical Association, 535 North Dearborn Street, Chicago

PHYSICIANS SPECIALIZING IN RADIOLOGY—1,003

The list contains the names of only those who responded to the questionnaire, who have been found to comply with the "Essentials," and who were recommended by the advisers for their respective States. Those who are still under consideration, and others who may apply, will, when accepted, be added in subsequent issues of *The Journal*.

The type of service rendered is given opposite the name "Radiology," under "Type of Service," always includes short wave therapy, also known as "deep therapy." The asterisk (*) on "roentgenology" indicates that short wave therapy is included.

THE MANAGEMENT OF RADIOLOGIC PRACTICE IN HOSPITALS¹

By D S BEILIN, M.D., Radiologist, Augustana Hospital, Chicago, Illinois

THE management of radiologic practice in hospitals is a very timely subject. This paper is not intended for those who are seasoned in hospital radiologic practice—I am sure there are many of you who are more competent to present this subject than I. However, I have been interested in this subject for some time, and the present paper is the result of observations and investigations, which have been made during the past five years. The ideas and facts presented have been effectively carried out in general hospital radiologic practice, during the same length of time. It is understood that no fast rules and regulations can be made, as many institutions have their individual problems. The size of the hospital, and the character of the practice, whether private or charity, as well as numerous other obvious factors, bear a definite relationship to the management of radiologic practice. In a relative, practical way the following aspects are of importance.

The department of radiology in a hospital is an integral part of the institution; it plays a rôle closely associated with the other departments. Harmony and compatibility in their interrelationships are of considerable importance in maintaining efficiency.

Personnel.—The director of the radiologic department must be a graduate physician, licensed to practise, ethical, in good professional standing, with sufficient clinical experience and, in addition, special training in radiology. If the volume of work is adequate, it is preferable that the director of the department be a full-time man. Small hospitals, not able to afford a full-time radiologist, should be encouraged to share the part-time services of such a person. The

small community with but one hospital will find it quite feasible for members of the hospital staff to pool their interests, and to select one of their number to make a special study of the subject, with a view toward directing the radiologic department. The radiologist should respond willingly to a call to the operating room, or to the bedside for consultation when necessary, for frequently he can be of considerable assistance. At all times the utmost co-operation between the radiologist and the medical staff should be maintained. The radiologist should be present at all clinical conferences, as well as at staff meetings. These views are in accord with those presented by the American College of Surgeons in the Manual of Hospital Standardization, and Hospital Standardization Report, for the year 1930. It is true that the radiologist has a referred practice, and should be considered as a consultant, but may I emphasize that if he expects to be considered as a consultant, he must so manage his department as to fulfill that status?

Radiologist's Compensation.—There is no strict uniformity in hospital practice in the manner of compensation for the services of the radiologist. We are all familiar with the various plans in practice. It is my opinion that the percentage basis of compensation for the services of the radiologist is productive of the best ultimate results to the hospital, its staff, its patients, and to the radiologist himself. The percentage basis gives the deserved reward for the maximum effort. Experience has taught that it is best to base the return on gross, rather than on net, income, chiefly because it obviates complicated bookkeeping and avoids misunderstandings, as well as resulting in happier attitudes. The percentage that the radiologist receives should be directly dependent upon

¹Presented before the Radiological Society of North America at the Seventeenth Annual Meeting, at St Louis, Nov. 30-Dec. 4, 1931.

form concept which may be generally applied

In the rules and regulations it should be definitely stated that the radiologist has entirely a referred practice. Each examination is considered a consultation, and the patient's charge is for the roentgen diagnosis, or a radiologic treatment. All reports and diagnoses are sent to the attending physician who has referred the case to the department. The patient will receive all information from his physician, thus maintaining the highest standard of medical ethics. The following rules and regulations for the radiologic department have been carried out efficiently during the past five years in the hospital of which I have most intimate knowledge.

Requisitions.—Every patient who is to have an X-ray examination is required to have a requisition made out for the examination in question by the attending physician, or by the interne on his service. Occasionally, requests are made orally to the supervisors on the floors, the attending physician being responsible for such orders. Requisitions must be completely filled out as to the following points. The patient's name, address, hospital admission number, clinical diagnosis, and the X-ray examination desired, stated specifically. All requisitions must be brought to the X-ray department before an examination can be made. The patient's hospital record must be brought to the X-ray department with him. The patient's name, address, name of attending physician, hospital case number, room number, X-ray admission number, the specific type of examination requested, and the charge for the examination, are all entered in the record book of the department. The patients are examined and instructed in detail regarding their orders. Requisition slips made out on Sundays, holidays, or outside of the regular hours of the department for examinations, should be placed either in the X-ray department or left with the clerk

in the admission office. The clerk in the admission office either sends the X-ray requisition to the department in the morning, or notifies the resident in the department or one of the technicians on call. The former, who resides in the hospital, may be consulted whenever necessary.

Hours of Service.—In any consultation practice the consultant is on call at any time. However, in radiologic practice in hospitals it is customary that the department be open when service is usually desired. Such hours are customarily from 8 A.M. to 5 P.M., with the exception of Sundays and holidays. It is not essential that the radiologist be available during the entire day, as the routine work is carried on by the assistants in the department. However, the services of many full-time radiologists are available from 9 A.M. to 5 P.M. Examinations desired outside of the regular hours may also be had by appointment.

Emergencies.—The urgency of the patient's symptoms alone constitutes an emergency. Emergencies will be given preference over regular routine work. Emergencies outside of the regular hours will be taken care of either by the resident or by one of the technicians on call. If necessary, communication should be had with the director of the department.

Ownership of Roentgenograms.—The question of the title in roentgenograms, so far as I have been able to ascertain, has not been decided upon by the Appellate or Supreme Court of Illinois. There are innumerable decisions on the use of films but the ownership is a question that, as far as I can find, has not reached the higher courts. It is basically a matter of contract, and comes under the same conditions as cover photographs and negatives. The law in the case of photographs is more or less settled, and there seems to be no question but that, in the absence of contract existing between the photographer and the subject, or the one engaging his services, the prints and nega-

the size of the institution, and the amount of work done, for instance, if a radiologist is in a small institution he should receive a larger percentage of the gross income. It should be borne in mind that, as a rule, the amount of work done is usually directly proportional to the ability of the radiologist in the department.

It is unfortunate that many physicians are insufficiently and inadequately taught on the subject of radiology in medical schools. It would appear that their chief enlightenment as to the real clinical importance and value of radiology commences with their hospital experience, and, therefore, it is usually a departmental program of education, instead of one which should have been given years before in the medical schools. This phase of the question is of the utmost importance, as, not infrequently the secret to success of a radiologic department in a hospital is directly dependent upon the enlightenment of the attending men in the institution. I feel fairly safe in saying that the physicians obtaining value received in clinical information from their radiologist will insist that their patients have the necessary radiologic work.

Resident in Radiology.—In an institution of two hundreds beds or more, it is advantageous, as well as advisable, to have a resident in radiology. The resident should be a qualified physician who has an accredited internship, and, if possible, some clinical experience, and particularly one who is desirous of specializing in radiology. The resident should have specific duties as well as regular services, and should be in charge of the department during the absence of its director. The hospital should provide full maintenance. The duties and services of the resident should embrace all branches of diagnostic work and as much therapeutic as the equipment of the hospital permits, so that on the completion of his service he shall be well qualified to set out in the field, either as an assistant in a large hospital or as a radiologist in a small organization. It

would be well if the small community hospital which cannot afford the services of a seasoned radiologist would engage a resident in radiology on the completion of his services. This would enable the smaller institutions to have a better qualified service, as well as affording the beginner in radiology an opportunity for further experience and knowledge.

X-ray Technicians and Assistants.—It is important and preferable that X-ray technicians be somewhat familiar with clinical medicine as well as with nursing care. This type of work is particularly suitable for graduate nurses. This statement, however, does not imply that only graduate nurses are capable of doing this particular type of work. It is always an advantage to a radiologist to select certain nurses in his institution, and to train them in the technical and routine aspects of radiology. The training of X-ray technicians is a very important subject, as well as a controversial one. It is the experience of many that an intelligent nurse who is properly trained, usually makes, in approximately one year an excellent radiographer, as well as an assistant in the department. The radiologist's secretary should be carefully selected and properly trained, in order to avoid errors which may result in serious circumstances.

Rules and Regulations Governing the Radiologic Department.—It is of paramount importance that rules and regulations governing the radiologic department be specifically stated and typewritten, and sent to the superintendent of the hospital, the superintendent of nurses, the attending physicians, internes, and supervisors of nurses on every floor, and be made available for the guidance of special and general nurses on duty. I know of no other practice which simplifies the management of radiology more effectively than this one. It is time that there should be some sort of consistency in these rules and regulations in hospital departments. A study of this phase of radiology by a special committee may result in a uni-

Old Films—Requests for old films (that is, for films more than four months old) should be made one day in advance if possible. When a large number of films is desired for study, lantern slides, etc., a notice of several days should be given. It is important that the rule for the removal of films from the hospital be adhered to.

Roentgen Reports—Reports of examinations are sent to the attending physician on the same day, if the work is completed and if time permits, otherwise, the report is sent the following day. Reports of examinations requiring several days are sent immediately upon completion of the work. In all house cases a report is sent to the attending physician, one is placed on the patient's chart, and a copy is filed in the X-ray department. The attending physician may also receive a report of a case over the telephone. It is always preferable that reports be sent when the examination is completed.

Examination of Films by the Attending Physicians—Films may be seen preferably in the X-ray viewing room in the afternoon, however, if necessary, they may be seen at any time during the regular hours of the department. If films are desired outside of regular hours, an appointment should be made with one of the personnel of the department. Physicians may consult the radiologist at any time, however, the afternoon is preferable.

Unsatisfactory Films—Films which are technically unsatisfactory will be retaken, and a request to have the patient return will be noted on the report. In such cases a requisition marked "retake" should be sent. The patient will then be called to the X-ray department in the usual manner.

Photographs, Lantern Slides, Prints, etc.—These are made by a competent photographer, requisitions for such work being properly filled out, stating specifically what is desired, etc. Unless otherwise stated the bill for such work will be rendered to the physician requesting it.

Attending Physicians, Internes, Nurses, and Employees, Desiring Radiologic Work—Such are examined without charge. Internes, nurses, and employees are required to have a requisition filled out for the examination in question by one of the attending physicians. Outside physicians desiring personal radiologic work are given a discount of 50 per cent.

Management of Radiologic Examinations—Complete instructions for the management of all roentgenologic procedures are given in the rules and regulations governing the radiologic department. It is a general rule that the orders for all roentgenologic examinations are received from the roentgenologic department. For example, in all examinations of the gastro-intestinal tract the previous orders are automatically suspended, and the regular roentgenologic instructions for said examination are adhered to.

Identification of Roentgenograms in Court—As a general rule of law roentgenograms can be identified only by the person who took and developed them. In some jurisdictions this is not as strictly held to as in others, permitting, at times, the head of the department, who is thoroughly familiar with the routine, to testify. However, in any event, the plates are not admissible as evidence unless properly identified, proper identification meaning the qualifying of the technician as an expert in his or her profession. On this point I am also advised that, once a subpoena is issued from any court of record, having jurisdiction over the technician, to appear in court with the roentgenograms, and he does not appear, he is, of course, subject to contempt proceedings. However, courts as a rule are disposed to be considerate of the technician, knowing that the nature of his profession is such that he cannot always appear when called. If it is very inconvenient or impossible for the technician to testify at the certain time set forth by the court, he may often arrange in ad-

tives belong to the subject. Of course, there is a custom of the photographers to retain negatives on orders for prints, but this custom has never given them title to the negatives, and, even if they have title, it is merely to the physical thing and not for its use for any purpose not permitted by the subject. In the matter of roentgenograms, the same law should logically apply. The fact that the roentgenograms are pictures of parts of the body seems to bring them within the category of photographs. The mere fact that they are taken in hospitals to determine a diagnosis should not change the relationship between the patient and the radiologist. It is, however, feasible and practical for the hospital to so arrange its routine with the patient as to have undisputed claim to the physical plates, or even to their promiscuous use. This can be done by a simple agreement on the face of the requisition for the X-ray work desired, signed by the patient at the time the roentgenograms are taken. In substance it can be stated as follows:

"All services rendered and billed for by the radiologic department shall be for roentgenologic diagnosis or for radiologic treatments, it being understood that the hospital retains title and ownership for all purposes to the physical plates developed."

This, however, is not very practical, although in certain instances it is preferable. It may be more to the point to have printed on the requisition slip, as well as on the bill and receipt submitted to the patient, the following:

"All services rendered and charges submitted by the radiologic department shall be for the roentgenologic diagnosis, it being understood that the hospital retains title and ownership for all purposes of the physical roentgenograms developed."

The mere posting of a notice to such effect in the radiologic department might also be effective if specifically called to the attention of the patient at the time.

Use of Plates.—The law is fairly well

settled that, regardless of contract or conditions, a patient has a right to subpoena from the institution all records necessary in any litigation that he may have as a result of injury sustained, in instances in which the records are pertinent to the issue in litigation. He can invoke this right by a subpoena *duces tecum*. The courts have held that, even in cases in which the hospital bill is not paid, the patient can avail himself of this right.

Removing Films from the Hospital.—It should be specifically understood that the patients pay for the roentgen diagnosis. The films are the property of the institution, and a part of the permanent record. Films may be removed from the hospital temporarily or permanently with the permission of the attending physician. If the attending physician does not wish to have the films removed, the patient may have prints made from the films at a nominal cost. When films are removed from the hospital, copies of them are placed in a "preserver" which is marked on the outside "property of the hospital" and the original "preserver" is kept on file.

Individuals, other than the attending physician and patient, desiring to remove films from the hospital, or to obtain reports. Attorneys, insurance adjustors, and other physicians, desiring to remove films from the hospital, or desiring to see roentgen reports of cases in question, may do so only with the permission of the attending physician on the case.

Removing Films from the X-ray Department.—Upon application to the secretary in the office in the X-ray department, films may be taken after they have been interpreted. Occasionally, films may be removed before interpretation, such films being returned as promptly as possible. Films needed in the operating room or in other departments may be sent for or delivered, but must be returned immediately after their use.

down in writing I ask for the *problem*. You do not send a boy into the basement to take a look at the basement. You send him down to see if a window is open, if the fire is burning in the furnace, if a prowler is there. You give him some reason for going.

So I adopted the practice of writing down the problem in my report. For instance, "The patient has an afternoon temperature, cough, etc," if it is a question of lung examination, or I note if the patient has hemorrhage, or certain symptoms after meals, and so forth. You would be surprised to see how, since I have adopted the scheme of stating the problem, the staff has really gone to a great deal of pains to write out a statement of the problem in the language they would like to see in typewritten reports. When no problem has been stated, I take pains to say, "The requisition failed to state the problem." It has been very helpful. I do not know why I did not think of it long ago.

I note the question of the practice of roentgenology in hospitals has been brought up. It is an economic problem about which we should do a great deal of thinking. Hospitals are hiring doctors to practise roentgenotherapy. They are hiring the radiologist to carry on not only the radiologic practice of the hospital, but they are opening the doors of the hospitals to anyone from outside practice who wants to come in to have radiologic work done.

That can lead to only one thing. It is absolutely in line with the practice that is gaining headway in a good many parts of the country of hiring a radiologist to do certain work, letting the hospital make and collect the fees. It is only the opening of the door to the time when they will hire a surgeon on salary to do the emergency work and let the hospital make the fees and collect for that emergency work. Then they will have somebody hired to do the emergency medical work. It is only a question of time until there will be a practising of medicine by the hospitals.

As to identification of films in a legal case in which the technician has left employment and cannot be located in one such case, by identifying the teeth which happened to show in the film, we were able to prove that it was the film of that particular patient.

I would like to state that, in going upon the stand to testify, I do not qualify myself as a radiologic expert. I qualify myself as a physician who is expert in radiology. One of my colleagues almost got into trouble for contempt of court, because, when he was first put on the stand, he neglected to state in his qualifications that he was a physician and that he practised medicine. They had him up there as a "picture taker." It serves some of us right to be put up as such, when we continue to talk about "pictures."

DR. S. A. CLARK (South Bend, Ind.) I just want to correct one statement that the essayist made in regard to the question of the courts having passed upon the ownership of the films.

In last week's (Nov. 21, 1931) issue of the *Journal of the American Medical Association* appeared this article "The question of whether the roentgenograms of the hospital patient belonged to the patient or to the hospital was answered by a court for the first time, so far as is known, in Hurley Hospital vs. Gage, decided on appeal April 21 by the Circuit Court of the County of Genesee, Michigan. In giving judgment the court pointed out that the hospital sold and the patient paid for, not the material that went into roentgenograms, but knowledge and experience. The protection of the hospital might depend largely upon the proper preservation of the roentgenograms, and, said the court, 'the films should remain with the hospital.' Judgment was given against the patient for the balance due on his bill."

DR. S. C. BARROW (Shreveport, Louisiana) I want to speak strictly from one angle, and what I say will be really more a discussion of Dr. Case's discussion than of the paper.

In all branches of medicine I think we realize that we need have no fear for future scientific development so long as the medical profession is permitted to manage its business as it, and it only, knows how it should be managed. That is applicable to the various specialties in medicine.

Personally, I have never seen the right, or the justness, or the appropriateness of the

vance, a suitable time for the taking of testimony

Expert Testimony—The average physician finds himself at a great disadvantage when he is called upon to appear in court as an expert witness. There are excellent articles on the medical expert witness so I shall touch on only a few important aspects. Frequently, in cross-examinations, attorneys seek to embarrass physicians by putting questions framed in such a way that the answers, if given as requested, would be only partial statements of the facts, disconcerting to both the doctor and the side for which he is testifying. The best way to meet this situation is to appeal frankly to the court upon the theory that the question as stated, or framed, cannot be answered fairly. If the court rules in favor of the cross-examining attorney, the doctor is compelled to answer. However, as a rule the court allows a good deal of latitude to save a physician in such a situation.

This does not apply in cases in which the cross-examining attorney is asking a question for the purpose of impeachment. The mere fact that a physician does not want to answer a question is no excuse. As sometimes happens, he has given testimony on direct examination, and under cross-examination reverses himself. The thing to keep in mind is that every cross-examining attorney seeks to do one thing with the physician who is not testifying for his side—to discredit his testimony as an expert. Often when roentgenograms are put in evidence the meaning of a certain mark, line, or density upon the roentgenogram comes into issue and it is not unusual for one group of physicians to interpret the line, mark, or density as significant, while the other side attaches no meaning to them whatsoever, or construes them as normal findings. This is solely a matter of opinion. The jury usually leans towards the decision of the doctors making the best impression. This impression is gathered both from the demeanor of

the physician on the stand and his experience in his given field, as brought out by the evidence. Sadly enough, the weight of such testimony has very little to do with the actual facts.

In conclusion, may I state that I appreciate the diversity of viewpoints on the subject of the management of radiologic practice in hospitals, and have presented those aspects which have been proved by practice during the past five years.

DISCUSSION

DR JAMES T CASE (Chicago, Ill.) It seems to me that Dr Beilin has admirably stated a manual of practice for the hospital in which he is engaged. Unfortunately the circumstances attending his practice are not duplicated in all hospitals. Evidently as the out-growth of a good deal of thinking and collaboration with the physicians of the staff, he has been able to bring about a rather satisfactory manual of practice such as that which he has presented.

First of all, we must satisfy the attending staff. They have a right to be satisfied, and if what they want is not reasonable, we cannot simply deny it; instead, we must endeavor to persuade them that there is a better way. According to the years of our personal experience and our relation to the staff, we will have more or less success in getting them to see things as we want them to be seen.

As for requisitions for roentgen work, I think the problems should always be stated. I have recently hit upon a very effective, and yet simple, means of getting the staff members to state the problem they wish studied roentgenologically. I became tired of having men send in patients for "gastro-intestinal examination" or "colon," or "sinuses," or some other vague request. Therefore, I kept asking the superintendent to send out instructions that the attending men should give us the problem for the solution of which they send patients to the radiologic department. I long ago ceased to ask for a tentative diagnosis because the average man is afraid to put it

financial arrangements with the hospital concerning the necessary free work

The hours of service were well enough put, but in the matter of emergencies it seems to me that it is not a sufficient service merely to provide a technician. That is a duty for the radiologist himself to perform, I believe.

DR BEILIN (closing) Irrespective of opinion, the subject is very important. One hears numerous complaints from physicians who are practising in general hospitals.

The first point that I wish to emphasize again is that the radiologist should impress on the attendants in the institutions in which he is practising, by his conduct and by the management of his practice, that he is not a roentgen photographer, but a consultant. Therefore, the roentgenologist should consult whenever possible with every attending physician who comes to see him in his department. He should, as Dr Case has stated, desire to find out what the problem is. He is not interested merely in the examination of the chest or of the gastro-intestinal tract. He is interested to see if he can be of help in eliciting a diagnosis, because diagnosis is the primary idea of the physician who is referring the case.

In regard to the question of requisitions, I feel the idea expressed by Dr Case is an excellent one, but in institutions in which one has a fair amount of work, it is important that one shall have a standard form of requisition. Our reason for demanding specific statements in filling out requisitions is to avoid errors in examinations.

We take a history of every patient who comes into our department, because we want to know something about the clinical condition of that patient. We do not care particularly what he is going to be examined for. We want to try to make a diagnosis of what he is complaining of.

We take the history for two purposes first, to be familiar with the clinical complaint, and, secondly, to see if the examination which is requested will elicit the complaints of the patient. If the doctor has ordered a gastro-intestinal examination, and if we find the gastro-intestinal tract is normal, we may then

advise an examination of the genito-urinary tract, if the clinical symptomatology indicates

DR NEWELL Who takes the history of the patient?

DR BEILIN The resident in the department, or one of the nurses. My technicians, who are all nurses, have been in my department for many years, and some of them are able to take a history as well as some physicians.

The assistants in the department study a set of questions pertaining to various clinical conditions which come to the roentgenologic department. At the beginning, the nurse refers to the typewritten questions relating to a certain examination. After a while she becomes familiar with all the cardinal symptoms pertaining to a certain disease so that a trained nurse in one's department is able to take a fairly competent history.

I agree that the size of an institution will present an individual problem. One must also take into consideration the fact that a roentgenologic department may have been inadequately managed before one has taken charge of it. The new director's first problem may be to straighten out the situation. It should be emphasized that the roentgenologic department is the roentgenologist's problem. It should be borne in mind that superintendents of hospitals have their own problems, and, as a rule, they are going to try to manage the entire institution as they see fit. In handling the professional and business administration of my department, I make it my business to know what the superintendent of the institution and board of trustees have in mind and what they expect.

In regard to the statement made by Dr Clark, I am familiar with what happened in the State of Michigan. I have that little extract before me, but I was speaking about jurisprudence in the State of Illinois.

I also agree with what Dr Newell has said about emergency examinations in particular. But I cannot agree with the point that, when an individual is sent in by an attending physician say at 10 or 11 o'clock at night, with a fracture, the director of the department should

American College of Surgeons' standardizing the X-ray department of a hospital, any more than I have seen the appropriateness of the American College of Physicians' doing it I was glad to see that the American Medical Association, which is really the one to control this standardization, has taken at least a step in that direction

Personally I am here to suggest that organized radiology take over the standardization of radiologic practice in hospitals I believe that the time has come and really passed, when we should do it for organized radiology of America At least it would be more appropriate that radiology do so than any other organization which has undertaken it

It is a notorious fact (and I am speaking now from direct knowledge) that over the whole country there are hospitals in which the X-ray department is being operated by a radiologist who is operating directly in competition with himself

That is a situation which cannot be overcome unless someone else than ourselves overcomes it There are numbers of men who cannot disconnect themselves from the hospitals for financial reasons Because of that, they have to submit to a financial situation which is embarrassing to say nothing of unethical I mean that certain hospitals in this country are using the X-ray department, reducing fees, or giving a schedule of fees which the same operator of that department cannot put into effect in his office The hospitals are using the X-ray departments because it is appealing to any industrial organization to be told, "We will give you your X-ray services for 50 per cent of what is usually charged" They know they are going to make up the low cost in another department

I do not charge those hospitals with directly violating their consciences as they see the situation You and I operate that department when the hospital has a contract with corporations to do their work for a fee that we cannot charge in a private laboratory, because we have no other means of charging that patient and the hospital has

Therefore, I feel very strongly that organized radiology should take this up, and, if it

does not, the situation is going to continue to grow worse I do not think, as Dr Case said, that there will ever be any chance of a hospital employing a surgeon and in that way removing the surgeons from private practice The surgeons are not going to stand for that We need not look to it.

As concerns the contacting of the local representative of the American College of Surgeons, who standardizes or reports on conditions, we cannot do that That is a too round-about way, and each man is attending to the business to which the organization should attend It is a deplorable situation and an unethical one It is a situation that we should get from under as quickly as possible I hope that organized radiology will come forward and assert itself and take action in the business that is its own

DR R R NEWELL (San Francisco, Calif.)
The ideal is for us to be consultants, and, if we are going to be consultants, we must act as consultants One of the best ways to train our physician friends to treat us as consultants is to be available, and also to use the telephone

It seems to me that our official relation to the hospital ought to be, as nearly as possible, the same as that of the other physicians and surgeons If the surgeons in the hospital have their own private practices, and if the physicians in the hospital conduct their own private practices, then the radiologists should be conducting their private practices in the hospital I admit that it is financially difficult, because the radiologist feels that he cannot, in a good many cases, afford to install expensive apparatus in the hospital Nevertheless, the most dignified relationship between the radiologist and the rest of the medical profession is that in which the radiologist is exactly on the same financial and professional basis as others in the profession A salary does not afford that, and a percentage arrangement does not afford that in the highest degree possible I know several radiologists who have decided that radiology is well conducted in a hospital They conduct their private practice in the hospital and have

THE RADIOLOGIST AS A CONSULTANT¹

By JOHN F HERRICK, M.D., F.A.C.S., F.A.C.R., OTTUMWA, IOWA

IT should be the aim of the radiologist to be considered a consultant in medicine

Too often he has accepted the rôle of technician, permitting his knowledge of medicine and surgery, as well as his knowledge of the science and art of radiology, to be submerged. His duty should not end with a simple report of structural findings. He should be able to analyze the findings in the light of the history and symptoms, to correlate them, and then give his conferee an opinion of practical value.

The radiologist has to do with two classes of physicians (*a*) those who do not desire an opinion from him, and (*b*) those who are desirous of obtaining any aid possible.

In the first class are those who, because of opportunity and experience, feel that they are quite competent to interpret the findings themselves. To them, the radiologist is little more than a technician. Others seem so jealous of their prerogatives that they undertake to make their own interpretations and diagnoses, notwithstanding their want of knowledge of the science of radiology. This class is hopeless. It is just as well to allow them, with the help of the technician, to make what they can of their work.

The second class, those who are conscious of their limitations, realize that they are not so well qualified to interpret fluoroscopic findings or X-ray films as those who make a special study of radiology. If the radiologist is to be a helpful consultant to this group, he must be able to interpret his findings in the light of physical conditions and physiologic variations, and to discuss them with his conferee as would a consulting physician or surgeon. Not until then may

he hope to take the place in medicine that rightfully belongs to him.

It is not an uncommon experience for the radiologist to be called upon to explain his findings. If he is well informed in medicine and surgery, he will be able to put the matter in such form that the physician may grasp its significance and apply it in the management of the case.

For instance, a patient is sent to the radiologist to seek for the cause of distressing abdominal symptoms. The radiologist finds no evidence of organic disease of the gastrointestinal tract. He sees a normally filling and emptying gall bladder, etc., but he does find a spastic colon which interferes with the normal function of that organ. A careful search having failed to reveal an organic cause, it becomes apparent that the etiology of the condition must be neurologic. Such cases are not uncommon; they are the source of grief to the attending physician. We see a number of such cases that, after going through some of the best known clinics, are sent home with a negative diagnosis to bring added woe to the home doctor. If the radiologist who handled the case were versed in physiology, he would be able to explain the nature of such a case to the referring physician and to suggest the possibility of securing relief by the prolonged and persistent use of belladonna, nux vomica, and cascara. The radiologist might make of the suffering, wretched patient, a happy, useful citizen, and win the gratitude and good-will of the attending physician.

A similar case may be made out for the gall bladder. A sense of gaseous distension, epigastric distress, and numerous other symptoms are the occasion for a radiologic examination of the gall bladder and its function. With such marked symptoms, often

¹Read before the Radiological Society of North America, at the Seventeenth Annual Meeting, at St Louis, Nov 30-Dec 4, 1931.

interpret the findings for the physician at that time. If the attending physician is not familiar with the roentgenologic interpretation of bones, the roentgenograms can well be interpreted the following morning. We do not allow any of our assistants, except a physician who is the resident in the department, to make an inter-

pretation of an examination in the absence of the roentgenologist. Many cases said to be emergencies are not. If one has reasonable rules for handling emergency cases, it will be unnecessary for his assistants to make roentgenographic examinations at all hours during the night.

Growth of Cancer-like Chicken Tumor Checked by Dyes—Scientists who have been studying chicken tumors in the hope of throwing light on the problem of cancer in man have for the first time been able to destroy the activity of one of the chicken tumor-producing agents by means of dyes, it appears from a report of Dr Margaret Reed Lewis and Warren Reed Lewis, of the Carnegie Laboratory of Embryology, Johns Hopkins Medical School, to the *American Journal of Cancer*.

Dyes are now used by some scientists to kill certain disease-causing organisms, such as the streptococci, and recently dyes have been tried in the treatment of cancer, although unsuccessfully. The Baltimore investigators wondered what the effect of dyes would be on chicken tumors. Viruses have been the subject of intense investigation in recent years, but so far it has been almost impossible to destroy the activity of any virus by a dye as can be done for larger, microscopic organisms. It is not known whether the virus is a living organism or a chemical substance.

The Lewises extracted the virus from one of these chicken tumors so they could work with it in a test tube. They combined it with eighty different dyes. After being mixed with

the dye, the virus was injected into the chicken to see if it could still produce a tumor. Two of the eighty dyes destroyed the tumor-producing activity of the virus. However, the investigators pointed out that the activity was destroyed in the test tube by an amount of dye which would be impractical to inject directly into the animal in the hope of destroying the tumor-virus in its body.

They consider eighty dyes a small number to have investigated. They feel from the results of their study that when a larger number of dyes are investigated, it may be possible to find more than two which can prevent the growth of tumors even when used in more dilute concentrations. Experiments on injecting the dye directly into the chickens suffering from this type of tumor are now being planned.

The world of science is already familiar with the studies of cell growth and cancer on which Dr Margaret Reed Lewis has collaborated with her husband, Dr Warren H Lewis, and it is interesting to note that in this latest investigation she had the assistance of another member of her family, her son, Warren Reed Lewis, now a medical student—*Science Service*.

primarily with the object of helping the patient to get well

In doing that, we must be careful not to give the clinician orders, in other words, we must not assume the direction of the case I mean, when we make an examination of the patient, it is our duty to describe our findings or give a record of our observations—what we observe in the roentgen examination, fluoroscopically and from the film findings—and then, distinctly separated from it, our interpretation in the light of the clinical knowledge which we have concerning that patient

I have frequently said that a condition may be due to this, or that, or that there are two, three, or four possibilities in the case which must be further interpreted in the light of clinical evidence at hand If I had some of that clinical evidence, I would say that such and such evidence would point to Number 1 as the most likely cause of the condition I even go further If I have in mind anything that will be helpful in getting the patient well, I believe it is my duty as a radiologist to make any suggestion The man in charge can throw away all my advice if he chooses

Gamma Rays and X-rays Have Different Effects—More exact knowledge of the differing biological effects of radiations used in treating tumors and other diseased conditions was urged upon medical experimenters and practitioners by Dr G Failla and Dr P S Henshaw, of Memorial Hospital, New York City, in speaking before the American Association for the Advancement of Science They described a series of experiments in which they tested the effects on various living things of equal-energy doses of X-rays and gamma rays from radium The effects tested included the extent of slowing-down of wheat seedlings, percentage of killing in insect eggs, and degree of skin erythema

In one series of "shots" it was found that parallel doses of X-rays and of gamma rays slowing down the growth of the shoot of

wheat seedlings to the same extent had different slowing effects on other parts of the plant and on other objects The gamma rays were 29 per cent more effective than the X-rays in slowing down root growth and 36 per cent more deadly to insect eggs, but they were 57 per cent less effective in causing artificial sunburn

This latter point is of some importance in practical medicine, for the effectiveness of a given dose of radiation on a tumor or other tissue under treatment is usually judged by the redness of the overlying skin But in the experiment the more destructive rays had the lower skin-reddening power, showing that unless the quality of radiation is taken into account the skin-reddening effect cannot be very closely relied on as an index to its other effects—*Science Service*

the gall bladder will fill and empty normally, again it may fill but fail to concentrate, or it may not be so much a failure in concentration as it is a failure of the liver to secrete the dye in the allotted time.

Such cases are often reported as diseased gall bladder when the disease is in the liver itself. Cholecystectomy fails to give relief, much to the embarrassment of the attending physician and surgeon. If the radiologist had in mind a correct history, if he had observed the coated tongue, foul breath, and muddy sclera, and had determined the extended time it took the liver to secrete the dye, all indications of a diseased liver, such a suggestion to the attending physician might prompt him to a course of treatment which would greatly benefit the patient, and, if surgery was necessary, lessen the mortality.

The radiologist may be asked to find in the chest the cause of a persistent cough. There may be no other symptoms, and physical examination of the chest may fail to locate the cause. Perhaps X-rays may also fail to show evidence of disease of the lungs, yet the cough persists. It often happens that a careful follow-up examination will reveal chronic cholecystitis or hepatitis. In such cases, slight pressure over the gall bladder or heavy percussion over the right costal cartilages will provoke the cough. Branches of the vagus nerve, which supplies the gall bladder, also serve the bronchi. Irritation at one point may cause reflex action at another, so, in this lesion, one may find cough, asthma, etc., as a result of disease of the gall bladder. Another not uncommon result of gall-bladder disease is cardiac disturbance through the vagus connections. Relief of hepatic or cholecytic disease will, in many cases, do more to relieve irregular or rapid cardiac action than any treatment directed to the heart alone.

It may be said that some of the conditions mentioned have no connection with roentgenology. They have not, from the tech-

nician's point of view. But the medical roentgenologist, as stated above, must be a true and helpful consultant if he wishes to occupy the position in the profession which he should. In order to do this, he needs a full and comprehensive knowledge of general medicine and surgery, especially of anatomy and physiology. Equipped with this knowledge, without intruding himself on his conferees, he may become so valuable an aid that his services will be much more in demand, to the advantage of the patient and to the satisfaction of the physician in charge.

DISCUSSION

DR G E PFAHLER (Philadelphia, Pa.) I think the sooner we, as radiologists, place ourselves in the position of consultants, the better off we will be, the better off the patient will be, and we will be making real progress in medicine.

I have always considered myself a consultant. Occasionally I have met men who thought I had exceeded my limitations. But, unless we consider ourselves physicians first of all, and make our radiologic practice secondary or a part of that position as a physician, we degenerate very rapidly to the position of technicians.

In every one of our cases, it is our duty to add anything to the case, or any information to the referring physician, that will help to get that patient well. After all, the patient is sick, the patient wants help. If we have an idea that may be helpful to that patient, it is our duty to express it to the referring physician, but not to the patient, just as any consultant would do. Sometimes those suggestions will be of value in proportion to our knowledge of general medicine. Therefore, it is our duty, as radiologists, to learn just as much about general medicine as we can, to learn the general practitioner's problems. Because if the radiologist interprets those problems only in the light of our technical knowledge the general practitioner does not get the effect. We must interpret in the light of the practising physician and his problems, and

waves of very short wave length which are set up when the velocities of electrons are altered suddenly

According to the quantum theory of the nature of radiation, roentgen rays are particles of energy (quanta) travelling linearly at the velocity of light

Note "Roentgen rays" is preferred by medical authorities, but "X-rays" is in more general use by physicists. The wave lengths concerned are usually between 0.006 and 1.0 millimicron.

Secondary Roentgen Rays 75 10 010

Secondary roentgen rays are the roentgen rays emitted in all directions by any matter irradiated with roentgen rays

Scattered Roentgen Rays 75 10 015

Scattered roentgen rays are roentgen rays which, during their passage through a substance, have been deviated in direction and also may have been modified by an increase in wave length

Characteristic Roentgen Rays

Characteristic Spectra 75 10 020

Characteristic roentgen rays are roentgen rays having wave lengths determined by the atomic constitution of the object which emits, transmits, or scatters them

Fluorescent Roentgen Rays 75 10 025

Fluorescent roentgen rays are secondary rays whose wave lengths are characteristic of the substance which emits them

Cathode Rays 75 10 030

Cathode rays are streams of electrons emitted from the cathode of an evacuated tube normal to its surface, under the influence of an applied voltage

Note By suitable means they can be brought outside of the tube

Lenard Rays 75 10 035

Lenard rays are cathode rays which have passed outside the discharge tube

Positive Rays 75 10 040

(Canal Rays)
Positive rays are streams of positive ions travelling at high speed from the anode of a partially evacuated tube

GROUP 75—RADIOLOGY

Section 20—Physical and Industrial Applications

Radiometallography 75 20 005

Radiometallography is the radiography of metals

X-ray Crystallography 75 20 010

X-ray crystallography is the study of the arrangement of the atoms in a crystal by the use of roentgen rays

Filtration of Roentgen Rays 75 20 015

Filtration of roentgen rays is the absorption of some of the rays of relatively long wave length by placing in the path of the beam an absorbing medium such as copper or aluminum

X-ray Spectrum 75 20 020

X-ray spectrum is the orderly arrangement according to wave length of a heterogeneous beam of roentgen rays

Minimum Wave Length 75 20 025
(Quantum Limit)

Minimum wave length is the shortest wave length in an X-ray spectrum. It is definitely related to the maximum voltage applied to the X-ray tube in accordance with the Planck-Einstein quantum equation

Absorption Coefficient 75 20 030

Absorption coefficient is the ratio of the linear rate of change of intensity of roentgen rays in a given homogeneous material to the intensity at a given point

Half Value Thickness 75 20 035
(Half Value Layer)

Half value thickness is the thickness of a given substance which, when introduced in the path of a given beam of rays, will reduce its intensity to one-half of the initial value

The following definitions are submitted by Subcommittee No 13, Radiology, and constitute a final report This is a revision of the original report circulated May 14, 1931, and printed in RADIOLOGY, October, 1931 page 800

GROUP 75—RADIOLOGY

Section 05—General Terms

Radiology 75 05 005

Radiology is the branch of science that relates to roentgen rays, radium rays, and other high frequency rays

Radiologist 75 05 010

Radiologist is a medical specialist in employing roentgen rays and/or radioactive substances

Roentgenology 75 05 015

Roentgenology is the branch of science that relates to the application of roentgen rays for diagnostic or therapeutic purposes

Roentgenography 75 05 020

Roentgenography is the art of producing roentgenograms

Radiography 75 05 025

Radiography is the art of producing radiographs

Radiation 75 05 030

Radiation is the radiant energy emitted

by an X-ray tube, by radio-active substances or by other sources

Roentgenogram 75 05 035
(Skiagraph)* (Skigram)*

Roentgenogram is a photographic record of the relative transparency of the various parts of an object to roentgen rays

Radiograph 75 05 040
(Radiogram)*

Radiograph is a record produced on a photographic plate, film or paper by the action of roentgen rays or radium

Note There seems to be no good reason for continuing the use of this word as here defined "Roentgenogram" and "curiegram" fully cover the two senses which are included in this definition

Fluoroscopy 75 05 045
(Roentgenoscopy)

Fluoroscopy is the use in diagnosis, testing, etc, of a fluorescent screen which is activated by roentgen rays

GROUP 75—RADIOLOGY

Section 10—Kinds of Rays

Roentgen Rays 75 10 005
(X-rays) (Rontgen Rays)

Roentgen rays are electromagnetic

*Deprecated

waves of very short wave length which are set up when the velocities of electrons are altered suddenly

According to the quantum theory of the nature of radiation, roentgen rays are particles of energy (quanta) travelling linearly at the velocity of light

Note "Roentgen rays" is preferred by medical authorities, but "X-rays" is in more general use by physicists. The wave lengths concerned are usually between 0.006 and 1.0 millimicron

Secondary Roentgen Rays 75 10 010

Secondary roentgen rays are the roentgen rays emitted in all directions by any matter irradiated with roentgen rays

Scattered Roentgen Rays 75 10 015

Scattered roentgen rays are roentgen rays which, during their passage through a substance, have been deviated in direction and also may have been modified by an increase in wave length

Characteristic Roentgen Rays

Characteristic Spectra 75 10 020

Characteristic roentgen rays are roentgen rays having wave lengths determined by the atomic constitution of the object which emits, transmits, or scatters them

Fluorescent Roentgen Rays 75 10 025

Fluorescent roentgen rays are secondary rays whose wave lengths are characteristic of the substance which emits them

Cathode Rays 75 10 030

Cathode rays are streams of electrons emitted from the cathode of an evacuated tube normal to its surface, under the influence of an applied voltage

Note By suitable means they can be brought outside of the tube

Lenard Rays 75 10 035

Lenard rays are cathode rays which have passed outside the discharge tube

Positive Rays 75 10 040
(Canal Rays)

Positive rays are streams of positive ions travelling at high speed from the anode of a partially evacuated tube

GROUP 75—RADIOLOGY

Section 20—Physical and Industrial Applications

Radiometallography 75 20 005

Radiometallography is the radiography of metals

X-ray Crystallography 75 20 010

X-ray crystallography is the study of the arrangement of the atoms in a crystal by the use of roentgen rays

Filtration of Roentgen Rays 75 20 015

Filtration of roentgen rays is the absorption of some of the rays of relatively long wave length by placing in the path of the beam an absorbing medium such as copper or aluminum

X-ray Spectrum 75 20 020

X-ray spectrum is the orderly arrangement according to wave length of a heterogeneous beam of roentgen rays

Minimum Wave Length 75 20 025

(Quantum Limit)

Minimum wave length is the shortest wave length in an X-ray spectrum. It is definitely related to the maximum voltage applied to the X-ray tube in accordance with the Planck-Einstein quantum equation.

Absorption Coefficient 75 20 030

Absorption coefficient is the ratio of the linear rate of change of intensity of roentgen rays in a given homogeneous material to the intensity at a given point

Half Value Thickness 75 20 035

(Half Value Layer)

Half value thickness is the thickness of a given substance which, when introduced in the path of a given beam of rays, will reduce its intensity to one-half of the initial value

GROUP 75—RADIOLOGY

Section 25—Medical Terms

Radiotherapy 75 25 005

Radiotherapy is the treatment of dis-

ease by the application of roentgen rays or the rays from radio-active substances

Roentgentherapy 75 25 010

Roentgentherapy is the treatment of disease by roentgen rays

Radiumtherapy 75 25 015

Radiumtherapy is the treatment of disease by the use of radium, radon, or its active deposit

Irradiation 75 25 020

(Raying)*

Irradiation is the application of roentgen rays, radium rays, or other radiation to a patient or other object

Section 40—Tubes

Discharge Tube 75 40 005

Discharge tube is a vessel of insulating material (usually glass) which is exhausted to a low gas pressure, and which permits the passage of electricity through the residual gas upon application of sufficient voltage

Note. The tube is usually provided with metal electrodes, but one form permits an electrodeless discharge with induced voltage

Gas Tube 75 40 010

Gas tube is a discharge tube which depends on the presence of residual gas in the tube for the supply of electrons

Vacuum Tube 75 40 015

Vacuum tube is a vessel of insulating material (usually glass) provided with metal electrodes, which has been so highly evacuated that the residual gas does not affect the current between the electrodes

X-ray Tube 75 40 020

X-ray tube is a device for producing roentgen rays, embodying (1) an airtight enclosure exhausted to the proper degree of vacuum, (2) a suitable electrode, forming the cathode, from which electrons are liberated, (3) a second elec-

trode electrically insulated from the first, forming the anode or target upon which the electrons impinge after being set in motion by the action of the applied voltage

Cathode-ray Tube 75 40 025

(Lenard Tube)

A cathode-ray tube is a discharge tube with a thin window at the end opposite the cathode to allow the cathode rays to pass outside

Geissler Tube 75 40 030

A Geissler tube is a special form of discharge tube for showing the luminous effects of discharges through rarefied gases

Note. The density of gas is roughly one-thousandth that of the atmosphere

Crookes Tube 75 40 035

Crookes tube is an early form of discharge tube devised by Sir William Crookes and used by him for the study of cathode rays

Note. The density of gas is roughly one-millionth that of the atmosphere

Hot Cathode Tube 75 40 040

Hot cathode tube is a vacuum tube in which the cathode is electrically heated (usually to incandescence) in order to increase the emission of electrons

Hot Cathode X-ray Tube 75 40 045

Hot cathode X-ray tube is a vacuum X-ray tube in which the electron stream is supplied by a heated cathode

Note. The cathode stream may be regulated by varying the current through the cathode filament

Target 75 40 050

(Anode) (Anti-cathode)*

Target is the electrode on which cathode rays are focused and from which roentgen rays are emitted. It is usually of a heavy metal such as tungsten

Cathode Dark Space 75 40 055

(Crookes Dark Space)

Cathode dark space is the non-luminous region which envelops and follows the

*Deprecated

outline of the cathode in a discharge tube at moderately low pressures

Negative Glow 75 40 060

Negative glow is the luminous glow which envelops the cathode in a discharge tube at moderately low gas pressures

Valve Tube 75 40 065

A valve tube is an electric valve consisting of a vacuum tube having for one electrode a hot filament

GROUP 75—RADIOLOGY

Section 45—Other Apparatus

X-ray Machine 75 45 005

X-ray machine is an assembly of electrical devices necessary to activate an X-ray tube and control its operation

X-ray Apparatus 75 45 010

X-ray apparatus is an X-ray tube and its accompanying accessories, including the X-ray machine

Electrostatic Generator 75 45 015

(Influence Machine) (Static Machine)
(Wimshurst Machine)

Electrostatic generator is a device which depends upon electrostatic action for the production of electric charges

Induction Coil 75 45 020

(Coil) (Spark Coil) (Ruhmkorff Coil)

Induction coil is a transformer with open magnetic circuit which is excited by an interrupted or variable current

Interrupter 75 45 025

[Break (of an induction coil)]

Interrupter is a device for interrupting the primary current mechanically or otherwise

Fluorescent Screen 75 45 030

Fluorescent screen is a sheet of suitable material coated with a substance which fluoresces visibly when roentgen rays, radium rays or electrons impinge upon it

Fluoroscope 75 45 035

(Roentgenoscope)

Fluoroscope is a device consisting of a

fluorescent screen suitably mounted, either separately or in conjunction with an X-ray tube, by means of which X-ray shadows of objects interposed between the tube and the screen are made visible

Intensifying Screen 75 45 040

Intensifying screen is a thin screen, coated with a finely divided substance which fluoresces under the influence of roentgen rays, and intended to be used in close contact with the emulsion of a photographic plate or film for the purpose of increasing the effect on the film

X-ray Spectrometer 75 45 045

X-ray spectrometer is an instrument for producing an X-ray spectrum and measuring the wave lengths of its components

Ionization Chamber 75 45 050

Ionization chamber is an enclosure containing two or more electrodes between which an electric current may be passed when the inclosed gas is ionized. It is commonly used for determining the intensity of roentgen rays and other ionizing rays

Penetrometer 75 45 055

(Qualimeter) (Radiosclerometer)*

Penetrometer is an instrument for indicating the hardness of roentgen rays

Dosage-meter 75 45 060

(Dosimeter) (Intensimeter)

Dosage-meter is an instrument designed to estimate the quantity of radiation, so as to determine the duration of exposure when using roentgen rays for therapy

Roentgenometer 75 45 061

(Roentgen meter) (Ionometer)

Roentgenometer is an instrument for measuring the quantity or intensity of roentgen rays

Oscilloscope 75 45 065

Oscilloscope is an instrument for making visible the presence and/or the nature

and form of oscillations or irregularities of an electric current

Note There are several different types of instrument serving this general purpose which have been designated by this name

GROUP 75—RADIOLOGY

Section 60—Characteristic Terms

Hardness 75 60 005

[Quality (of Roentgen Rays)]

Hardness is the attribute which determines the penetrating ability of roentgen rays. The shorter the wave length, the harder the rays and the greater their penetrating ability.

Hardness (of a gas tube) 75 60 010

Hardness is the degree of rarefaction of the residual gas

Note The higher the vacuum, the higher the voltage required to cause a discharge with a cold cathode, and hence the shorter the wave length of the resulting roentgen rays

Intensity (of Roentgen Rays) 75 60 015

Intensity is the attribute of a beam of roentgen rays which determines the rate of ionization of air at a given point, under the conditions stipulated in the definition of roentgen (See 75 60 025). It is expressed in roentgens per unit of time

Quantity of Roentgen Rays 75 60 020

(Quantity of X-radiation)

Quantity is the product of intensity and time

Note It should be clearly understood that quantity is used here in a sense different from that customary in other fields, such as radiant energy in general. It is not proportional to energy, but, rather, to the product of energy density and a coefficient expressing the ability to cause ionization

Roentgen

75 60 025

Roentgen is the international unit of quantity of roentgen rays adopted by the Second International Congress of Radiology at Stockholm in 1928. It is the quantity of X-radiation which, when the secondary electrons are fully utilized and the wall effect of the chamber is avoided, produces in one cubic centimeter of atmospheric air at 0 deg cent. and 760 mm of mercury pressure, such a degree of conductivity that one electrostatic unit of charge is measured at saturation current

GROUP 75—RADIOLOGY

Section 95—Not Otherwise Classified

Ionization 75 95 005

Ionization is the process by which neutral atoms or molecules become charged, either positively or negatively

Ionization Current 75 95 010

Ionization current is the electric current resulting from the movement of electric charges produced by the action of an applied electric field upon an ionized medium

THE EFFECTS OF ULTRA-VIOLET, X-, AND CATHODE RAYS ON THE SPORES OF *MUCORACEÆ*

By BASILE J LUYET, Sc.D., Rockefeller Institute for Medical Research, NEW YORK CITY

THE experiments about to be described are preliminary observations of the effects of X-rays, of cathode rays and of ultra-violet light upon the development and growth rate of spores of the fungus *Rhizopus migrans* + As such they form part of a study being carried out in this laboratory of the action of these radiations upon a variety of simple organisms

TECHNIC

The experimental arrangements for producing and measuring the radiations have already been described¹. The cathode-ray tube, of Coolidge type, was operated at a potential difference of 155 kilovolts. In these tests no estimation was made of the number of electrons striking the irradiated surface but the dose was roughly that used in earlier studies on bacteria. The soft X-ray beam, from a copper target tube, was filtered through thin nickel foil and consisted mainly of the Cu K α line ($\lambda = 1\ 537\text{ \AA}$). Its air ionization as measured at the surface of irradiation was 130 E.S.U. per second. Ultra-violet light of a single wave length was obtained with a powerful mercury lamp and a large monochromator. The approximate energies in the several beams used, as found from readings of a standardized thermocouple, were for 2,536 Å, 8 ergs/mm²/sec., for 2,652 Å, 9 ergs/mm²/sec., for 2,900 Å, 11 ergs/mm²/sec., for 3,132 Å, 48 ergs/mm²/sec. In all cases care was taken to have the intensity of radiation as uniform as possible over the exposed region. This was determined by the use of fluorescent screens and, more sensitively, by the requirement that the biological effects be the

same on different parts of the irradiated surface.

Before irradiation the original culture was inoculated to test tubes containing Coon's agar medium. After two weeks' growth at 22° C to insure that the only spores present were mature and resting, a suspension of them was prepared in the nutrient solution. The surfaces of Petri dishes poured with Coon's agar medium were inoculated with the suspension thoroughly shaken and stirred to break up the sporangia. Areas on these plates were irradiated as soon as the spore-bearing solution had dried into the agar. After incubation for 24 hours at 22° C, a count was made, under the microscope, of the total number of spores on a given area and of the number of those which showed growth. Similar counts upon unirradiated areas gave the percentage of cells which failed to develop under normal conditions. Applying this correction the survival ratios of Table I were obtained. At the same time estimates were made of the average length of mycelial growth 24 hours after different dosages with radiation. This was accomplished by drawing under known magnification and with a suitable eyepiece the mycelia of sprouted spores. Tracings of the resulting lines with the wheel of a planimeter then determined the total length of mycelium due to a given number of spores. Results of this count, averaged to give the mycelial length of one spore, are recorded in Table II and Figure 2.

DISCUSSION

The survival ratios with all three types of radiation give similar multiple-hits-to-kill curves when plotted on semilogarithmic paper (Fig. 1). Evidence for the progressive

SUMMARY

Spores of the fungus *Rhizopus nigricans* have been irradiated with cathode, X-, and

ultra-violet rays. Survival ratios with each type of radiation give curves which indicate that more than one hit or quantum absorp-

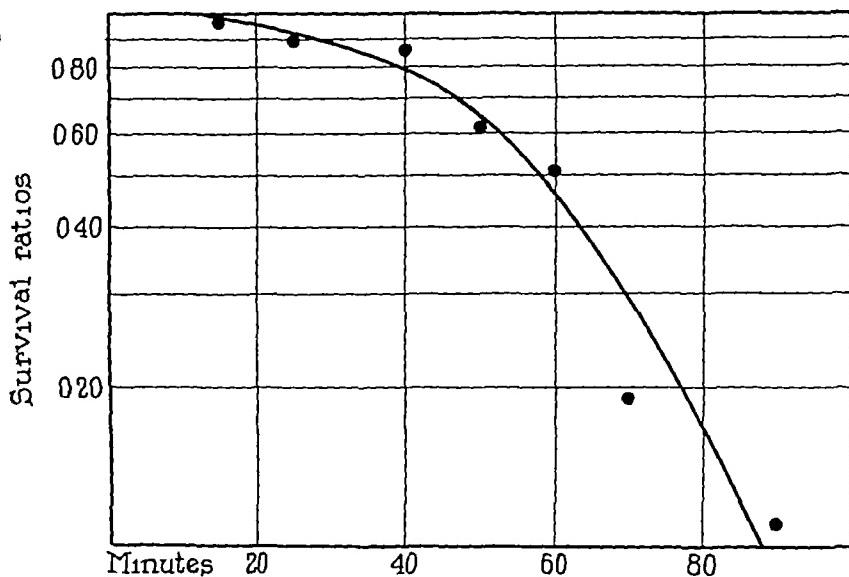

Fig. 1 The survival ratios of the spores of *Rhizopus nigricans* under the action of copper K α X-rays. Similar curves are given by the other radiations

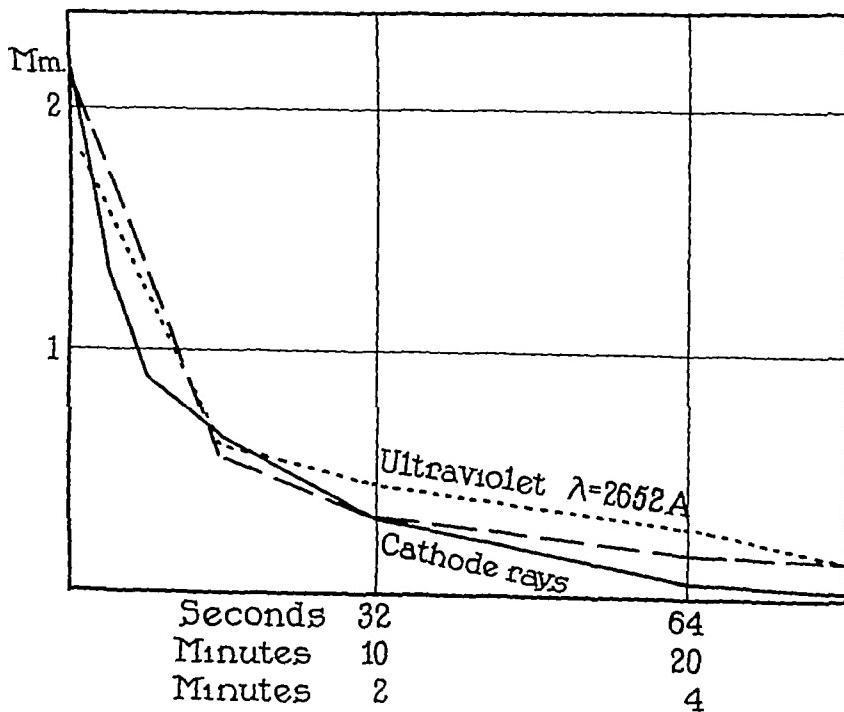

Fig. 2 A plot of the data of Table II, showing the average mycelial length of irradiated spores

stages of injury implied by these curves is to be seen in the arrested growths of Figure 2

Comparison of their killing curves shows that these spores are much more resistant than yeast cells.² At the point of 50 per cent killing, for example, it takes about twice as many cathode rays, about three times the soft X-ray energy and as much as six times the ultra-violet energy to prevent development of the fungus spores as it does to destroy yeast cells.

Many of the spores in preparations which have been subjected to cathode rays for from one-half to two minutes swell to giant size without ever producing mycelia. Sometimes they reach nearly five times their initial diameter, they are translucent and do not take on the brownish color and cytolized appearance of dead cells. Most of them stop growing within a day after irra-

diation Besides the giant spores without mycelia, others are found which, growing short mycelia before their development ceases, represent all transition stages towards normal cells X-rays and even ultra-violet light produce this effect but much less markedly The presence of swollen spores obviously makes it difficult to set up the accurate criterion of death necessary for obtaining significant survival ratios In making the counts of Table I a cell has been taken as dead if it fails to develop as much as a mycelial beak

It should also be remarked that no evidence whatsoever has been found of a stimulative effect from small doses of radiation.³

The writer is indebted to Dr Ralph W G Wyckoff, in whose laboratory the present experiments were carried out, for many suggestions and for help in the preparation of this note.

SUMMARY

Spores of the fungus *Rhizopus migrans* have been irradiated with cathode, X-, and

ultra-violet rays. Survival ratios with each type of radiation give curves which indicate that more than one hit or quantum absorp-

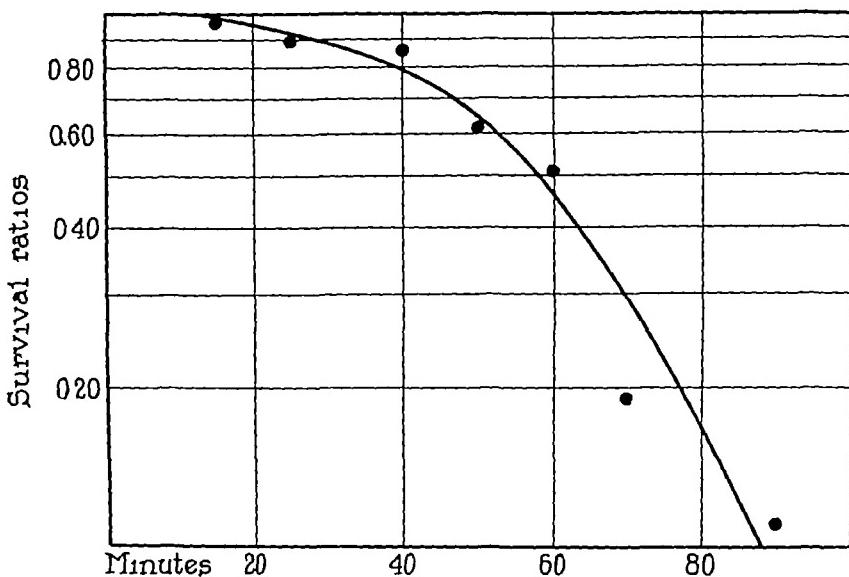

Fig. 1 The survival ratios of the spores of *Rhizopus migrans* under the action of copper K α X-rays. Similar curves are given by the other radiations

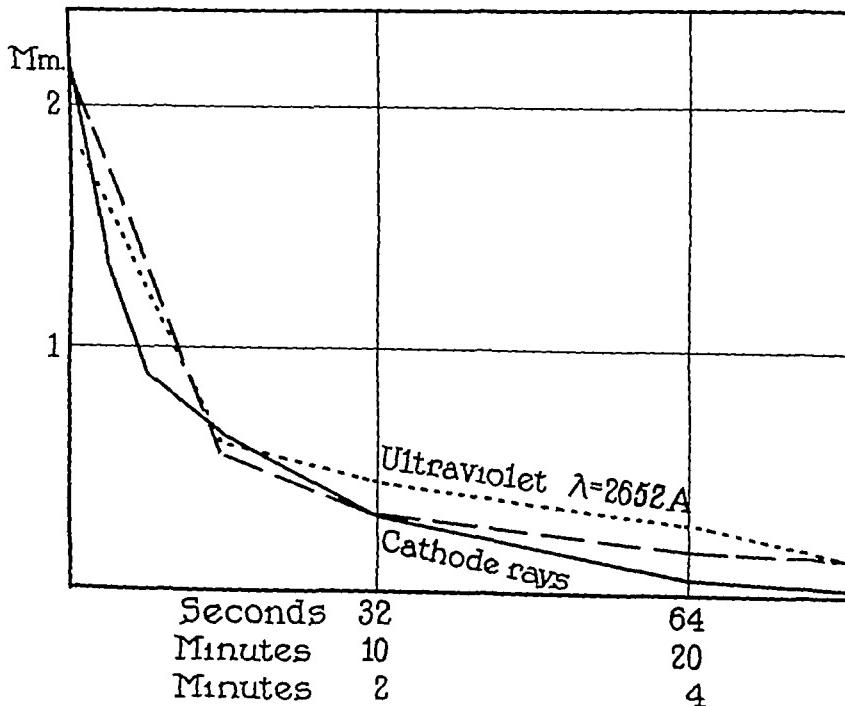

Fig. 2 A plot of the data of Table II, showing the average mycelial length of irradiated spores

tion is necessary to kill. Measurements have also been made of the decrease in growth occasioned by sub-lethal doses of each radiation.

The production of giant cells which ultimately die without undergoing further de-

velopment has been noted. They become most numerous under cathode rays and are least often seen after ultra-violet irradiation. No evidence has been found that small doses of any of these radiations are stimulative.

Electrons Speed within Dense Solids—A method used by astronomers to determine the velocity of stars has been applied in a slightly modified form to the atom to furnish the first direct evidence that electrons, negatively charged electrical portions of atoms, move about at high speeds in solid bodies.

The experiment, conducted at the California Institute of Technology by Dr. Jesse W. M. DuMond, research fellow, and Dr. Harry A. Kirkpatrick, teaching fellow in physics, was the second crucial test of activities of the electrons within the atom. The first test was reported in January, 1931.

In explaining the application of the Doppler effect to the experiment, Dr. DuMond declared that if the source of the light or sound is in motion the successive vibrating waves or ripples are crowded together on the forward side of the motion's direction, and spaced farther apart on the rearward side.

A similar phenomenon explains the fact that the sound from a train whistle approaching a stationary listener is of higher pitch than the sound of the same whistle when the train is receding from the listener. In the same way, stars approaching an observer emit spectral lines shifted toward the violet end of the spectrum, whereas receding stars emit lines shifted toward the red.

When the electron scatters X-radiation a similar effect occurs. If that part of the radiation which is scattered at a definite angle to the incoming beam is observed with a spectroscope, the spectral line which was in the original radiation is found to be shifted toward longer wave lengths and the spectral line is found to be broadened. The shift may be re-

garded analogically as a Doppler effect caused by the velocity of the electron recoiling away from the light under the impact that the light has given it. The increased breadth of the line may be regarded as a composite Doppler effect of the chaotic motion of all the electrons in the myriads of atoms scattering the X-radiation.

Dr. DuMond set the average speed of the invisible electrons which make up solid matter at 1,500 miles per second for the case of carbon. The experiment not only throws more light upon the internal activities of an atom, but proves two predictions made by Dr. DuMond in 1929. These were first, that in the spectrum of X-rays scattered by solids of low atomic number the breadth of the Compton shifted line would be proportional to the sine of one-half the scattering angle, second, that it would be proportional to the primary wave length.

The latest experiment testing the second of the above predictions was conducted with the multi-crystal spectrograph developed at the California Institute of Technology. Measurements were made of characteristic X-rays from molybdenum, silver, and tungsten scattered by carbon at an angle of 156 degrees. Spectrum photographs were made of the radiation from each element. Each exposure lasted 1,000 hours.

Dr. DuMond based his predictions two years ago upon the hypothesis that the breadth of the shifted line in the spectrum of scattered X-rays is caused by the movement of electrons in atoms. The fulfillment of the two predictions is, therefore, confirmatory evidence for the hypothesis on which they were based.—*Science Service*

DIAGNOSTIC PNEUMOTHORAX

AN AID IN THE DIAGNOSIS OF PLEURAL TUMORS

By WILLIAM B FAULKNER, JR., M.D., Department of Surgery, University of California Medical School, SAN FRANCISCO, and EDWARD C FAULKNER, M.D., Department of Thoracic Surgery, St Mary's Hospital, SAN FRANCISCO

EVEN for those who constantly see large numbers of patients with varied diseases of the chest, it is not always easy to differentiate pleural tumors from those within the lung and mediastinum. In addition it may be difficult to say with any degree of certainty which of these patients probably can be helped by surgical measures and which are beyond surgical aid. We have been faced by this problem on more than one occasion. We have seen instances in which physical examinations, plain roentgen studies, iodized oil injections, and bronchoscopic examinations either failed entirely to establish the exact diagnosis or left us uncertain as to which patients could be helped by operation, which type of operation to select, and which method of anesthesia to employ. Hence our enthusiasm in the use of a procedure which furnishes this information. Such a procedure is diagnostic pneumothorax.

In its clinical trial since its introduction by Brauer (1), in 1912, it has stood the test of usefulness (2, 3, 4, 5) and we feel that it should be adopted by a greater number of those interested in the study of intrathoracic disease. This is especially true inasmuch as diagnostic pneumothorax furnishes valuable information, is relatively safe and easy to perform, and does not aggravate the patient's condition.

The technic depends on whether or not there is an associated pleural effusion. In the absence of pleural fluid, the air usually is introduced under local anesthesia by a method similar to that employed in the treatment of pulmonary tuberculosis. A mid-axillary intercostal space is selected as the point of puncture, unless pleural adhesions are present at this point. If the tumor is

situated in the axillary region, a point of puncture on the anterior chest wall should be selected, so as to avoid the danger of perforating the tumor.

Usually from 250 to 500 cc of air will be sufficient to give the desired information, but occasionally slightly larger or smaller amounts may be necessary. We have had occasion to use as much as 1,000 and as little as 100 cc of air. In general, the total amount employed is determined by the intrapleural pressure, the vital capacity, and the subjective reaction of the patient. When the intrapleural pressures are negative (normal), the pneumothorax can be induced with safety, but the pressures must be rechecked after the introduction of every injection of from 25 to 50 cc of air. This permits discontinuance of the pneumothorax before the pressure becomes positive. In

Fig 1 Roentgenogram showing a tumor in the hilus region. From this plate one cannot say whether the tumor is in the mediastinum, lung, or parietal pleura. *T*—tumor; *unlettered arrow*—aorta.

Fig 2 Same patient as in Figure 1 Diagnostic pneumothorax roentgenogram taken at the end of inspiration. *U*-left upper lobe containing iodized oil is displaced downward by the pneumothorax. Arrows indicate the tumor (*T*) which is not attached to the lung.

Fig 3 Same patient as shown in Figure 2 Plate taken at the end of forced expiration. The unlettered arrows indicate the tumor which has moved toward the sound side. Compare with Figure 2. *U*-upper lobe containing cangioid (iodized oil), *E*-edge of displaced upper lobe.

patients in whom the initial manometer readings fail to show the normal fluctuation, or indicate a positive intrapleural pressure, no air at all should be introduced. Similarly, extreme pain, undue anxiety, dizziness, shortness of breath, or unusual subjective reactions should be taken as indications for the discontinuance of the pneumothorax regardless of the amount of air that has been introduced at the time the symptoms appear. These precautions lessen the likelihood of tearing pleural adhesions and producing pulmonary trauma, spontaneous pneumothorax, empyema, and cerebral air embolus. In the debilitated, and in those with a decidedly lowered vital capacity, much smaller amounts of air are to be employed and especial caution is to be observed during the induction of the pneumothorax.

If a pleural effusion is present which interferes with the roentgen visualization of the suspected tumor it would be both faulty and dangerous to remove all the fluid and then attempt the introduction of air into

the pleural cavity. Such a technic leads to sudden alterations in the intrapleural pressure, produces sudden and marked changes in the position of the heart and mediastinal structures, and leaves the patient liable to

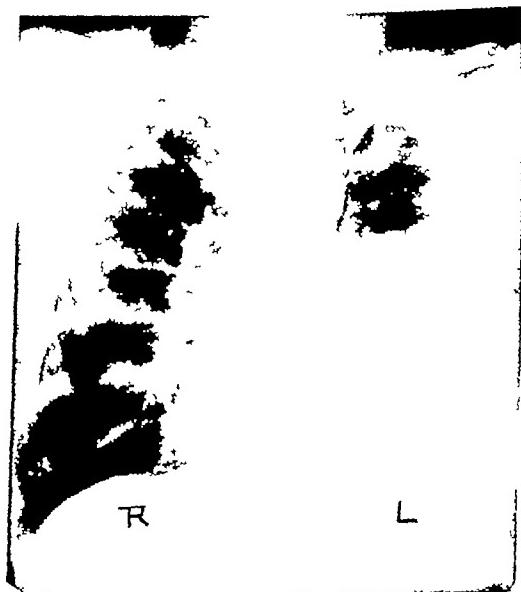

Fig 4 Roentgenogram before diagnostic pneumothorax.

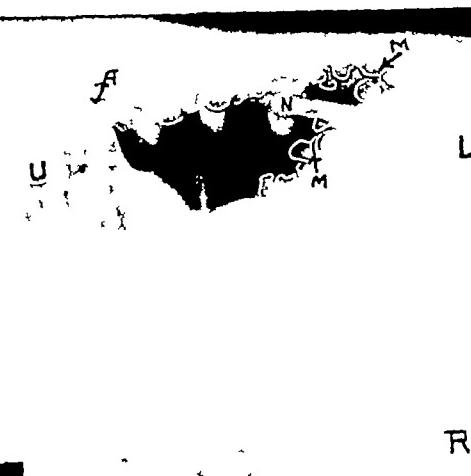

Fig 5 Diagnostic pneumothorax roentgenogram of same patient as in Figure 4 (Plate taken with patient lying on right side) *M*-Nodular masses involving the lower two-thirds of the pleura and the diaphragm, *U*-upper lobe adherent to lateral chest wall at *A*, *N*-Needle and cannula in place so that the air can be removed at the completion of the roentgen studies

severe respiratory and circulatory disturbances A thoracentesis should be performed, but, if severe disturbances are to be avoided, each syringeful of fluid should be replaced at once by an equal amount of air

After the introduction of the air, the patients are examined fluoroscopically and X-ray plates are made with the patient in various positions The aim of these various postures is to allow the air to collect at the areas that we wish to study Most often, the anteroposterior, lateral, horizontal, and Trendelenburg positions suffice, but, in exceptional cases, it is advisable to employ additional postures The initial fluoroscopic examinations not only determine the positions best for the taking of the X-ray plates, but also indicate the presence or absence of pleural adhesions, the amount of mediastinal movement, and the influence of respiration upon the position of the tumor As will be shown, these factors are important in differentiating pleural tumors from those within the lung or mediastinum

In the absence of pleural adhesions and when the patient is in the erect position, the pneumothorax displaces the lung down-

Fig 6 Specimen from the same patient as shown in Figures 4 and 5 *L*-Lung, note the nodular masses of various sizes and shapes on the diaphragm, *D*, and pleura *P*

ward, medially and away from the costal pleura The air serves as a contrast medium so that tumors of the parietal pleura stand out in bold relief Their position is unchanged following pneumothorax, or upon postural changes of the patient, inspiration or expiration On the other hand, pulmonary tumors

Fig 7 Plain roentgenogram of patient with suspected pleural tumor *T*-Trachea displaced to the

are displaced by the air. They change their position with changes in the posture of the patient, move toward the pneumothorax side on inspiration, and return toward the opposite lung on expiration. Mediastinal tumors

thoracentesis revealed a serosanguineous exudate, which was removed and replaced by air. The roentgenogram taken, following the introduction of air, indicated that the condition was more than a simple hemo-

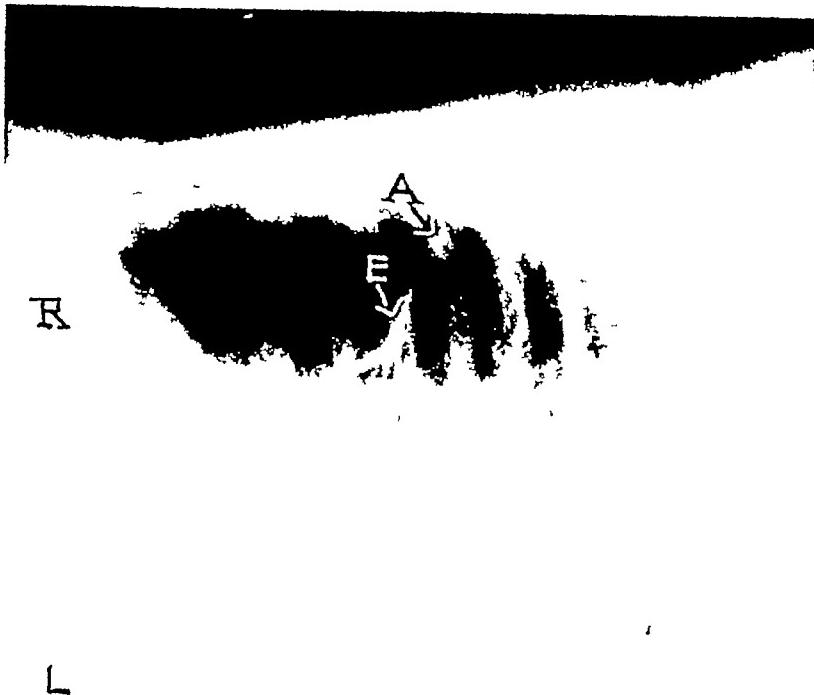

Fig. 8. Diagnostic pneumothorax roentgenogram (same patient as shown in Figure 7), horizontal position. The pleura is smooth and shows no evidence of a growth. E—lung edge, A—adhesions to lateral chest wall.

are much less often displaced downward or upward by the air, their only appreciable movement being the swing toward the pneumothorax side on inspiration and the return on expiration (Figs. 1, 2, and 3).

CASE REPORTS

The practical value of diagnostic pneumothorax was well demonstrated in two of our recent cases.

Case 1 In a male patient, aged 60 years, who complained of chest pain, dyspnea, and weakness of three months' duration, the physical findings and plain X-ray films pointed to an effusion at the left base, the

thorax, for the parietal pleura was involved by large nodular masses (Figs. 4 and 5). From these plates it was evident immediately that this was not a case for surgery and the prognosis was established as decidedly bad. X-ray treatments were employed but the patient died a few months later. A comparison of the pneumothorax roentgenograms with the pathologic specimen indicates clearly the value of pneumothorax in accurately localizing pleural tumors and in determining the cases that are suitable or unsuitable for surgery (Fig. 6).

Case 2 In another elderly patient, a pleural tumor had been suspected following the usual clinical examinations, but the diag-

nostic pneumothorax demonstrated that the pleural surface was smooth and without evidence of a growth. This was confirmed later at necropsy (Figs 7 and 8).

For each of the foregoing patients, an exploratory thoracotomy had been considered seriously, but, following the diagnostic pneumothorax, the correct diagnosis, the extent of the involvement, and the unsuitability for operation were established. Accordingly, both patients were spared unnecessary surgical procedures.

DISCUSSION

As with other diagnostic procedures, pneumothorax has its limitations, largely because of pleural adhesions which may be so generalized that no air at all can be introduced or so situated as to interfere with the displacement of the lung and mediastinum. In such cases, an exact pre-operative differential diagnosis cannot be made by this method. In many other instances, pneumothorax will be of service and will supplement the other accepted methods of investigation. By determining the site and extent of adhesions and the mobility of the mediastinum, pneumothorax guides the way in the selection of proper surgical approach and choice of anesthesia for the individual patient.

In patients who present definite indications for surgery, the air may be left in the pleural cavity so that the patient can adjust himself gradually to the changes which would otherwise occur suddenly during the opening of the thorax. If a two-stage operation is planned, with suture of the lung to the parietal pleura at the initial operation, the air should be withdrawn before the surgical procedure.

Generally speaking, there are two rules to observe. When patients have no associated pleural effusion, as much air may be withdrawn as was introduced. This is not true when there is an extensive pleural effusion.

In these cases, only enough air should be removed to permit the trachea, heart, and mediastinal structures to return to their normal positions. This can be determined rather satisfactorily by palpating the trachea and by percussing the area of cardiac dullness, but the safest and most accurate guide during air withdrawal is the manometric registration of intrapleural pressure. The pressure should not be allowed to become more negative than -6 cc of water on expiration and -12 on inspiration, because, if too much air is removed, the mediastinal structures will be drawn toward the involved side and serious and alarming symptoms may ensue.

CONCLUSIONS

1. The term "diagnostic pneumothorax" is used to designate the introduction of air into the pleural cavity for diagnostic purposes.

2. The procedure is safe, relatively easy to perform, and does not aggravate the patient's condition.

3. Diagnostic pneumothorax is of definite value in the differentiation of parietal pleural tumors from those within the lung and mediastinum.

4. It furnishes essential information in the selection of chest cases for operation, and it indicates the type of anesthesia and surgical approach that will be best fitted to the individual case.

MEDIASTINAL PLEURISY¹

CASE REPORTS AND X-RAY DIAGNOSIS

By HENRY SNURE, M.D., LOS ANGELES, CALIFORNIA

WHILE mediastinal pleurisy is not a frequent lesion it is probably more often overlooked or incorrectly diagnosed than any other pleural condition. Unless an X-ray examination is made, it is not often diagnosed until rupture into a bronchus or other organ of the chest occurs, this latter complication being frequently a serious one. However, mediastinal pleurisy was known and diagnosed in Laënnec's clinic long before the roentgen era. Both the dry and serofibrinous types of mediastinal pleurisy are occasionally overlooked by X-ray methods but these heal practically spontaneously without permanent injury to the patient. The non-tuberculous type of purulent effusion may be fatal unless surgical intervention is begun early and drainage established. It would seem that the pure pneumococcus type of effusion is about the only form that can rupture into a bronchus and the patient survive, this rupture usually taking place within a twenty-day period.

The index of the Surgeon General's Library and the Cumulative Index of the American Medical Association list 53 papers dealing with mediastinal pleurisy, most of which are in the French and German literature. The papers of Devic and Savy, 1910 (1), and of Savy, 1910 (2), are the ones to which reference is most often made. Worthwhile papers in the American journals are those of Frick (3), and of Sagel and Rigler (4). A considerable number of the recent foreign papers deal with conditions simulating mediastinal pleurisy, such as bronchiectasis and childhood tuberculosis. Dolley (5) has recently collected 106 cases

from the literature. Because the actual number of case reports is small, three are included in this paper.

Several classifications have been suggested for mediastinal effusions, the one most commonly used describing the location of the effusion as right or left, anterior or posterior mediastinum. Combinations of the foregoing occur, and at times a further division into upper or lower has been made. Another classification divides mediastinal effusions according to the type of exudate: serofibrinous (tuberculosis), hemorrhagic (tuberculosis, trauma, tumor), and purulent (tuberculosis, tumor, trauma, pneumonia, mediastinitis). The mediastinal effusions are encapsulated mesially by the mediastinal pleura and laterally by the pulmonary visceral pleura. When extension occurs to the sinuses of the pleural cavity, it is designated as the costomediastinal type by Herrnheiser (6). Barjon (7) alludes to a so-called hilus type and describes three cases.

A good description of the clinical syndrome is given by Dieulafoy, quoted by Rose (8). Dieulafoy states "Mediastinal pleurisy starts as an acute febrile attack with pain, fever, cough, and dyspnea. The symptoms caused by pressure on the mediastinum are dyspnea, stridor, sucking in of chest wall, dysphagia, distention of the veins of the chest, fits of coughing and suffocation, hoarseness, dysphonia, and spasm of the glottis. All, or only some, of the symptoms may be present, due to whether the pressure is on the trachea, esophagus, azygos vein, the pneumogastric or recurrent laryngeal nerve." The clinical sign of dullness, usually posterior, appears about the tenth day. Voice changes should suggest a bronchoscopy examination. The pneumo-

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting at Los Angeles Dec 1-5, 1930

coccus type of effusion is ushered in by sudden onset and high temperature, if rupture into a bronchus occurs, the discharged mate-

are more circular in outline and are not apt to extend to the opposite side. Infected cysts have caused effusions. Whereas the

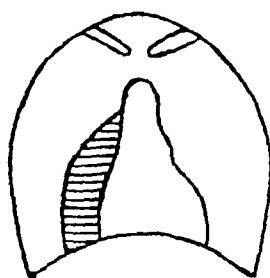

Fig 1 Right anterior mediastinal pleurisy (Devic and Savy)

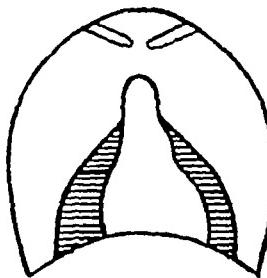

Fig 3 Right and left anterior mediastinal pleurisy (Devic and Savy)

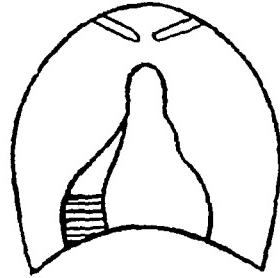

Fig 4 Right anterior, with pneumothorax (Devic and Savy)

rial is thin in consistency and does not have a foul odor.

Roentgen technic consists of a thorough fluoroscopic examination of the chest followed by films made not only in the usual positions but also in such other positions, as indicated by the fluoroscopic examination, as will best visualize the pathology under consideration. Over-exposed films are useful in doubtful cases, especially left-sided effusions (Fig 6) that might be obscured by the heart shadow. Injection of a small amount of air at the time diagnostic puncture was made proved to be of great aid in one case observed by myself. Destot (7) suggests the inflation of the stomach with air when pericardial and mediastinal effusions are to be differentiated because pericardial effusion causes bulging of the shadow into the air bubble of the stomach. The barium meal will rule out dilatation, diverticula, or ulcerating carcinoma of the esophagus.

The differential diagnosis of tumors and mediastinal pleurisy is sometimes difficult as both usually have convex borders extending into the lung area; however, tumors and enlarged glands are more likely to be in the hilus area and the effusions to be nearer the diaphragm. The effusions high in the chest may resemble cysts (Fig 8), however, cysts

shadow of pericardial effusion is of even density, in mediastinal effusion the heart can be definitely outlined within a larger shadow, and pulsation is not of much help unless it is one-sided. Ruggles (9) states the sign of greatest value is the paradoxical movement of the heart with forced respiration which occurs when mediastinitis is present. While cold abscesses are visualized as fusiform shadows including the spine, pleurisy is usually on one side, with no destruction of the vertebrae present. Assmann (10) illustrates a tuberculous type that has a concave lung border instead of the usual convex border; however, tuberculosis as a rule is diagnosed by clinical methods, and X-ray evidence of the disease is often present in other parts of the chest. Mediastinal pleurisy may become interlobular and then rupture into a bronchus, as described by Schinz (11). Rupture into a bronchus is well shown by Sante (12), who also presents diagrams showing interlobular extension. The heart shadow is not often displaced. Aneurysm and substernal thyroid have at times caused confusion. Assmann found several typical shadows of mediastinal pleurisy that at postmortem were proved to be indicative of some other lesion. On the right side a vena cava inferior simulated the tuberculous type, on the left side,

a large fat pad at the apex of the heart was confusing, again a typical posterior left-sided triangular shadow, paravertebral in

painful cough, stabbing sharp pains in the lower right chest, dyspnea, very rapid pulse, and post-influenzal asthenia

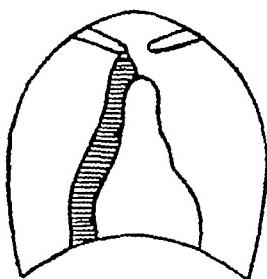

Fig 5 Right posterior, paravertebral type (*Assmann*)

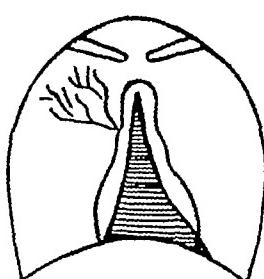

Fig 6 Left posterior, tuberculous origin (*Assmann*)

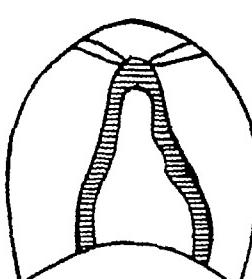

Fig 7 Early right and left posterior (*Decic and Savv*)

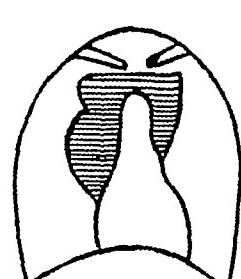

Fig 8 Right and left posterior mediastinal (*Groedel*)

position, visualized through the heart shadow, was found to be a densely infiltrated extra lobe of the lung Lenk (13) also illustrates a typical right-sided mediastinal pleurisy that later proved to be a neurofibroma of the right vagus nerve Groedel (14) reports a case of non-infectious mediastinal collection of fluid, namely, a hemorrhage into the right posterior mediastinal space following penetration of the chest by a granite splinter He also illustrates an unusual case of right upper posterior mediastinal effusion that extended to the left posterior mediastinal space in its upper portion In this latter case effusion did not extend much below the hilus area

I have compiled a chart (Figs 1-8) showing the most common types of mediastinal pleurisy, although combinations are not unusual These diagrams are copied from text-books and authors' names are appended Diagrams were made of my own cases (Figs 9-11) because direct prints from the films failed to bring out the proper contrast

CASE REPORTS

Case 1 H. E., male, age 31 years, entered the hospital on Jan 21, 1929, complaining of a persistent, non-productive,

Clinical examination revealed an advanced mitral stenosis and myocarditis Moist râles were present over both lower lobes, as was dullness on percussion on the right side of the heart anteriorly and posteriorly Except for a few days after admission, the man's temperature was continuously under 99 degrees Respiration was almost constantly at 24 The pulse was very irregular, often reaching 120

During his stay in the hospital the leukocyte count varied between 13,000 and 15,000, with 80 to 85 per cent polymorphonuclears On admission, the urine contained an occasional hyaline cast Casts and albumin increased gradually up to the time of death The blood cultures were negative

The first films (Fig 9) of the chest showed a sharply defined shadow along the right cardiac border, with a small amount of free fluid in the left costophrenic angle The right diaphragm was of normal curvature and excursion, with no free fluid in the right costophrenic angle The shadow gradually enlarged and a diagnosis of right posterior mediastinal pleurisy was made About 300 c.c. of purulent material, which gave a pure culture of *Staphylococcus aureus*, was removed from the right poste-

rior mediastinal area. The shadow had almost disappeared three days after surgical drainage, only a few stringy lines radiat-

X-ray examination on admission showed the lower half of the right chest area to be increased in density and this density changed

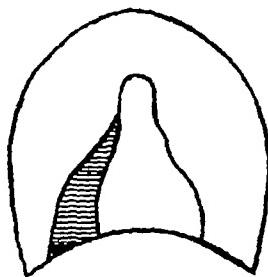

Fig. 9 Right posterior,

rior, Case 3

ing from the hilus region remaining. Ten days later the films showed no further changes.

The patient died of acute dilatation of the heart three weeks after surgical drainage and seven weeks after admission to the hospital. Autopsy was refused.

Case 2 H. S., male, age 23 years, grocer, entered California Hospital on Nov. 3, 1929, complaining of pain in the right chest at the level of the eighth rib in the axillary line, also coughing of the non-productive type. The history was of sudden onset two weeks earlier. There were no physical signs on admission.

The urine contained a trace of albumin. The respiration varied between 20 and 25 throughout the course of the infection. The pulse rate was practically fixed at 95. The temperature varied from 99 to 101 degrees. On admission, the leukocyte count was 11,300, with 68 per cent polymorphonuclears; from November 15 to 19 the pulse rate increased to 100, temperature to 103 degrees, and the leukocytes gradually increased from 12,000 to 25,000, with 86 per cent polymorphonuclears. Surgical drainage was then instituted and laboratory findings soon returned to normal, but a slight discharge continued for about four weeks after operation.

with position. A clear, straw-colored fluid to the amount of 500 cc was aspirated in the axillary area. Cultures from this fluid remained sterile. X-ray examination a few days after aspiration showed no free fluid in the costophrenic angle, but a sharply defined shadow (Fig. 10) was present along the right side of the mediastinum. This shadow increased in size for one week, extending to the right posterior chest wall. Aspiration posteriorly at the level of the right transverse process of the seventh dorsal vertebra yielded 160 cc of pus containing Gram-positive cocci in chains and pairs. Surgical drainage was instituted at the site of puncture. Many small cavities separated by soft adhesions were found to be present between the mediastinal pleura and the pulmonary visceral pleura. The adhesions were broken down until one large cavity existed, but great care was taken not to involve the parietal pleural cavity. Complete recovery took place six weeks after operation.

Case 3 M. P., female, age 9 years, entered the hospital on March 7, 1929, complaining of a painful cough which began three weeks earlier, following a cold.

Examination revealed dullness on the right side of the heart posteriorly as far as the inferior angle of the scapula. Ante-

riorly it was continuous with liver dullness. No râles were present.

On admission the leukocyte count was 16,800, with 78 per cent polymorphonuclears, gradually dropping, twelve days later, to 9,000, with 75 per cent polymorphonuclears. Smears for bacilli of tuberculosis were negative. The temperature was below 100 degrees at all times. The pulse varied greatly, frequently up to the rate of 120. The respiration varied between 20 and 30.

X-ray films (Fig. 11) on admission showed a sharply defined triangular shadow with its base on the diaphragm in the right cardiophrenic angle, posterior in location. The right diaphragm had a normal curvature and excursion, with no free fluid in the costophrenic angle. Five days later, the triangular shadow was seen to have increased about 25 per cent in size. One week after this second examination no change in size was demonstrated but the patient was much improved clinically. The child was discharged one week after this X-ray examination as cured and has had no recurrence of symptoms since.

COMMENT

It will be noted that in all three cases the temperature, pulse rate, and leukocyte count were only slightly increased. All patients had a non-productive cough, with pain on the right side. The symptoms were of several weeks' duration before admission to the hospital. At first, these patients were placed in bed at home and treated as ordinary pleurisy cases, if X-ray examinations had not been made the true conditions would not have been discovered. Cases 1 and 2 were proven by operation. Case 3, when viewed in the anteroposterior plane, resembled the anterior type of effusion (Fig. 1), which is explained by Herrnheiser as due to extension to the costomediastinal sinus, quite common in posterior types of medi-

astinal effusions. Case 3 did not resemble a collapsed lower lobe as there was no compensatory emphysema in other lobes, nor did it resemble a collapsed lobe with bronchiectatic cavities, as suggested by Stoloff (15). The shadow remained of even density, increased in size for one week, and then showed a small interlobular extension. Tuberculosis was not demonstrated before or after the effusion occurred.

In all obscure chest conditions it is well to keep the possibility of mediastinal pleurisy in mind, and, for the present, at least, these cases should be reported. No doubt many cases of mediastinal pleurisy have been overlooked in the past.

VIENNA ROENTGENOLOGIC SOCIETY

SESSION OF APRIL 14, 1931

Chairman PROFESSOR G SCHWARZ

Secretary DR. PRESSER

Professor Kienbock and Professor G Schwarz were elected Chairmen of the Vienna Roentgenologic Society Professor H H Berg, Dortmund, and Privatdozent G Herrnheiser, Prague, were elected corresponding members Professor G Schwarz took the chair and delivered an address in memory of Professor Dr Martin Haudek, deceased

Martin Haudek is gone from our midst The morning of March 9, we received the sad news that this apparently perfectly healthy man, with happy disposition, had suddenly passed away Haudek succumbed within a few minutes to an attack of angina pectoris, the harbingers of which had sounded a warning some time previously but had been unable to diminish to the slightest degree the creative force of this highly energetic man Two days before his death, Haudek delivered a long address at the headquarters of the Public Health Service concerning the equipment for his newly erected Roentgen Institute in the Wilhelminkenspital, to which he had devoted himself most completely during the previous months There were no indications that all his magnificent plans were to be brought to an abrupt end In Martin Haudek not only Vienna but international radiology has lost a representative of unusual make-up

On the occasion of the death of its unforgettable member, the Wiener Rontgengesellschaft received many expressions of sympathy that revealed most eloquently though sorrowfully the extraordinary esteem in which Haudek's personality and Haudek's scientific accomplishments were held throughout the world The communications came from the Deutsche Rontgengesellschaft, the Swedish Radiologic Society, the

Vereinigung Deutscher Rontgenologen und Radiologen in Czechoslovakia, the Roentgen Association of the Union of Socialist Soviet Republics, and the president of the International Congress of Radiology in Paris, likewise from Prof Hans Meyer, Bremen, and many other colleagues

Haudek, before taking up roentgenology, had been associated originally with the department of internal medicine After a course of thorough training in the Nothnagel Clinic and in the Weichselbaum Institut fur Pathologie, Haudek became, in 1907, acting director of the Frisch department of internal medicine in the Vienna General Hospital The inadequate nature of the status of gastric ulcer diagnosis brought him in contact with the method of roentgen examination, which at that time was just beginning to be developed, and awakened in him a special liking for our specialty, which grew stronger as time went on On May 1, 1908, Haudek became associated with the Holzknecht Institute, where he developed his pre-eminent ability Here Haudek, in collaboration with the Eiselsberg surgical clinic (Clairmont), developed his method for the demonstration of ulcerations of the stomach, here he worked out the symptom of the filling defect (*mschensymptom*), which has been taken up by all textbooks throughout the world, here he elaborated the radiologic criteria for the differentiation of carcinoma from a benign ulcer, the radiologic indications for stomach operations, and other forms of technic

During the World War, Haudek directed the roentgen institutes of several large hospitals, and also in these places carried on some valuable scientific researches on roentgenologic determination of the size of the

heart and the interpretation of heart roentgenograms, on chronic bone suppurations, and the roentgenologic diagnosis of internal diseases. In 1920, Haudek became director of the roentgen institute in the Vienna Wilhelmina Hospital. In addition to the further development of gastro-intestinal diagnosis, he devoted himself here chiefly to researches on the course of healing processes in pulmonary tuberculosis, to which medicine is indebted for new and valuable disclosures.

In the field of therapeutics, likewise, Haudek's restless mind was active, to mention only the important publications on the roentgen treatment of exophthalmic goiter, and irradiation treatment of conditions following operations on the digestive tract.

All the works of Haudek are characterized by perfect linguistic expression, keen logic, and unerring judgment as to what is important from the medical point of view. Haudek was right in not regarding roentgenology as a subordinate, merely technical adjvant procedure whose province is to furnish purely mathematical or purely formal findings, as, for example, the chemical and microscopic research method but as an all-embracing medical specialty equal in every way to other specialties. He never grew tired of emphasizing this point of view in smaller and in wider circles and in impressing it on his followers. He was an outstanding teacher and his pupils have carried his fame and the reputation of the Vienna radiologic school to the ends of the earth. Equipped by nature with a remarkable flow of language, a ready wit, and an engaging personality, Haudek was destined to score many triumphs in scientific assemblies, whether serving as chairman, as essayist, or as leader of the discussion. His inherent capacity for organization, for establishing useful connections, for composing differences with wisdom, firmness, and moderation, made him everywhere, within a short time, a leader in both word and

action. Since 1913, Haudek had been a permanent member of the executive committee of the Deutsche Rontgengesellschaft, and at the assembly in 1926 served as its chairman. We who have been intimately associated with Haudek will never forget the energy and judgment he displayed in preparing for the congress of Vienna in 1929. The giant task, which necessitated countless sessions with the representatives of all manner of boards and corporations and with individual interests, was solved by Haudek with pre-eminent success. Beloved by reason of his affability and his kindness and esteemed by all classes, he knew how to use his unusual popularity, just when it was needed, in the service of our specialty. He whose early passing fills us with deep sorrow was one of those figures for which there is no substitute, and whose merits and outstanding qualities are handed down to posterity, not merely for the exaltation of the deceased but also for emulation by his followers. Honor be to his memory! [The members of the assembly rose from their seats.]

HALDER'S SCIENTIFIC WORK DR. FLEISCHNER

The task assigned to me, to speak on the scientific work of my teacher, has been made more difficult by an unfortunate event that has occurred at the last moment. Professor Holzknecht,¹ who was to have spoken on the discovery of the significance of the filling defect, has been taken ill, and there is no one who can present the subject as well as he. My paper will have to be a combination of narrative and readings, and it will consequently lack the spontaneity that Professor Holzknecht, as an eye-witness and participant, might have injected into it.

It was the important period of the first development of the application of roentgenologic methods to the diagnosis of gastrointestinal disorders. Many valuable facts

¹Professor Holzknecht did not recover.

had been learned since the use of the Rieder bismuth paste. Except for a few isolated, far-from-frank observations, peptic ulcer defied roentgenologic diagnosis. It was the discovery of diverticulum-like shadow spots in the silhouette of the stomach that Haudek (at first purposely avoiding any anatomic inferences) designated the "niche" (later known in English as the "filling defect"). A wonderfully exact roentgen analysis and description of findings (considering the technical aids that were then available), together with a few operative results, led him, within a very short time, to narrow down the diagnostic significance of the filling defect, to clarify it by connecting it with a number of signs or symptoms, and to announce it as the roentgenologic expression of the penetrative callous gastric ulcer. It was a period of feverish activity. Haudek was present at the operation on every patient that he had examined. Supplementary reports followed in quick succession. At the roentgenologic congress, held in April, 1910, he reported at first on only two cases, but when the Naturforscherversammlung was held in September, the number had increased to 17, and, two months later, there were 25 cases with 14 necropsy findings. In 1911, there appeared as the result of the collaboration with Clairmont, of the Eiselsberg Clinic, the monograph on the importance, for surgery, of roentgenologic diagnosis of stomach conditions, together with the publication of 35 clinicorontgenologic case histories. It was a great disappointment for Haudek that a supplementary volume on the progress of gastro-intestinal diagnosis, which he had planned in collaboration with Holzknecht and which was almost ready for the printer, could not, for financial reasons, be published.

Haudek did not overlook the difference between the roentgen and the morphologic findings of ulcer. Little was known at that time about the anatomy of the living

stomach, and the anatomy of the cadaveric stomach was a poor correlate to the roentgenograms. Hence he explained the diverticulum-like constriction of the filling defect on the part of the stomach as a circular spasm of the muscularis mucosæ. Through recent researches (Forssell) we have learned that a swelling of the mucosa surrounding the ulcer plays the chief part in this constriction. His further research had to do with the elaboration of the morphologic ulcer diagnosis and the differential diagnosis of ulcer and cancer. Even at that time we find Haudek's differentiation, which has now become famous. The ulcer is a heavier shadow and the cancer is a lighter shadow. Although deeply interested in the elaboration of the technic of the diagnosis of gastric functioning (Haudek had substituted the testing of the 6-hour remnant in place of the examination of a 24-hour remnant, and had introduced also the expeditious double meal procedure), yet, in his mental make-up, and, in part, doubtless also influenced by the constantly confirmed diagnostic significance of his morphologic ulcer symptom, he was not inclined to overestimate the value of functional manifestations. I go back in thought to the time when, inspired by the endeavor to learn more about the pylorus and the duodenum, one differentiated and classified, for want of reliable morphologic signs, the velocity and rhythm of gastric evacuation in a most delicate manner, and (from the standpoint of our present-day knowledge) drew venturesome diagnostic conclusions therefrom. Haudek endeavored at an early period to make the filling defect and the deformations of the bulbus the basis of his diagnoses.

We will not follow further the individual phases of his work. The World War found him engaged, in part, with other problems. Studies on the estimation of the degree of disability of persons affected with heart injuries, the results of bone injuries,

and, finally, the roentgenologic diagnosis of internal diseases, written for the practitioner, and appearing in Holzknecht's "Roentgenology," were the products of this period.

In the post-war period, after his transfer to the Wilhelmenspital, his collaboration with W. Neumann and Sorgo led him to make comprehensive studies on pulmonary tuberculosis. The fruits of this labor, as published in several articles, were, above all, the calling attention to the possible retrogression of tuberculous infiltrates of the lungs and to the retrogressive and healing capacity of extensive cavity processes, without surgical intervention. Haudek was one of the first roentgenologists to call attention to the necessity of differentiating the lung apex processes. On the basis of observations in large series of cases he brought out the comparative insignificance of certain forms of tuberculosis of the apex. Passing over the large number of further articles dealing with the various fields of roentgen diagnosis and roentgen therapy, we will complete the circle by giving a more detailed account of his last researches in the field of stomach diagnosis. He began by laying the foundations and establishing the synthesis, further development and sifting characterized the closing arguments. With justified criticism, Haudek attacked the assertion that diagnostic errors of various practitioners were due to the unreliability of his filling defect symptom. Endeavoring to uphold the filling defect as a pathognomonic sign of peptic ulcer, he devoted himself indefatigably to the more delicate roentgen analysis of tumors that had broken down into ulcers. In his last extensive research on the changes in the pyloric gastric region, we find as a valuable diagnostic contribution the cancer stage or the subcardiac stage, and an exact morphology of the crateriform cancer-ulcer. From a large series of cases reported in detail, we learn here that the cancer crater forms what is usually an un-

evenly delimited shadow area within a filling defect, or, as Haudek called it, in precise terms, "a plus in a minus shadow." Whereas peristalsis usually passes unhindered over an ulcer, here the surrounding wall shows no peristaltic movements and forms by steps a contrast with the healthy stomach wall. The prepyloric filling defect, though not often observable, is a sharply demarcated shadow projection in the middle of a scutiform, smoothly contoured part of the stomach wall with a bay-like indentation. The fact that the canalis comes to a point is discussed in detail and its significance for the differential diagnosis is brought out. The difficulty and the frequent impossibility of distinguishing benign wall changes of the canalis from cancerous changes is emphasized. Especially this last great research, rich in carefully studied material extending over a long period of years, sifts, free from any preconceived intention of following any particular schema, the facts, and leads us, on the one hand, to unsuspected refinements of diagnosis, and shows us, on the other hand, the limits of our knowledge and insight. In this particular research we see Haudek, at the height of his activity, drawing from his incomparable experience, and whereas many older discoveries have long since become common property, this research permits us to recognize with no little chagrin how much Haudek might have taught all of us, if he had lived.

The chronologic study of Haudek's roentgenologic researches does not merely teach us many individual facts. We see from them—and I have observed it even more than others, owing to my collaboration with him for nearly ten years—that what gave the central direction to his researches was always primarily the clinical questioning. Haudek's principal endeavors began at the point where the clinician demanded a clarification of uncertain distinctions with reference to the treatment to be followed. From

the first to the last researches he always kept in mind the question of therapeutic indications, and he plainly limits and at the same time emphasizes the part that roentgen procedures must play. He always endeavored to test every technical measure to discover whether or not the required expenditure of time and means was justified by the anticipated success. He always sought to make his research technic as expeditious as possible and as little disturbing to the patient as was feasible. He regarded that as an essential requirement for the widest possible application of roentgen diagnosis in practical medicine.

Haudek's scientific work is not, however exhausted in the publications that lie before us in completed form. In numerous addresses delivered at congresses and assemblies, and in many discussions he expressed thoughts and gave suggestions that he did not live to follow up and to develop. Not only to his close associates but also to countless physicians who came from far and near to see the master at his work he always gave without stint out of his rich experience. He was a teacher of the old peripatetic type. One could plainly see him become animated by every kind of scientific discussion even when dealing with the youngest members of the specialty. He was a good listener when others made their presentations and on the other hand he was able to interest others in his own ideas. Taking it all in all, Haudek's work is a sheet-anchor of medical roentgenology and will remain a landmark in the history of medicine.

GRAWITZ TUMOR AFRIDIL ROENTGENOGRAMS

This demonstration concerns a patient aged 62 who, suffering from complete retention of urine and severe hematuria sought aid at the urologic ambulance of Prof. Paschkis and, after a thorough urologic examination was referred to the

Roentgen Institute. The speaker presented the intravenous pyelogram taken after injection of abrodil in which normal excretory conditions of the contrast medium in the region of the left kidney are recognizable while in the right field a filling defect is visible in the lower half of the renal pelvis. As the shadow of the right kidney is not plainly visible, a tumor is suspected and that finding is strengthened by means of retrograde pyelography which reveals likewise a filling defect in the right renal pelvis. Right nephrectomy was then performed by Prof. Paschkis. Result: a tumor of the right kidney of the Grawitz type.

CALCULUS OF THE RENAL PELVIS

A patient aged 42 after an attack of colic sought aid in the urologic "ambulance." Prof. Paschkis sent him to our Roentgen Institute. The ordinary roentgenogram reveals a finger-breadth to the left of the median line at the level of the lower sacral vertebrae a rough shadowy lobulated mass (Suspicion of calculus). As the position was atypical for a ureter stone (too far toward the median line) several roentgenograms with a sound were made, which the speaker presented. Finally retrograde pyelography was done which revealed a dys-topia of the left kidney, with a stone in the left renal pelvis (Left-sided pelvic kidney with stone.) The demonstrated roentgenograms taken by means of intravenous pyelography after injection of abrodil confirm this supposition.

PILATERAL PELVIC KIDNEY WITH STONE

The patient was a small frail man who at the time noted only vague symptoms in the lower right abdominal quadrant associated with bacterial pyuria. In the demonstrated plain roentgenogram a large coral stone in the region of the right sacro-iliac

and, finally, the roentgenologic diagnosis of internal diseases, written for the practitioner, and appearing in Holzknecht's "Roentgenology," were the products of this period.

In the post-war period, after his transfer to the Wilhelmenspital, his collaboration with W Neumann and Sorgo led him to make comprehensive studies on pulmonary tuberculosis. The fruits of this labor, as published in several articles, were, above all, the calling attention to the possible retrogression of tuberculous infiltrates of the lungs and to the retrogressive and healing capacity of extensive cavity processes, without surgical intervention. Haudek was one of the first roentgenologists to call attention to the necessity of differentiating the lung apex processes. On the basis of observations in large series of cases, he brought out the comparative insignificance of certain forms of tuberculosis of the apex. Passing over the large number of further articles dealing with the various fields of roentgen diagnosis and roentgen therapy, we will complete the circle by giving a more detailed account of his last researches in the field of stomach diagnosis. He began by laying the foundations and establishing the synthesis, further development and sifting characterized the closing arguments. With justified criticism, Haudek attacked the assertion that diagnostic errors of various practitioners were due to the unreliability of his filling defect symptom. Endeavoring to uphold the filling defect as a pathognomonic sign of peptic ulcer, he devoted himself indefatigably to the more delicate roentgen analysis of tumors that had broken down into ulcers. In his last extensive research on the changes in the pyloric gastric region, we find as a valuable diagnostic contribution the cancer stage or the subcardiac stage, and an exact morphology of the crateriform cancer-ulcer. From a large series of cases reported in detail, we learn here that the cancer crater forms what is usually an un-

evenly delimited shadow area within a filling defect, or, as Haudek called it, in precise terms, "a plus in a minus shadow." Whereas peristalsis usually passes unhindered over an ulcer, here the surrounding wall shows no peristaltic movements and forms by steps a contrast with the healthy stomach wall. The prepyloric filling defect, though not often observable, is a sharply demarcated shadow projection in the middle of a scutiform, smoothly contoured part of the stomach wall with a bay-like indentation. The fact that the canalis comes to a point is discussed in detail and its significance for the differential diagnosis is brought out. The difficulty and the frequent impossibility of distinguishing benign wall changes of the canalis from cancerous changes is emphasized. Especially this last great research, rich in carefully studied material extending over a long period of years, sifts, free from any preconceived intention of following any particular schema, the facts, and leads us, on the one hand, to unsuspected refinements of diagnosis, and shows us, on the other hand, the limits of our knowledge and insight. In this particular research we see Haudek, at the height of his activity, drawing from his incomparable experience, and whereas many older discoveries have long since become common property this research permits us to recognize with no little chagrin how much Haudek might have taught all of us, if he had lived.

The chronologic study of Haudek's roentgenologic researches does not merely teach us many individual facts. We see from them—and I have observed it even more than others, owing to my collaboration with him for nearly ten years—that what gave the central direction to his researches was always primarily the clinical questioning. Haudek's principal endeavors began at the point where the clinician demanded a clarification of uncertain distinctions with reference to the treatment to be followed. From

the first to the last researches he always kept in mind the question of therapeutic indications, and he plainly limits and, at the same time, emphasizes the part that roentgen procedures must play. He always endeavored to test every technical measure to discover whether or not the required expenditure of time and means was justified by the anticipated success. He always sought to make his research technic as expeditious as possible and as little disturbing to the patient as was feasible. He regarded that as an essential requirement for the widest possible application of roentgen diagnosis in practical medicine.

Haudek's scientific work is not, however, exhausted in the publications that lie before us in completed form. In numerous addresses delivered at congresses and assemblies, and in many discussions he expressed thoughts and gave suggestions that he did not live to follow up and to develop. Not only to his close associates but also to countless physicians who came from far and near to see the master at his work, he always gave without stint out of his rich experience. He was a teacher of the old peripatetic type. One could plainly see him become animated by every kind of scientific discussion, even when dealing with the youngest members of the specialty. He was a good listener when others made their presentations, and, on the other hand, he was able to interest others in his own ideas. Taking it all in all, Haudek's work is a sheet-anchor of medical roentgenology and will remain a landmark in the history of medicine.

GRÄWITZ TUMOR ABRODIL ROENTGENOGRAMS

This demonstration concerns a patient aged 62, who, suffering from complete retention of urine and severe hematuria, sought aid at the urologic "ambulance" of Prof. Paschkis and, after a thorough urologic examination was referred to the

Roentgen Institute. The speaker presented the intravenous pyelogram taken after injection of abrodil, in which normal excretory conditions of the contrast medium in the region of the left kidney are recognizable, while in the right field a filling defect is visible in the lower half of the renal pelvis. As the shadow of the right kidney is not plainly visible, a tumor is suspected, and that finding is strengthened by means of retrograde pyelography, which reveals likewise a filling defect in the right renal pelvis. Right nephrectomy was then performed by Prof. Paschkis. Result: a tumor of the right kidney of the Grawitz type.

CALCULUS OF THE RENAL PELVIS

A patient aged 42, after an attack of colic, sought aid in the urologic "ambulance." Prof. Paschkis sent him to our Roentgen Institute. The ordinary roentgenogram reveals, a finger-breadth to the left of the median line, at the level of the lower sacral vertebrae, a rough shadowy lobulated mass (Suspicion of calculus). As the position was atypical for a ureter stone (too far toward the median line), several roentgenograms with a sound were made, which the speaker presented. Finally retrograde pyelography was done, which revealed a dystopia of the left kidney, with a stone in the left renal pelvis (Left-sided pelvic kidney with stone). The demonstrated roentgenograms, taken by means of intravenous pyelography after injection of abrodil, confirm this supposition.

BILATERAL PELVIC KIDNEY, WITH STONE

The patient was a small, frail man who, at the time, noted only vague symptoms in the lower right abdominal quadrant, associated with bacterial pyuria. In the demonstrated plain roentgenogram, a large coral stone in the region of the right sacro-iliac

synchondrosis was to be seen. The application of the sound to the ureters and the use of retrograde pyelography revealed finally a bilateral dystopia of the kidneys (pelvic kidneys), with a large coral stone at the right. Whether an amyloid kidney in the small pelvis is present or whether only a bilateral dystopia of the kidneys exists, cannot be decided from the roentgenograms. Intravenous pyelography, although carried out most carefully, failed in this case.

POLYPS OF MIDDLE EAR

L. Forschner and F. Windholz report on histologic changes in irradiated polyps of the middle ear. Among these, there were two granulation tumors that had disappeared spontaneously following roentgen irradiation, furthermore, a larger blocking antrum polyp, which extended far into the auditory meatus and which offered an opportunity, before and after the irradiation, to make several excisions of tissue, in order to compare the X-ray changes in the tissues with the unirradiated tissue. Finally, a nodule-like elevation in an acute, likewise irradiated middle ear suppuration was examined. First the histologic picture of the unirradiated piece of the blocking middle-ear polyp was demonstrated. After the application of relatively few irradiations a change in the cell content and in the cellular composition of the polyps could be noted. The number of polymorphonuclear leukocytes, lymphocytes, and plasma cells decreased materially, and an increase of the connective tissue cells and of the intercellular substance could be observed. The cell changes, the karyopyknosis, the karyolysis, and the complete degeneration of the leukocytes was demonstrated with a number of photographs. The proliferation of the connective tissue originated in the vicinity of the blood vessels. The latter had undergone varying degrees of modification. The

endothelium was swollen, while the stainability of the nuclei had decreased. The protoplasm presented vacuoles and showed degeneration, and the lumen of the vessels was frequently narrowed and gave evidence of degeneration. Also, in the capillary vessels were several layers of large, swollen cells whose nuclei and cell protoplasm gave plain evidence of the previously described conditions, in place of the simple layers of endothelium.

The speakers emphasized also that the spontaneous retrogressive changes of the middle-ear polyps showed a similarity with the demonstrated findings, of which fact they were able to convince themselves by comparison with the unirradiated polyps.

Wittmaak thought he saw a causal connection between the spontaneous healing process in the ear polyps and the degenerative processes in the blood vessels. In the same sense, it appeared not impossible that the reparative process produced by roentgen rays, aside from the direct destruction of the inflammatory cells, also the changes in the blood vessels produced by the irradiation, play a part. It is worthy of note that the appearance and the extension of the changes run by no means parallel with the irradiation dosage and duration, for occasionally after relatively small doses a marked histologic reaction is observed, which possibly, with the exception of the vascular changes, scarcely increases following prolonged irradiation. This circumstance is to be considered also in marking out the plan of irradiation. In the experience of the speakers, it appears indicated, after a few weak irradiations, to await the effect and only after an interval of from four to eight weeks to renew the irradiation as it has been shown that the therapeutic effect, if it does not appear immediately after the first irradiations, is not perceptibly increased by irradiations continued over a longer period.

ANNOUNCEMENT

We have been asked to announce that all correspondence relative to business matters connected with the Radiological Society of North America and *RADIOLOGY*, the official Journal of the Society, should be addressed to Donald S Childs, M D, Secretary-Treasurer, 607 Medical Arts Building Syracuse, New York

IS ROENTGENOLOGY, AS A SPECIALTY, DESTINED TO SURVIVE?

Will the interests of scientific medicine be best served, in the long run, by the survival or extinction of roentgenology as a specialty? Does competent diagnosis by means of X-rays demand sufficient special training and study to justify its practice as a medical specialty? Or should it, like inspection, palpation, percussion, and other methods of physical examination, be employed simply as a part of the routine of the surgeon, the internist, the urologist, the general practitioner? These questions are not merely of academic interest to students of medical trends but are of immediate vital interest to some hundreds of roentgenologists and to some scores of young men now in training for the practice of this seriously menaced specialty.

The existence of specialties in medicine is predicated on the assumption that the theory and practice of modern medicine have grown beyond the grasp of any one man that no one can any longer be truly a "physician and surgeon" and in addition a urologist, otolaryngologist, etc. Legally, anyone possessed of a degree of Doctor of Medicine and a license to practise in his State may assume and claim special aptitude for the practice of any medical specialty, with none to say him nay. Practically, in urban communities, the amount of harm to be done by the occasional surgeon, the self-trained urologist, the incompetent otolaryngologist, is limited, since the body of medical opinion is against him. He is not encouraged to work in the best hospitals, cases are not referred to him by the qualified and ethical men who mold medical opinion. He must depend for his practice on a personal appeal to a limited circle among the laity. The tendency of the qualified specialist in any line is naturally to resent unwarranted assumptions of special qualifications which do not exist. By this mechanism the position of the well trained man, in most lines, is protected even though existing laws regarding medical licensure take no account of medical progress of the last thirty or forty years.

The position of the roentgenologist is, for a variety of reasons, quite different. The public has been trained, largely through lack of vision on the part of early X-ray workers, to marvel at the physical equipment of the roentgenologist instead of his mental equipment, to see the machine, not the man, to focus its interest on the work of technicians, rather than the work of the man in front of the viewing box. Thus, to most laymen, and unfortunately to too many med-

synchondrosis was to be seen. The application of the sound to the ureters and the use of retrograde pyelography revealed finally a bilateral dystopia of the kidneys (pelvic kidneys), with a large coral stone at the right. Whether an amyloid kidney in the small pelvis is present or whether only a bilateral dystopia of the kidneys exists, cannot be decided from the roentgenograms. IS ROENTGENOLOGY, AS A SPECIALTY, DESTINED TO SURVIVE?

Will the interests of scientific medicine be best served, in the long run, by the survival or extinction of roentgenology as a specialty? Does competent diagnosis by means of X-rays demand sufficient special training and study to justify its practice as a medical specialty? Or should it, like inspection, palpation, percussion, and other methods of physical examination, be employed simply as a part of the routine of the surgeon, the internist, the urologist, the general practitioner? These questions are not merely of academic interest to students of medical trends, but are of immediate vital interest to some hundreds of roentgenologists and to some scores of young men now in training for the practice of this seriously menaced specialty.

The existence of specialties in medicine is predicated on the assumption that the theory and practice of modern medicine have grown beyond the grasp of any one man that no one can any longer be truly a "physician and surgeon" and in addition a urologist, otolaryngologist, etc. Legally, anyone possessed of a degree of Doctor of Medicine and a license to practise in his State may assume and claim special aptitude for the practice of any medical specialty, with none to say him nay. Practically, in urban communities, the amount of harm to be done by the occasional surgeon, the self-trained urologist, the incompetent otolaryngologist, is limited, since the body of medical opinion is against him. He is not encouraged to work in the best hospitals, cases are not referred to him by the qualified and ethical men who mold medical opinion. He must depend for his practice on a personal appeal to a limited circle among the laity. The tendency of the qualified specialist in any line is naturally to resent unwarranted assumptions of special qualifications which do not exist. By this mechanism the position of the well trained man, in most lines, is protected even though existing laws regarding medical licensure take no account of medical progress of the last thirty or forty years.

The position of the roentgenologist is, for a variety of reasons, quite different. The public has been trained, largely through lack of vision on the part of early X-ray workers, to marvel at the physical equipment of the roentgenologist instead of his mental equipment, to see the machine, not the man, to focus its interest on the work of technicians, rather than the work of the man in front of the viewing box. Thus, to most laymen, and unfortunately to too many med-

ical men, an X-ray examination speaks completely and finally for itself without regard to whether or not it is competently interpreted. For this reason there exists almost no public demand for the services of a physician especially trained in X-ray diagnosis, providing any other person, trained or untrained, professes intelligence and ability to take over his function. The cases of the ethical roentgenologist are almost entirely referred by other physicians. He makes no initial or independent contact with his patients. Often in hospital, and sometimes in office practice, he does not even see them, hence he has no opportunity to build up an independent clientele among the laity. Indeed, he has had no desire to do so, being well satisfied to gain the support and confidence of his medical colleagues. His position, frequently a difficult one through the necessity of maintaining friendly and equitable relations with a large group of medical men whose personal interests often conflict violently, is best fortified by his willingness to remain somewhat in the background, making no effort to project his personality upon the patient's attention.

With the advent of the Coolidge tube, the simple, compact, and reliable X-ray transformer, and dependable photographic materials, many of the technical difficulties which hindered the making of satisfactory X-ray films were removed. It became possible for a reasonably intelligent person to learn in a few months to make technically excellent roentgenograms. With the expansion, brought about by war orders, in the factories of makers of X-ray equipment, it became incumbent on their sales forces to find buyers for hundreds of new X-ray outfits. With the growth in the scope of X-ray diagnosis, conditioned by the willingness, indeed the almost frantic insistence, of the public to have X-ray examinations made for any ailment whatever, there was created a great potential market to absorb the over-production of X-ray equipment. Human greed,

never a factor to be overlooked but perhaps particularly rampant during the inflation period, was the motif of the sales argument which placed thousands of X-ray machines in the offices of medical men no more versed in roentgenology than in astrology and with no more intention of making a serious study of the one than the other. Let me hasten to add that desire for financial gain was not the only argument, and probably not often the chief argument, by which the surgeon or the internist convinced himself that he ought to take over the work of his roentgenologist. There were other, and in some respects excellent, arguments for this course of action. These will be considered later.

The chief weakness in the roentgenologist's position as a specialist lies in the almost universal application of his specialty. A tremendous proportion of patients seeking relief from illness require an X-ray examination at one time or another. The internist sends a few of his patients to the otolaryngologist, a few to the urologist, a few to the surgeon, but almost all of them require an X-ray examination. He would not think of doing his own appendectomies, or tonsillectomies, or cystoscopies, he has no special training along those lines—to attempt those procedures would be to lose caste. Men who perform them competently send him patients. But how convenient it is to have the necessary X-ray studies made in his own office! And the result of an incompetent X-ray examination is not immediately apparent, not often promptly fatal. The surgeon's problem is similar, the answer frequently the same.

The so-called commercial X-ray laboratory, conducted by technicians with perhaps a medical man nominally, but not actually, in charge, menaces the roentgenologist's position from another angle but to much the same effect. It provides the physician, who does not recognize the desirability of expert medical interpretation of X-ray findings, with a cheap and inexpert X-ray service.

without the necessity of investment in equipment. The result, so far as the patient is concerned, is apt to be much the same as though the physician or surgeon referring him to the commercial laboratory had his own X-ray equipment, except that the service may cost him less.

In hospital practice, the theoretic position of the roentgenologist as a specialist is for the most part unassailed. He occupies, however, in the modern hospital set-up, a unique and unenviable position. His relations with other members of the staff are largely of his own making and likely to be most agreeable, though in smaller institutions there may be a slight tendency to rate him somewhere between a laboratory technician and a doctor. But his remuneration for his professional services usually derives from a fee-splitting arrangement with the business management of the institution. The fees are often fixed by the business management at a figure to conform with local practice. If, through his efforts, the roentgenologist succeeds in building up a larger volume of work in his department than the hospital board thought possible when the original arrangement was made, he is very likely to find the business management casting covetous glances at his monthly earnings. If he does not accept a reduction in his percentage, he is apt to be replaced by a cheaper man. Thus the hospital roentgenologist is oftentimes sampling the joys of socialized medicine some years in advance of his confrères.

Clearly any field of endeavor which does not promise adequate reward for effort and considerable scope for ambition will not long continue to attract men of ability. It should not be understood that the tendencies described have become fully effective, nor that they are equally active throughout the country. There are still many roentgenologists in clinics, in hospitals, and in private practice who, so far as their personal experience extends, would hardly realize that

roentgenology as a specialty has suffered serious inroads in these past few years. To the majority, however, it is an all too evident fact.

Presumably it is the aim and intention of the medical profession, as a whole, to give the public the most effective possible medical service in the most efficient, feasible manner, efficiency being defined as the ratio of results achieved to effort expended. Does, or can, the roentgenologist earn a permanent place in the ideal scheme of effective medical service which the public expects, and particularly, at this time, demands, in return for its huge outlay? We hear much of the high cost of medical care. Will the survival or the extinction of roentgenology as a specialty best serve to decrease this cost?

There is evident very little tendency on the part of the profession to deny the roentgenologist's superior skill in the interpretation of roentgen findings. This is proven by the regularity with which physicians demand for themselves, their families, and medical men under their professional care the opinion of the full-time, rather than the occasional, roentgenologist. It is shown by the frequency with which the roentgenologist is called on for interpretations, usually as a favor, of films made by the amateur X-ray worker, if the surgeon or internist who operates his own X-ray apparatus may be fairly so called. It is evidenced by the uniformity with which highly trained and usually very well remunerated roentgenologists are employed by great clinics, teaching hospitals, and like institutions. It is, then, not in the interest of greater diagnostic accuracy that private X-ray plants and commercial laboratories are so common.

Considerable stress is often placed on the greater convenience to the physician and the patient of having the X-ray examination conducted in the physician's own office, of the saving in time of having films immediately available for interpretation. This argument has some force. Offsetting it is

the fact that the amateur roentgenologist tends to make his X-ray interpretations conform to his clinical impressions At the time when he needs an independent and unbiased point of view, he inclines to interpret what he sees in the light of physical findings, history, and laboratory reports Only the most strikingly contradictory appearances on the films or screen can lead him away from his already made tentative diagnosis When the patient should have, and is usually paying for, a consultation, he often gets only the empty routine of a roentgenologic investigation Everyone who has checked closely the roentgen interpretations even of men very able in other lines, who elect to do their own X-ray work, knows that this happens often, causing enough missed diagnoses to controvert the argument of convenience—if the patient's welfare or even the physician's prestige is to be the basis for decision of the usefulness of the roentgenologist Furthermore, in this connection as elsewhere, time can often be saved, but at too great a cost Except in emergency, a less hurried and more considered interpretation of dry films makes for greater accuracy

Turning to the economic aspect, expensive equipment occupying costly floor space can add to efficiency only if it is frequently and profitably used There are at present in this country, installed in doctors' offices, enough modern X-ray equipment to do the X-ray diagnosis work of the entire world and one or two other planets besides Most of it stands idle a great part of the time Obviously the patient pays depreciation and upkeep on this huge collection of machinery Two-thirds of it is not paying its way even in the narrow sense of bringing its owners sufficient cash return to meet overhead and operating expenses Such a state of affairs must be abhorrent to the economic-minded examiner into the cost of medical care Physicians being notoriously poor business

men, many owners of such semi-idle equipment do not realize what a financial burden it is Others, with more acute financial sense, realizing it, are tempted to find more work for it to do, even if the indications for extensive or repeated X-ray examinations do not clearly exist Thus grows the cost of medical care

Certainly there can be no just criticism of the physician who, owing to his location, finds it necessary to have his own X-ray equipment or deny his patients, and himself, the protection of X-ray diagnostic service In this, as in other fields, he does the best he can, often shaming the specialist, and he is only to be complimented

Objection has sometimes been made to the high cost of X-ray examination This cost has been sometimes offered as an excuse for installing private X-ray equipment—the physician wishes to protect his patients from the exorbitant charges of roentgenologists The general run of basic X-ray fees has not changed since 1914, when the dollar had somewhat more buying power in other lines than it now has The roentgenologist operates under a tremendous overhead expense, and, having no other source of professional income to divert, consciously or unconsciously, to meet a deficit in his X-ray operations, he usually knows about what it costs him to make an X-ray examination He has no abnormal desire to get rich, which is as well for his peace of mind It is estimated that the overhead expense of the average, fairly busy X-ray laboratory amounts to 50 per cent of the collections, a proportion considerably higher than obtains in any other medical specialty Net incomes of roentgenologists, as far as can be learned, average less—not more—than those of other medical men in special practice It is clear to anyone who studies the figures of overhead and income pertaining to X-ray laboratories that any general reduction in X-ray diagnostic charges can come only through

fuller utilization of existing facilities and through greater volume of work in efficiently conducted roentgen laboratories—not through additional duplication of equipment and scattering of effort

The roentgenologist who wishes personally to survive, who desires to protect his specialty from what he considers unfair attack, apparently has no recourse save the education of the profession or the public in the need for his specialized effort. He is reluctant to appeal to the public, impersonally and with largely altruistic motives, after the manner of, for instance, the cancer education campaign, though it could be done, as many think, justifiably, ethically, and successfully. Can he succeed in educating his professional colleagues?

Note—Throughout the above discussion the terms "roentgenology," "roentgenologist," "roentgen laboratory," etc., have been employed as applying to the use of X-rays in diagnosis only. There is relatively little tendency on the part of the profession at large to encroach on the treatment field, a fact which has proven the salvation of many radiologists.

CHARLES D. ENFIELD, M.D.
Louisville, Ky.

RADIOLOGIC EDUCATION

RADIOLOGY presents this, its Educational Number, containing different articles of educational interest, so that its readers may have a true conception of the status of radiologic education in the United States and Canada.

It was thought for a long time that, because radiology is a highly specialized branch of medicine, it should be taught only in the graduate schools of medicine, for this reason many of the undergraduate schools held it to be of minor consequence. The science of radiology has advanced so rapidly

since then that at present it is considered essential in the undergraduate curricula of medical schools.

An examination of the report contained in a paper entitled "A Statistical Study of Radiologic Teaching in the Medical Schools of the United States and Canada," appearing in this issue of RADIOLOGY, shows much interesting and valuable information. Each of the 81 recognized schools of the United States and Canada gives a substantial number of hours to the teaching of radiology. It is interesting to note that six of our schools offer 20 hours of radiology in the freshman year and 10 schools offer 95 hours in the sophomore year. Canada does not give radiologic instruction in the freshman year, but one school offers 30 hours in the sophomore year. One of the main reasons why radiology is being given this consideration in freshman-sophomore medicine is because of its practical application in some of the subjects, particularly anatomy and physiology, taught in these years.

For years the only means of teaching anatomy was principally by demonstrations on cadavers, but to-day, with the use of the roentgen ray, anatomists are teaching the structure of the living. Oscar V. Batson, M.D., a well known anatomist, once said, "I have taught first-year medical students and first-year dental students, and I am now teaching graduate doctors, preparing for special fields of practice. I have excellent opportunity to observe a bird's-eye view of the results of medical school teaching in anatomy and I am more convinced than ever that the teaching of anatomy must be in fact the teaching of anatomy of the living."

Likewise, the roentgen ray has a distinct application for teaching purposes in the other fundamental branches of medicine—physiology, pathology, etc. It can be appreciated, therefore, that radiologic teaching is not restricted to the clinical, or the last two years of medicine, but a fair amount of time

is also given to the students in the first two years

It is most gratifying to observe that a large number of medical schools have separate Departments of Radiology, also that many of the radiologists connected with these departments hold professorial positions, and but a very small percentage occupy minor positions, such as assistants and lecturers in radiology. Then, again, we find that a total of 1,797 hours is assigned to the teaching of radiology in our medical schools and 293 hours in the Canadian schools, a grand total of 2,090 hours for both Canada and the United States.

This large number of hours devoted to the teaching of radiology is but another evidence of the importance in which radiology is held. Its recognition on a parity with other highly specialized branches of medicine was to be expected but that its recognition should come from such authoritative sources is the highest tribute paid to radiology since its very inception. While radiologists have always been proud of the marvelous progress of their specialty, they have refrained from any ostentatious demonstrations concerning its exalted position in medicine. On the contrary they have perhaps been too modest in proclaiming its many achievements. This may explain why so few of us know of the important position radiology occupies in the curricula of our medical schools. Even the Council on Medical Education of the American Medical Association apparently failed to appreciate fully its importance in this regard. A communication received from this body in 1930 in answer to an inquiry regarding radiologic teaching in medical schools, stated that most medical colleges do not require a student to take a course, or courses, in radiology. Most of them, the Council said, have short elective courses, either in the radiologic department or combined with medical clinics. Nor are there any requirements listed for radi-

ology in their publication, "Essentials of an Acceptable Medical College." They further state that all of the medical students receive some instruction in X-ray interpretation and this is continued in the interne, or fifth, year. The inference drawn from this communication was that radiology was not held in very high esteem by our medical schools. Yet we offer proof to the contrary.

There can be no argument as to the future of radiology in medicine, as it has established itself so firmly and become so indispensable that its continued progress can safely be predicted. In spite of the large number of hours now devoted to radiologic teaching, numerous medical schools believe that more time should be given this subject.

The present status of radiologic education is such that it should attract the attention of the Council on Medical Education of the American Medical Association, the National Board of Medical Examiners, the Federation of State Boards of Medical Examiners, the American College of Surgeons, the American College of Physicians, organized medicine, and organized radiology. All of these, by their kind consideration of the material contained in this issue of *RADIOLOGY*, can exert a tremendous influence in those States which have not as yet appreciated that a radiologist is a physician deserving of being considered on an equal basis with other members of organized medicine.

IN MEMORIAM

Arthur C. Heublem, M.D., died in Hartford, Connecticut, on April 8, 1932, at the age of 52, following a two months' illness from pneumonia, with complications.

Dr. Heublem became interested in radiology almost twenty-five years ago, and he devoted all his time and energy to this specialty until his death. He was a member of

all the radiological societies in this country, and on the staffs of several hospitals in Hartford and neighboring cities, either as attending radiologist or consultant. About two years ago he was appointed consulting roentgenologist to the Memorial Hospital, New York.

Those who knew Dr Heublein intimately were impressed by the unusual ability, earnestness, and sincerity which he exhibited in the practice of radiology. He was a true physician, ministering to the sick always to the best of his ability, and with the best interests of his patients at heart. The pleasure he derived from his work he regarded as sufficient compensation for his efforts.

On account of his innate modesty, Dr Heublein wrote few papers, although his knowledge of the subject and his personal contributions to it fully justified the publication of many more. He was actually distressed when his friends insisted that he read a paper at one of the radiological meetings.

Dr Heublein's keen analysis of the problems of radiation therapy and his ingenious methods of attacking them may be appreciated from the following examples. At the time when unfiltered glass "seeds" were used for interstitial radium therapy, and beneficial effects were attributed to the beta rays emitted by these seeds, Dr Heublein thought the beta rays were harmful and should be eliminated. Accordingly he conceived the idea of surrounding each glass seed in the tissue with a sufficient layer of bismuth paste to absorb the beta rays in the region where intense necrosis was produced by the seeds. He worked out a combination of trocar and syringe which made possible the practical application of this idea. After some preliminary experiments on animals, Dr Heublein treated some patients in this way both in Hartford and at the Memorial Hospital. The development of gold implants made the more complicated procedure with bismuth paste unnecessary but the fun-

The late Arthur C. Heublein, M.D.

damental idea is the same and is generally accepted to-day.

The experiment which best characterizes Dr Heublein's type of mind is the one which, indirectly, caused his demise. For years he had been disturbed by the poor end-results obtained by ordinary means of treatment in cases of generalized neoplastic disease, even of the radiosensitive type. He was convinced that the range of successful radiation therapy could be extended to include at least some of these patients, if the proper method were used. He set out to devise such a method, and he arrived at the following conclusions. Since tumors in these cases are apt to be present in any part of the body, the entire body should be irradiated. Furthermore, the irradiation should be such as to reach the deep structures. Hence a long target-skin distance and hard X-rays should be used. To avoid injury to

normal organs, while attempting to influence favorably the tumor processes, the patients should be irradiated with a very low intensity for a long time

Realizing that such a method of treatment could be given a thorough practical test only in a large cancer institution, Dr Heublein made arrangements with the Memorial Hospital to carry out this work. A suitable ward in which four patients could live in a beam of X-rays for two or three weeks at a time was constructed last year, and the first patients were treated in May. The clinical work has been carried out since then under the direct supervision of Dr Heublein and a special committee of the Medical Board.

Dr Heublein used to spend two days a week at the Memorial Hospital in connection with this work. He was so interested in the experiment that, without exaggeration, he spent the rest of the week in Hartford looking forward to his next visit to the Memorial Hospital. The last time he came to New York he was ill and was advised to return home immediately. But he stayed for another day, and a few days later hovered between life and death. He passed this crisis successfully, only to succumb eight weeks later.

Dr Heublein read a paper on his work at the Memorial Hospital at the meeting of the Radiological Society of North America in St Louis.¹ Since then, a great deal of interest has been shown in the experiment. Prominent radiologists in this country and abroad have said that the eyes of the radiological world are now focused on two experiments of equal importance. (1) The continuous irradiation of the entire body, and (2) the use of X-rays approaching the quality of gamma rays. The former has been referred to by some one as the "telepanirradiation method," but if such a term is to be used, the method will be known as the "*Heublein telepanirradiation method*"

As to personality and character, no adequate superlatives can be found to convey the proper meaning. And so this brief sketch may be concluded by saying that radiology has lost a lucid mind and devoted worker, and the world a real gentleman.

G. FAILLA, D.Sc.

ANNOUNCEMENTS

A MEMBER OF THE SOCIETY HONORED

The Royal Society of Medicine, of England, through its Secretary General, Mr Geoffrey R. Edwards, of London, has notified Byron H. Jackson, M.D., of Scranton, Pennsylvania, of his election as a Corresponding Honorary Member of the Society.

Others elected at the same time were Prof Gosta Forssell, of Stockholm, Sweden, Dr J. Murdoch, of Brussels, Belgium, Prof Dott Mario Ponzio, of Turin, Italy, Prof F. Haenisch, of Hamburg, Germany, and Prof H. R. Schinz, of Zurich, Switzerland.

The radiologists of America are particularly pleased to note that this eminent society has seen fit to select for such signal honor one who ranks so high in his own country as does Dr Jackson. The Radiological Society of North America likewise is sensible of the honor paid to its President-elect. The Journal tenders its congratulations.

INTERNATIONAL CONGRESS ON BILIARY LITHIASIS

This Congress will be held at Vichy Sept 19-22, under the presidency of Professor Paul Carnot. Of the four sections into which the program is divided, one is devoted to radiology and physiotherapy.

The program and full information may be obtained by writing to Dr J. Aimard, Secretary General, 24 Boulevard Capucines, Paris (IX), France.

¹Soon to be published.

CINCINNATI RADIOLOGICAL SOCIETY

The radiologists of Cincinnati have recently organized the Radiological Section of the Academy of Medicine of Cincinnati. Membership in this group is limited to those who practise radiology or roentgenology exclusively and who belong to the Academy of Medicine.

Informal monthly meetings are to be held in the various X-ray laboratories in the hospitals of the city. It is planned to present a radiological program before the entire Academy of Medicine each year. The officers for the current year are Samuel Brown, M.D., President, and Harold G. Reineke, M.D., Secretary.

CLEVELAND RADIOLOGICAL SOCIETY

The officers of the Cleveland Radiological Society are A. Strauss, M.D., President, and Merthyn A. Thomas, M.D., Secretary and Treasurer. The regular annual meeting takes place in May. Regular meetings are monthly on the fourth Monday. At each meeting a regular program is presented.

ANNUAL MEETING OF THE AMERICAN SOCIETY OF RADIOPHERS

The annual meeting of the American Society of Radiographers is to be held at the Hotel Statler, St. Louis, May 24-27, 1932.

A most interesting program is being prepared. The following are to present papers on "Doctors' Day," Thursday, the 26th:

D. A. Rhinehart, M.D., of Little Rock, Ark.; Harold Swanberg, M.D., of Quincy, Ill.; P. C. Schnoebel, M.D., of St. Louis; Llewellyn Sale, M.D., of St. Louis; Arthur E. Strauss, M.D., of St. Louis; F. D. Gorham, M.D., of St. Louis; John S. Young, M.D., of East St. Louis; Duff S. Allen, M.D., of St. Louis; Bertram C. Cus-

way, M.D., of Chicago; Robert S. Landauer, Ph.D., of Chicago; and Robert A. Arens, M.D., of Chicago.

Edwin C. Ernst, M.D., of St. Louis, is to act as Toastmaster of the annual banquet (Thursday evening), with the following speakers: LeRoy Sante, M.D.; Paul C. Schnoebel, M.D.; Paul C. Titterington, M.D.; E. C. Jerman, D.Sc.; and R. E. Lee. The speaking is to be followed by entertainment, music, and dancing.

Many interesting subjects are to be presented by the Radiographers, including a chest symposium by the St. Louis Society of Radiographers on the opening afternoon. Wednesday evening there is to be a Round Table Discussion led by D. A. Rhinehart, M.D., assisted by E. C. Jerman, D.Sc., to which the Radiographers may bring their confusing problems and an attempt will be made to solve them. The whole meeting will be well worth the time of anyone wishing to attend.

VIRGINIA H. ELLER, R.T.,
Chairman of Program Committee

NOTE

Readers will note the omission of Abstracts of Current Literature from this issue. This does not indicate a future policy or any lack of material, but is done simply that more space may be devoted to the papers which constitute this Educational Number.

BOOK REVIEWS

TECHNIQUE DE L'OSTÉO-SYNTHÈSE, ÉTUDE DE QUELQUES PROCÉDÉS By ROBERT DANIS, Professor of Clinical Surgery, at the University of Brussels. A paper volume with 162 pages and 149 figures. Published by Masson et Cie, Paris, 1932. Price, 55 francs.

This book presents a method of open reduction of fractures by the use of sutures of non-oxidizable steel wire. Much detail of technic

is offered, adequately explained and well illustrated. The author has described a table which may be used not only for abdominal work but, with its various attachments, is suitable for all sorts of fracture work (Invented by Man, of Angiers). Special motor drills, instruments to pass the wires, and instruments to secure these as sutures are described. Finally, an instrument to fuse the ends of the wire sutures is described and its use illustrated.

Another form of fixation by a special screw with threads on the distal end and much wider spaced than usual is described, also a fixation material of wire mesh held with wires, all of non-oxidizing steel, is described.

With these combinations of methods the author is able to accomplish reduction of the various types of fracture by open method. He describes special apparatus for taking pre-operative as well as post-operative X-rays.

Some space is devoted to a description of bone-grafting technic in non-union. A specially devised motor saw is illustrated, the graft being held in place by autogenous bone screws. The graft is of the type known in this country as "inlay grafts." No case illustration of this method is given. The method is no doubt valuable in the hands of the author, but the complexity of the apparatus described and of the methods used makes its wide adoption unlikely.

LES TUMEURS DES OS (TUMORS OF BONE) By

J. SABRAZES, Professeur à la Faculté de Médecine, Chef de service au Centre Anticancéreux de Bordeaux et du Sud-Ouest

G. JEANNIN, Professeur agrégé à la Faculté de Médecine, Chirurgien adjoint au Centre Anticancéreux de Bordeaux et du Sud-Ouest, R. MATHEY-CORNAT, Électroradiologue des Hôpitaux, Chef de Laboratoire au Centre Anticancéreux de Bordeaux et du Sud-Ouest. Pages, 437, with 165 figures. Published by Masson et Cie, Paris, 1932. Price, 80 francs.

This volume covers in a concise and well-arranged manner the present knowledge of bone tumors. The authors have arranged the material in a manner somewhat different from the classifications accepted in this country.

However, their reasons for thus classifying these tumors are well stated and, in the light of our present knowledge, may be said to be as acceptable as any of the other classifications thus far offered. In the introduction the classifications of Codman (Registry Classification), Kolodny, Ewing, and Geschickter are given.

The authors have divided their book into three parts, as follows:

I. Benign bone tumors, *i.e.*, chondromas, osteomas, exostoses, fibromas, lipomas, myomas, and angiomas of bone.

II. Giant-cell tumors. This part includes also bone cysts and osteitis fibrosa.

III. Malignant bone tumors, primary and secondary, *i.e.*, osteogenic sarcoma, Ewing's sarcoma and myelomas or chloromyelomas, and, finally, metastatic tumors.

In each section there is a discussion of the historical aspects of that particular tumor, its clinical and pathological manifestations, including the roentgenographic findings, the value of biopsy, and the treatment, including surgery and X-radiation. Each type of tumor is considered as fully as its importance seems to justify. The authors quote freely from other writers and there is included a well-arranged and very complete bibliography on the subject of bone tumors. The illustrations consist chiefly of excellent roentgenograms which are amplified in each instance by an adjoining pen-and-ink sketch depicting the significant changes. The photomicrographs have not reproduced well and in some cases are rather disappointing.

The authors have attempted and have succeeded quite well in bringing the subject matter pertaining to bone tumors up to date. This is a very difficult task, since in treating of a subject like bone tumors, changing conceptions are constantly before us. However, as a text-book devoted to this subject, this book can be recommended as among those of first rank.

PRÉCIS DE RADIO-DIAGNOSTIC By P. LAMARQUE, Professeur agrégé à la Faculté de Médecine de Montpellier, with a Preface by PROF. E. FORGUE, Associé National de

l'Academie de Medecine, Membre correspondant de l'Institut There are 374 radiographs and explanatory line drawings supplementing the text (746 pages) Published by G Doin & Cie, Paris, 1932 Price, 125 francs

This book aims to serve as a text for students of radiology and as a reference book for general practitioners For that reason the purely technical aspects of radiography, description of apparatus, controversial questions, and citations of the literature are largely omitted by the author, being treated in a superficial way merely to emphasize some clinical point The presentation of the subject matter is so facile and concise that anyone knowing even the fundamentals of French can read the book with much profit In the first brief chapter (pages 1-13) apparatus is discussed The skeleton and its lesions are considered in the second chapter (pages 23-249) The respiratory system is considered in Chapter III (pages 253-361), the cardiovascular in the fourth chapter (pages 363-398) The chapter on the gastro-intestinal tract covers pages 403-598, the seventh chapter (pages 601-636) concerns itself with the urinary tract, and the eighth (pages 639-668) the genital The "specialties" are next discussed briefly otorhinolaryngology on pages 671-684, ophthalmology on pages 685-690, neurology on pages 693-706, and stomatology on pages 707-715 In each chapter the normal is presented as a basis of comparison with the pathologic both in the text and in the reproductions of radiographs, each of which has an explanatory line drawing As far as the reviewer knows, this is the best single-volume presentation of the subject to the student or beginner in radiology, yet the specialist may well read the book with profit

The make-up of the book is first-class, though it does suffer from the mediocrity of many of the cuts It rather seems that it would have been worth while to make many of them full, rather than half, page in size, which fault will undoubtedly be corrected in future editions

TUMORS OF THE BREAST THEIR PATHOLOGY, SYMPTOMS, DIAGNOSIS, AND TREATMENT By SIR G LENTHAL CHEATLE, KCB, CVO, FRCS, Consulting Surgeon and Emeritus Lecturer on Surgery, King's College Hospital, London, Late Surgeon to and Lecturer on Surgery at King's College Hospital, London, Walker Prizeman, 1926-1930, and MAX CUTLER, BSc, MD, Director of Tumor Clinic, Michael Reese Hospital, Chicago, Late Clinical Fellow, Memorial Hospital, New York, Director of Research Division of Cancer Department of Hospitals, New York, Attending Radiation Therapist, New York City Cancer Institute J B Lippincott Company, Philadelphia, 1931 Pages 596, with 18 colored plates and 468 other illustrations Price \$12

This massive volume is the most recent and probably the best comprehensive study published on breast tumors The contents, collected from the literature and from thirty-five years of experience, reveals a wealth of material which is of inestimable value to all students of breast pathology The compilation of this material bespeaks tedious, persevering, and concentrated effort

The book is subdivided into fourteen chapters, each containing a complete bibliography The long, tedious discussions and occasional repetitions sometimes carry the reader far away from the original trend of thought and leave him with uncrystallized ideas

The microscopic, whole breast sections giving the detailed location and extent of tumefactions, together with the histopathological picture of the surrounding tissues, are one of the most attractive features of the book They are distinctly an advance in the study of breast pathology

The division of epithelial growths into desquamative hyperplasia and neoplasia is an interesting feature of the new classification Desquamative hyperplasia includes mazoplasia and cystiphorous changes Mazoplasia comprises the more physiological tumefactions of "chronic cystic mastitis" and may be treated by ovarian residue Cystiphorous desquamative epithelial hyperplasia is considered as the

other phase of desquamative hyperplasia and is distinguished from mazoplasia by its susceptibility to undergo benign and malignant changes. The malignant change is reported to be 20 per cent of all cases of breast carcinoma.

Cysts are believed to arise in the acini and carcinoma to arise in the ducts. Small cysts, which are usually seen in multicystic conditions, are more susceptible to benign and malignant changes. Because of the possibility of carcinoma arising in cystiphorous changes of the breast, these changes are considered as menacing neoplastic states and are treated by routine mastectomy, if malignancy is found, they are treated by radical amputation. Frozen sections are made after the removal of the breast.

All papillomas are believed to ultimately become malignant. A single papilloma is considered as having a bad prognosis for, unless a whole section of the breast be examined microscopically it is impossible to say that the growth is single. When removed, the stimulus causing the first papilloma may cause the formation of others, and for these reasons, a papilloma is regarded as a pre-cancerous condition and is treated by mastectomy.

The discussion of carcinoma is based on the location of the growth and is presented fully from the angles of histopathology, modes of extension, grades of malignancy, radiosensitivity, diagnosis by inspection, palpation, transillumination, and biopsy and treatment by surgery and irradiation. The diagnosis of carcinoma is rendered according to the cellular pathology regardless of the presence of intact basement membranes. A few such cases showing metastasis are demonstrated by the au-

thors. The differential diagnosis covers the major field of breast pathology.

Transillumination is thoroughly discussed. The points of differentiation between cystic, papillomatous, and solid tumors are made clear and a warning against over-illumination given.

Paget's disease of the nipple is amply covered by seventeen beautifully illustrated and completely worked up cases. The disease is considered as a primary one and though there seems to be a relation between duct carcinoma and Paget's disease, carcinomatous changes occurring in the breast are considered as spontaneous and independent.

Sarcoma occurs in from 2 to 39 per cent of breast tumors. Round-cell sarcoma is considered the most malignant and giant-cell sarcoma the least malignant. The majority of the sarcomas are radioresistant, but some are highly radiosensitive.

Irradiation, in general, more quickly affects anaplastic lesions. In carcinoma of the breast a small number of cases show great radiosensitivity, but the majority show slight, and, in a small number of cases, no radiosensitivity. In spite of the fact that cure in late cases, occurring in old individuals, cannot be effected, a growth restraint, by sublethal doses can be produced. Finally, it is admitted that irradiation is still in the experimental stage.

The book is an excellent survey of breast tumors and clearly demonstrates the degree to which breast pathology has become specialized. It is not the book for a novice, but nevertheless should prove an invaluable aid both as an atlas and as a reference to students, practitioners, and specialists.

A PRELIMINARY REPORT ON CONTINUOUS IRRADIATION OF THE ENTIRE BODY¹

By ARTHUR C HEUBLEIN, M.D.,² HARTFORD, CONNECTICUT

THE purpose of this paper is to present a new method of X-ray therapy consisting of continuous irradiation of the entire body at long distances from the tube. The following considerations have led the writer to the belief that this method may prove valuable in the treatment of certain types of neoplastic diseases.

1 As stated in the law of Bergonié and Tribondeau (1), "Immature cells and cells in an active state of division are more sensitive to the X-rays than are cells which have already acquired their fixed adult morphologic and physiologic characters."

A corollary of this law is that treatment should extend over a period sufficiently long to include the various times of mitosis of all the cells of the tumor. Under these conditions, it is supposed that, although a low intensity of radiation is necessitated by the long treatment, the dose received by the cancer cell at the time when it is most sensitive nevertheless is sufficient to destroy it or arrest its growth.

2 Dr Ewing (2), in his Caldwell Lecture, states "It is no longer possible to maintain that the body furnishes no aid in radiation therapy Effective irradiation

excites a favorable reaction on the part of the body as a whole. The nature of this reaction is complex and the factors are largely unknown. It is probably of much importance in the cure of malignant tumors by radiation." He further states, "The immediate improvement in health and strength in leukemic subjects following irradiation suggests some such action."

The biologic work of Kok and Vorlaender (3) and of Caspari (4) shows the importance of generalized body irradiation in that a considerably smaller part of a skin erythema dose is required to cause tumor regression than is necessary for equal regression of tumors treated locally. Similarly, the work of Murphy and Nakahara (5) shows that irradiation of the entire body of cancer mice stimulates a defense mechanism against cancer invasion.

3 Physical considerations demand as an ideal the most uniform distribution of radiation throughout the tissues undergoing treatment. Uniformity of distribution is necessary in order to take full advantage of the relative radiosensitivity of normal and neoplastic tissues.

4 Certain types of neoplastic diseases, which tend to become widely disseminated early in their course, cannot be controlled effectively by the usual local treatments. Since the early stages of such dissemination are often unrecognizable, and since the ear-

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting, at St Louis Nov 30-Dec 4 1931

²Dr Heublein passed away before proof of this paper could be submitted to him. It has been read by his friend, G. Tailla D.Sc. of Memorial Hospital, New York City. A sketch of Dr Heublein's life and work will be found in the May 1932 issue of RADIOLOGY.

liest possible treatment of metastases offers the best chance for their control, it appears that the greatest hope of success in treating these cases lies in the irradiation of the entire body

A practical method of treatment, based on the above considerations, involves the prolonged irradiation of the whole body with very hard X-rays at long target-skin distances. The question of the optimum duration of treatment immediately arises. While very little is known about this, we may, perhaps, get some information from experience in the usual radiation therapy.

In radium therapy, prolonged irradiation of low intensity is usually necessitated by the small quantity of radium available. In the use of permanent gold implants, where the major portion of the dose is delivered over a period of two weeks, the good results obtained may be attributed, at least in part, to the long irradiation time. Regaud, who has stressed the value of prolonged irradiation by means of needles of small radium content, recommends a treatment lasting about one week.

In roentgen therapy, at the Radium Institute of the University of Paris, divided treatments are used over a period of about three weeks. Pfahler's saturation method may be regarded as a variant of this technic. Twenty-five years ago, satisfactory and permanent results were obtained in the treatment of superficial skin neoplasms when small divided X-ray dosage, over long periods of time, was the only method of irradiation known. In the absence of any more definite information, it would appear that, in the method of continuous irradiation of the whole body, the duration of treatment should be between one and three weeks, at least in the beginning.

In the choice of the radiation to be used, one is limited by the X-ray tubes which can be obtained readily. For continuous operation, it is preferable not to run the tube at

its maximum rated capacity. At 185 K.V. and 3 ma, ordinary tubes work very well. With a filter thicker than 0.5 mm. of copper, the radiation is hard and quite homogeneous.

In order to obtain a nearly uniform distribution of radiation throughout the body, the target-skin distance should be long, in comparison with the thickness of the body. For the economic utilization of X-ray equipment it is desirable to treat several patients simultaneously. These two requirements can be met by having several patients in a room so planned that all are farther than 5 meters from the tube. To secure the desired prolongation of continuous treatment to one week or longer, at the same time restricting the dose to a safe amount, it is necessary to adjust the intensity of radiation received by the patient to the proper value. This can be done by a suitable choice of filter and distance, other conditions remaining constant.

Irradiation of the entire body with hard rays and at a very long distance, so that all parts of the body receive nearly the same dosage, is a new procedure. Simultaneously irradiating the entire hematopoietic and reticulo-endothelial systems, as well as the various glands of internal secretion, might lower the patient's vitality. Since the tolerance doses under these conditions are unknown, if we attempt to apply the above principles it is necessary to proceed cautiously. In the past, all portions of the body have been heavily irradiated in sections, without serious permanent damage being observed. It is a different matter, however, to irradiate them all simultaneously. Nevertheless, there must be some safe dose, tolerated by the whole body, which may be sufficient to produce beneficial results. Very radiosensitive tumors, one would expect, could probably be controlled by such a dose of radiation, acting directly upon the tumor cells. The more resistant tumors might

conceivably be controlled by an unknown, indirect mechanism, such as some influence on glandular structures, the circulating blood, the reticulo-endothelial system, or possibly the tumor bed, together with direct effect on the tumor cells, whereas either mode of action alone might not be sufficient to cause regression.

Reports have appeared in the recent European literature referring to *intermittent* treatment of the entire body or prolonged treatment of parts of the body. These reports, which are also encouraging as to the results that may be hoped for, may serve as a guide in deciding the dose to administer with the new procedure.

Tomanek (6) reports a case of myelogenous leukemia which responded brilliantly to prolonged irradiation of the spleen by means of the continuous application of radium for a period of three weeks. The patient, who had ceased to respond to small divided doses of X-rays, was in the terminal stage of the disease when continuous irradiation was begun.

Fuhs (7) has been using roentgen irradiation of the entire body in long continued or resistant dermatoses, with promising results.

In skin tuberculosis, Thedering (8) has used a "roentgen bath," combined with the usual therapeutic measures. He has reported satisfactory results.

Teschendorf (9) has irradiated the entire body in various forms of leukemia and in malignant granuloma. He has noted greater remission periods in these diseases than by using small ports in the ordinary way.

Chaoul and Lange (10) reported promising results in their treatment of Hodgkin's disease with generalized roentgen irradiation in weak doses. Twelve advanced cases so treated showed restoration of the patients to their full working capacity. Of these, 80 per cent have remained free from recurrence on an average of about two and one-

half years. The remaining 20 per cent died of intercurrent disease after intervals of from eight months to two and one-half years.

In the chronic, slowly developing forms of Hodgkin's disease, Schwarz (11) obtained excellent results with small protracted roentgen-ray dosage, giving from 8 to 10 treatments in 14 days. Finding that massive dosage given in one treatment had very little effect, he explained this by the hypothesis that a large number of cell areas may, at a given time, be in a condition of metabolic inactivity and, consequently, have a very low radiosensitivity. He concluded that small doses given over a protracted period have a greater chance to catch all the cells at the best moment for their destruction.

Frimann-Dahl and Forsberg (12) used interrupted dosage directed to the entire body in the leukemias, with the head, neck, and genitals screened. The exposures were from 12 to 18 minutes at one meter distance. They delivered from 0.1 to 0.8 of an erythema dose in a period of from four or five days to five weeks, using daily exposures. These authors maintain that general irradiation is superior to local roentgenotherapy because it is more lenient, enabling the patient to keep up his work longer.

For several years, the author has had in mind the practical application of the above-mentioned method of radiation therapy. The problem, however, requires intensive study of its different aspects, which can be best carried out in a well-organized cancer center. For this reason a co-operative arrangement was made with the Memorial Hospital, of New York, to initiate the work under the proper auspices. The necessary equipment was installed in May, 1931. The clinical work has been conducted under the direction of a special committee of the Hospital on experimental roentgenotherapy in co-operation with the author.

The X-ray machine employed was spe-

liest possible treatment of metastases offers the best chance for their control, it appears that the greatest hope of success in treating these cases lies in the irradiation of the entire body

A practical method of treatment, based on the above considerations, involves the prolonged irradiation of the whole body with very hard X-rays at long target-skin distances. The question of the optimum duration of treatment immediately arises. While very little is known about this, we may, perhaps, get some information from experience in the usual radiation therapy.

In radium therapy, prolonged irradiation of low intensity is usually necessitated by the small quantity of radium available. In the use of permanent gold implants, where the major portion of the dose is delivered over a period of two weeks, the good results obtained may be attributed, at least in part, to the long irradiation time. Regaud, who has stressed the value of prolonged irradiation by means of needles of small radium content, recommends a treatment lasting about one week.

In roentgen therapy, at the Radium Institute of the University of Paris, divided treatments are used over a period of about three weeks. Pfahler's saturation method may be regarded as a variant of this technic. Twenty-five years ago, satisfactory and permanent results were obtained in the treatment of superficial skin neoplasms when small divided X-ray dosage, over long periods of time, was the only method of irradiation known. In the absence of any more definite information, it would appear that, in the method of continuous irradiation of the whole body, the duration of treatment should be between one and three weeks, at least in the beginning.

In the choice of the radiation to be used, one is limited by the X-ray tubes which can be obtained readily. For continuous operation, it is preferable not to run the tube at

its maximum rated capacity. At 185 K.V. and 3 ma., ordinary tubes work very well. With a filter thicker than 0.5 mm. of copper, the radiation is hard and quite homogeneous.

In order to obtain a nearly uniform distribution of radiation throughout the body, the target-skin distance should be long, in comparison with the thickness of the body. For the economic utilization of X-ray equipment it is desirable to treat several patients simultaneously. These two requirements can be met by having several patients in a room so planned that all are farther than 5 meters from the tube. To secure the desired prolongation of continuous treatment to one week or longer, at the same time restricting the dose to a safe amount, it is necessary to adjust the intensity of radiation received by the patient to the proper value. This can be done by a suitable choice of filter and distance, other conditions remaining constant.

Irradiation of the entire body with hard rays and at a very long distance, so that all parts of the body receive nearly the same dosage, is a new procedure. Simultaneously irradiating the entire hematopoietic and reticulo-endothelial systems, as well as the various glands of internal secretion, might lower the patient's vitality. Since the tolerance doses under these conditions are unknown, if we attempt to apply the above principles it is necessary to proceed cautiously. In the past, all portions of the body have been heavily irradiated in sections, without serious permanent damage being observed. It is a different matter, however, to irradiate them all simultaneously. Nevertheless, there must be some safe dose, tolerated by the whole body, which may be sufficient to produce beneficial results. Very radiosensitive tumors, one would expect, could probably be controlled by such a dose of radiation, acting directly upon the tumor cells. The more resistant tumors might

hours This apparatus requires no X-ray technician to operate it, and the attending nurses are protected from exposure to X-rays by an automatic cut-out switch, which stops operation of the tube as soon as the door of the treatment room is opened The time that the machine is shut down is automatically registered A graph indicates the intensity of X-radiation emitted at all times The machine, which has been in constant operation since May, 1931, has required practically no attention

Our first X-ray tube, the old Coolidge deep therapy type, ran 768 hours before breaking down A new type Coolidge therapy tube with hard glass was substituted This has operated continuously up to November 5 for 2,161 hours, and is still functioning perfectly The current consumption has been 26 kilowatt-hours per day, entailing an expense of from \$1.00 to \$1.25

With one Coolidge tube, five patients are simultaneously irradiated, four continuously at long distances, and one at comparatively short range, 150 centimeters In the main ward in which there are four beds, the average distance to the far beds is 732 cm, approximately 24 feet, and, to the two near beds, 548 cm, approximately 18 feet The time required to administer a given dose, kilovoltage and milliamperage being constant, depends upon the thickness of the filter and the distance employed Up to the present, several different dosages have been used with varying irradiation times The tube has been operated at 185 KV and 3 ma so far With a filter of 2 mm of copper, the intensity of radiation at the near beds is 1.26 r per hour, at the far beds, it is 0.68 r per hour, measured in air Accordingly, to deliver 25 per cent of an erythema dose (that is, 25 per cent of 750 r) a patient in a near bed must be irradiated for 149 hours (or about 7.5 days at 20 hours a day) To receive the same dos-

age a patient in a far bed must be irradiated for 278 hours (or 13.9 days at 20 hours a day) Initially, a much heavier filter (5 mm copper) was employed in order to reduce the intensity of radiation, so that smaller percentages of an erythema could be administered without reducing the time factor

Although the lethal X-ray dose for a canary is unknown, on May 26, one was placed in a cage in the X-ray room with the patients, one-half the distance to the far beds This was done to give an indication of the possible harmful effects of prolonged irradiation Up to November 5, this canary had received a total of 5,000 r, or 6.3 skin erythema doses A second canary, used as a control, was placed outside the X-ray beam, receiving only a small amount of scattered radiation Both are still alive and are apparently in as good condition as when we started³

As this work is largely experimental, it has been necessary to proceed with the utmost caution and to increase doses slowly, starting with 5 per cent of a skin erythema and gradually increasing to 30 per cent This dose will be increased from time to time, if no harmful effects are observed

It has been our feeling that beneficial effects might be hoped for in the following groups of cases

- 1 The leukemias
- 2 The lymphomas
- 3 The radiosensitive carcinomas

At first, however, the main purpose was to establish a dose the entire body could safely tolerate Accordingly, cases which one would expect to influence favorably by any of our present well established methods of treatment were excluded All patients receiving treatment by this method presented a wide dissemination of their disease Many had radioresistant tumors

³The first canary died later after receiving about 7 erythema doses At autopsy it showed marked radiation changes

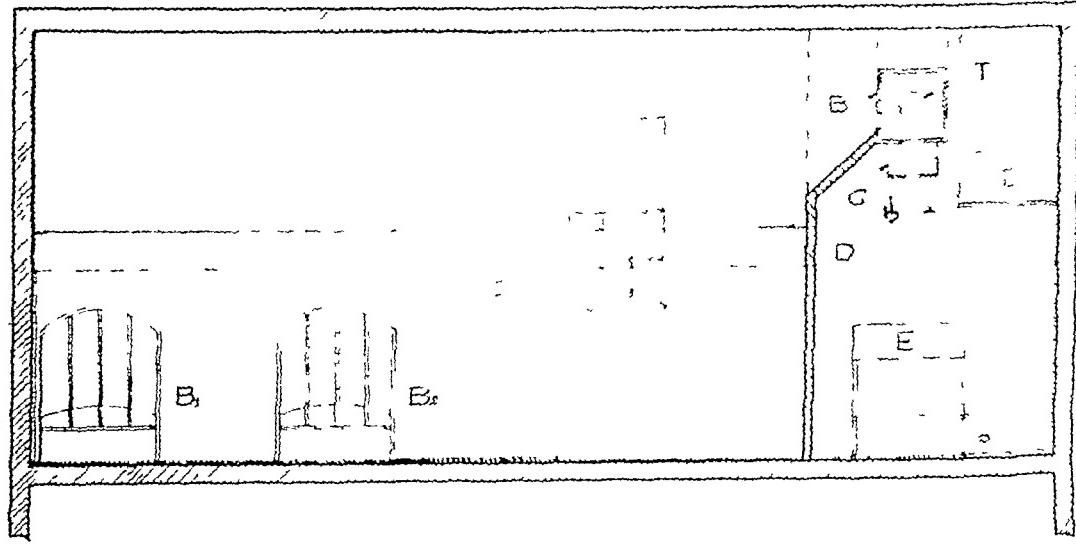

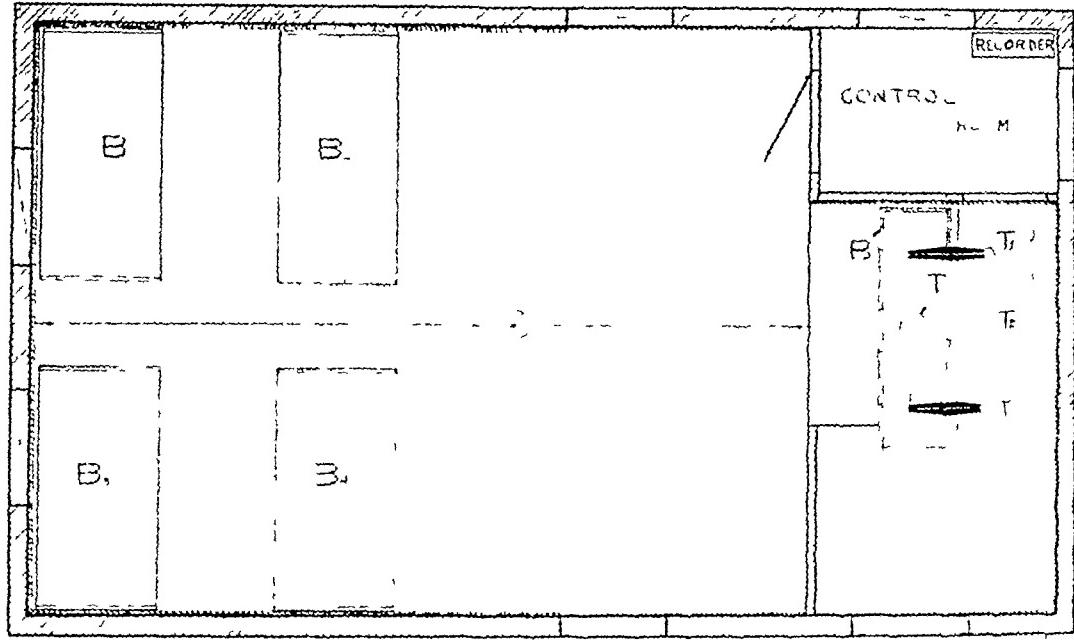

Fig 1 A schematic drawing of the lead-lined radiation ward. Here, with a single X-ray tube, irradiation of the entire body at long distances, as well as interrupted treatment at shorter distances, may be carried on continuously.

cially designed according to specifications drawn up by Dr G Failla. It is silent and automatic, and permits the continuous operation of a roentgen tube, day and night,

except for such time as is required for the necessary nursing care of the patients. In practice, we have found that the machine operates approximately 20 out of the 24

in the abdomen became slightly larger. The patient was able to resume work.

UNIMPROVED CASES (RADIOSENSITIVE GROUP)

Five patients were unimproved; one with lymphosarcoma, one with lymphatic leukemia, one with Hodgkin's disease, one with lymphatic pseudoleukemia, and one with myeloid leukemia. The first four received, respectively, 5.4, 5.9, 15.2 and 15 per cent of an erythema dose. The patient with myeloid leukemia, who received 15 per cent, has been too recently treated for us to draw any conclusions.

The remaining four patients in this group died; one had subacute Hodgkin's disease, one, chronic Hodgkin's disease, one, a lymphatic pseudoleukemia, and one lymphosarcoma. They received, respectively, 5.6, 6, 10, and 25 per cent of an erythema dose. The deaths in these cases could not be directly attributed to this therapeutic procedure. One died of bronchopneumonia, and three of the natural progress of their disease.

RADIORESISTANT GROUP

There were eight patients who were treated at long distances. Two showed symptomatic improvement.

A patient who had an adenocarcinoma of the breast, with metastases to the lungs and lumbar spine, received 15 per cent of an erythema dose. In this case there was considerable relief from pain caused by bone metastases.

A patient who had carcinoma of the breast with widespread metastases to the lungs, lumbar spine, and pelvis received 15 per cent of an erythema dose, resulting in relief from pain caused by bone metastases.

Of the unimproved patients, there were three who had metastatic carcinomas of the breast. One received 8.4 per cent of an erythema dose and two received 15 per cent.

The fourth patient, who presented metastatic melanoma, received 30 per cent of an erythema dose. However, he has been treated too recently to permit one to draw any definite conclusions.

The other two patients in this group died. One had a widespread metastatic squamous-cell carcinoma of the left renal pelvis and died of coronary thrombosis. The other had a carcinoma of the breast with metastases to the lung. They received 6 and 15 per cent of an erythema dose, respectively.

A thorough physical examination, tumor measurements, basal metabolism estimate, blood pressure, and routine urine examination are made on all patients treated by the continuous method before they are admitted to the treatment ward. Special laboratory tests are as follows:

- 1 A biopsy specimen
- 2 Blood Wassermann
- 3 Blood calcium
- 4 Blood phosphorus
- 5 Blood sugar
- 6 Non-protein nitrogen
- 7 Blood CO₂ combining power
- 8 Blood P_H
- 9 Icterus index
- 10 Complete blood count
- 11 Fragility test
- 12 Platelet count

A careful follow-up system is maintained of these tests, which are made before, during, and after the treatment. In this small series, no changes attributable to the treatment were noted in any of the tests. Thus, valuable information of the tolerance dose has been accumulated, based on the general reaction of the body.

The results obtained so far, with the continuous long distance method of treatment, are not striking, but some definite evidence of improvement has been noted, particularly in the patients with radiosensitive neoplastic disease who have received the higher dosages. In this connection, it should be noted

From the latter part of May, when the first patient was placed in the X-ray ward, until the middle of October, 20 patients were treated at long distances. The doses delivered varied from 5 to 30 per cent of an

Following the first course, in which 87 per cent of an erythema dose was delivered, the patient showed improvement, evidenced in the regression of his nodes and a feeling of general well-being. Three months later, he

Fig 2. Photograph of the ward for continuous irradiation of the entire body at long distances.

erythema, only one receiving this latter dose. Of the 20 patients treated at long distances, 12 are classified in the radiosensitive, and eight in the radioresistant group.

RADIOSENSITIVE GROUP

- 1 Two cases of lymphosarcoma
- 2 Four cases of Hodgkin's disease
- 3 Six cases of leukemia
 - (A) One myeloid
 - (B) Two lymphatic
 - (C) Three lymphatic pseudoleukemia

Two of the patients in this group showed distinct improvement and a third was moderately benefited.

IMPROVED CASES (RADIOSENSITIVE GROUP)

A patient with widely disseminated lymphatic leukemia, with a mass in the abdomen, received two courses of treatment

was admitted for a second course of treatment, receiving at this time 16.3 per cent of an erythema dose, a total of 25 per cent of an erythema dose for both courses. This patient showed satisfactory progress as far as a general feeling of well-being was concerned, a gain in weight, and almost complete regression of his nodes.

A patient having Hodgkin's disease with widely distributed nodes and a mass in the abdomen, who received 15 per cent of an erythema dose over a period of 253 hours, showed distinct improvement in general well-being. The nodes regressed appreciably in size and the patient gained in weight.

A patient, having lymphatic leukemia with widely distributed nodes and a mass in the abdomen, received 15 per cent of an erythema dose. This was followed by a general improvement in well-being and diminution in the size of the nodes, although the mass

administered With proper precautions, this can be done without danger of exceeding the safety limit

In order to utilize the X-ray machine to its full extent, a treatment table was placed beneath the tube in a separate room Here patients received intermittent treatments at 150 cm distance through ports 27 cm in diameter, or smaller, if desired The X-ray beam is filtered through 1 mm copper and 4 mm aluminum As the intensity delivered is 306 r per hour, it requires 24.5 hours to deliver 750 r Two ports cover one side of the entire torso The depth dose at 10 cm with this field is 58 per cent

At this shorter distance (150 cm), 10 cases were treated with interrupted dosages, delivering 61.2 r through each of two ports daily until a total of from 750 to 1,000 r to each port had been attained The time consumed is approximately from 12 to 24 days

A total of 10 cases, four radiosensitive and six radioresistant, were treated as follows

Radiosensitive Group—1 A patient who had a recurrent teratoma testis, who has received prophylactic radiation directed to the abdomen, has remained well for four months Previously radium had been used for recurrences in the scar, causing their complete regression

2 A patient with recurrent teratoma testis with a large mass in the abdomen, which resisted high voltage treatment one month before the present treatment, showed complete regression of the tumor He has remained well for four months

3 A patient with a very extensive Grade IV carcinoma of the neck of the urinary bladder, with metastases to the lung, showed complete regression of the tumor masses in the lung in six weeks from the beginning of the treatment There was also marked improvement in the size of the bladder tumor which has regressed to one-third its former size This patient received 800 r to

the chest and abdomen anteriorly and posteriorly so that the whole torso was covered A second course of treatment is now being given When admitted for treatment, this patient appeared to be in a terminal stage of his disease and received repeated blood transfusions In spite of his generally bad condition, the tumor regression has been most satisfactory

4 A patient who exhibited an advanced lymphosarcoma with metastases to the pubic bones, to the nodes, and mediastinum, showed no distinct improvement

Radioresistant Group—1 No improvement was noted in an adult type teratoma testis with widespread metastases to the lung and abdomen

2 Two carcinomas of the urinary bladder, Grade II, showed no regression after receiving 1,000 r anteriorly and posteriorly

3 A carcinoma of the cardiac end of the stomach showed no improvement This diagnosis was based on clinical and X-ray findings only

4 A primary Grade II carcinoma of the lung showed no improvement

5 A hypernephroma with metastases to the lungs showed no improvement

To date the results with the short distance intermittent technic, while more striking than the long distance method, may be accounted for by the greater total dosage delivered The number from which to draw conclusions, however, is too small

SUMMARY

1 Theoretic considerations and practical observations led the author to the conclusion that it is desirable to test the value of prolonged continuous irradiation of the entire body in certain types of neoplastic diseases

2 At the Memorial Hospital, an automatic X-ray machine is in use in a special lead-lined ward in which four patients may be simultaneously and continuously irradiated

that the maximum total dose administered so far is probably too low, since it has produced no detectable blood changes. Furthermore, all the patients selected for this

mode of treatment have been in the advanced stages of their diseases. Accordingly, it is desirable to continue the experiment and to increase gradually the total dose.

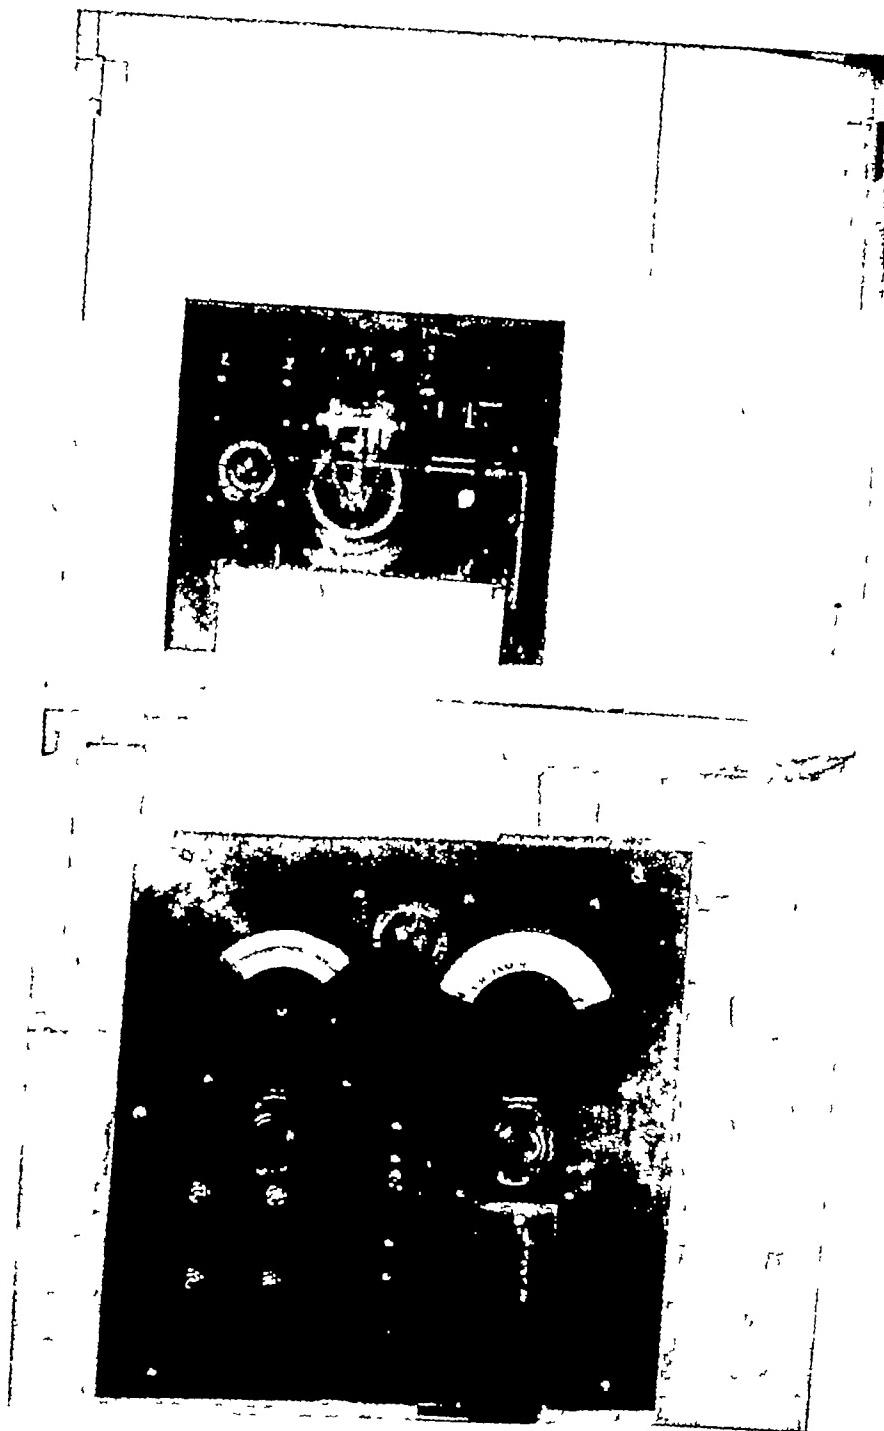

Fig. 3 Panel board of X-ray control and recording meter

DISCUSSION

DR. L. F. CRAVER (New York City) I would emphasize three points in connection with this work. They are the method is new, it appears to be safe, within limits, and it appears to be valuable.

When this method was first proposed to us at Memorial Hospital, it encountered a feeling of considerable skepticism and uncertainty. So many biologic factors are involved about which little is known that we felt obliged to begin with very small doses and to proceed cautiously, watching the condition of the patients carefully. Particularly we made frequent counts of the blood cells and blood platelets, together with numerous other laboratory tests, so that, as far as possible, we might avoid exceeding the body tolerance dose. It should be emphasized that, up to the present time, our selection of patients for this form of treatment has been purposely restricted to those whose prognosis was hopeless with any other form of therapy.

We began seven months ago with 5 per cent of a skin erythema dose, and have found ourselves able to increase this gradually by successive steps to 10, 15, 25, 30, 40, and even 50 per cent. To our surprise, frequently repeated blood counts and other tests have, in all instances, failed to show any consistent change that could be ascribed to radiation effect, except in the leukemias, in which the usual decrease in the number of white cells has occurred. There has been no instance of marked drop in blood platelets nor has purpura hemorrhagica occurred in any case.

As to changes in the menstrual function, only three women were below the menopause age. One of these was a young woman with generalized Hodgkin's disease, in whom the menses had been suppressed for several months before she was treated. In her case, apparently the disease itself had caused the amenorrhea. The other women who were still having menstrual periods have been treated too recently to permit observations as to the effect of the treatment on this function. No attempt has been made to shield the eyes, hair of the scalp, or genitals.

To sum up, then, the safety of the method,

we feel certain that, with doses up to 50 per cent of a skin erythema, delivered to the entire body with the factors of distance and filtration which we are using, no deleterious effects have been detected. How much further we can increase the dose we do not know. That is the part of the problem that lies immediately before us.

The method promises to be valuable. Thus far, 27 patients have been treated. There were 15 in the radiosensitive group, and 12 in the radioresistant group. The radiosensitive group comprised one case of myelogenous leukemia, three of lymphatic leukemia, four of pseudoleukemia, five of Hodgkin's disease, and two with lymphosarcoma. In the radioresistant group there were five with carcinoma of the breast with metastases to the bones or lungs, or both, one with squamous carcinoma of the renal pelvis with extensive lymph node metastases, one ovarian carcinoma with extensive lymph node metastases, three of metastasizing melanoma, and one with widespread metastases in the bone from a prostatic carcinoma.

Four of the patients in the radiosensitive group died, all, we believe, of the natural progress of the disease. Three patients in the radioresistant group died, one of acute cardiac failure, the other two of the natural progress of the disease. None of these deaths, so far as we could see, could in any way be ascribed to the effects of the treatment.

We have noted some distinct beneficial effects, particularly with the larger doses. Two of the patients with metastasizing cancer of the breast involving bones had relief from pain. The patient with metastasizing prostatic carcinoma, who received recently a 50 per cent dose, has had considerable relief from pain, accompanied by a distinct improvement in general condition.

It is particularly in the radiosensitive group, however, that we have, in some instances, seen striking improvement. One recent case—pseudoleukemia, with generalized lymphadenopathy and bilateral parotid and temporal tumors—showed regression while under treatment. This regression has continued and the patient is markedly better in general condition.

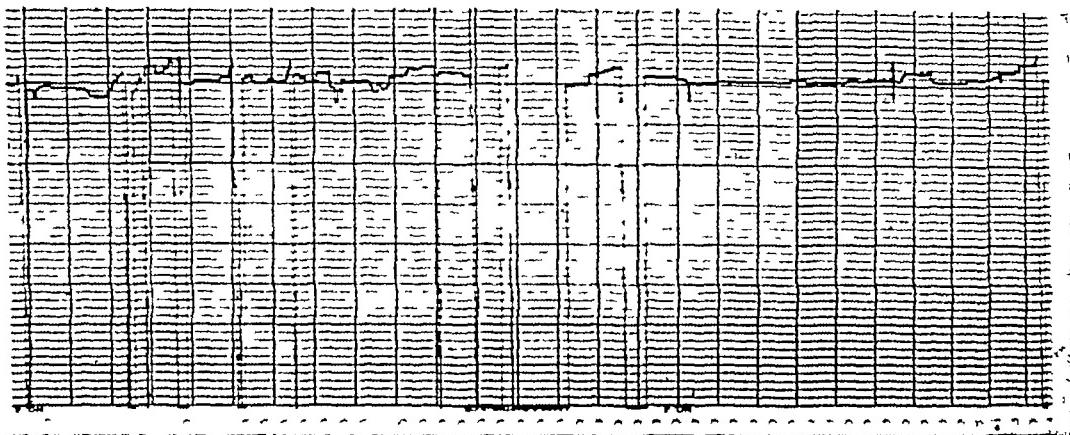

Fig 4. A graph indicating the intensity of X-rays emitted, as well as the periods and length of time of interruptions in the treatment

ated. In addition, provision has been made for the administration to other patients of local intermittent treatments at a target-skin distance of 150 cm, making use of the same X-ray tube. This machine is dependable and economical in operation.

3 The cases selected for the long distance irradiation method are well advanced, and many present widely disseminated lesions. This choice is made primarily to establish a tolerance dose for the entire body, and in the hope of observing some beneficial clinical manifestation, such as a stimulation of some defense mechanism against malignant disease.

4 The maximum dose which the entire body will tolerate has not yet been established. However, investigations to determine this dose are being carried on. At present, we believe that 25 per cent of a full erythema dose of 750 r measured in air, delivered at the rate of 126 r per hour, is a safe dose. Clinical observations and extensive special laboratory tests confirm this opinion.

5 To date, no pronounced beneficial clinical manifestations have become evident, although in some instances encouraging improvement has been noted. It is too early

to say whether or not a favorable systemic effect has been, or can be, produced by this method.

6 With intermittent local treatment at 150 cm, definite regressions have been noted in the radiosensitive group of cases.

7 The number of cases in both groups is too small to permit any definite conclusions at this time, although it is believed that the evidence accumulated thus far fully warrants the continuation of the experiment with increasing dosage, within safe limits.

CANCER IN THE YOUNG

By M J SITTENFIELD, M D, NEW YORK

THE popular conception of a definite cancer age has overshadowed the actual fact that cancer occurs quite frequently in the young. The occurrence of cancer in childhood has been distinctly underestimated and its rarity very much exaggerated, an attitude which really accounts for its scanty mention by most writers. It is my belief, however, that much more attention should be accorded this chapter of malignancy, both by the cancer student and also the clinician. For example when isolated cases of cancer in the young are reported in the literature, it is surprising to note that these neoplasms are described usually in the terminal stage, or at a period when widespread metastases compel recognition, especially tumors which belong to certain well defined groups. Obviously a great many are overlooked, because it is the common experience that when a single neoplasm in a child is reported, within a comparatively short time a surprisingly large number of similar cases are described.

In a survey of cancer in the young, it is particularly noticeable that writers who have given much thought to this subject generally record a remarkably large number of cases.

Cushing (1) for instance, cites that out of 1,108 cases of intracranial tumors in his service at the Peter Bent Brigham Hospital, in Boston, from 1913 to 1926, 20 per cent occurred during the first two decades of life. He further states that half of these tumors should have been diagnosed at the bedside, and postulates, in his series, a definite clinical syndrome. He suggests that the recognition of certain well defined symptoms should point the way to early diagnosis.

Leavitt's report (2) of 350 cases of brain tumors, from the records of the Philadel-

phia Hospitals, states that clinically only 23 were recognized in children. He explains, however, that many brain tumors were not diagnosed clinically and believes that the larger proportion in Cushing's series was due to the greater "tumor consciousness" on the part of the examining staff at the Boston Hospital.

Tooth (3) analyzed 500 intracranial new-growth verified either at operation or post-mortem examination at the National Hospital in London, over a period of ten years, and determined that 139, or 27.8 per cent, were in individuals from one to twenty years of age.

A similar condition of affairs exists in malignant growths of the spinal cord. For example, in a collection of 251 tumors of the spinal cord from autopsy records, Schlesinger (4) found 60 tumors, or nearly one-fourth, in children under fifteen. In this series, 33 occurred before the age of nine, and 27 between the ages of nine and fifteen.

Quite in keeping with this is the frequency of neuroblastomas of the suprarenals and tumors about the kidney. The studies of Warner (5), Wollstein (6, 7), Sturtevant and Kelly (8), Kwartin and Twiss (9), Bendixen and Lamb (10) and others, indicate that nearly 20 per cent of all tumors in childhood are renal tumors. It is particularly noticeable that the greatest proportion of these tumors occur in the first five years of life, and are not so common after the fifth year.

Primary carcinoma of the liver is another group not uncommon in children, according to Rosenbusch (11), who collected 32 cases, of which 20, or nearly two-thirds, were in children under five years of age.

Aside from the tumors just mentioned sarcomas of the ovary in the young are not

One young man, with Hodgkin's disease, showed good regression of nodes and a gain in weight. One patient with pseudoleukemia, who early in the course of the work had received, without improvement, a dose of approximately only 8 per cent, was later brought back to receive enough additional treatment to bring the total dose up to 25 per cent. With this dose his improvement has been definite. Another patient with lymphatic leukemia, who received 15 per cent, has improved sufficiently to be able to return to work.

DR G FAILLA (New York City). I can add little to the present discussion, because it is almost entirely a question of the dose which patients can tolerate under these conditions.

As far as the machinery is concerned, I may say that it is very simple, requires little attention, and has given us practically no trouble. We made a large ionization chamber in order to produce a current large enough to operate a Leeds and Northrup recorder. In this way we obtain a graphic record of the intensity of radiation used during a treatment and the intervals during which the machine was shut down. Furthermore the chart enables us to tell at a glance how the machine is functioning at any time, and particularly dur-

ing the night when no technical help is available.

I am very much interested in the experiment, however, on account of its relation to the problem of differential action we have been studying in the laboratory. The prolongation of the time during which the radiation is administered is one of the factors which may influence favorably the relative radiosensitivity of pathologic and normal tissues. That is, the prolonged treatment may make it possible for the normal tissues to receive, without injury, a dose of radiation which at the same time is injurious to the pathologic tissues. It is too early to say whether or not such is the case in this experiment, but the results are encouraging.

DR HEUBLEIN (closing). One of the interesting observations made in this experiment is that, with the administration of amounts of radiation ranging from 5 to 25 per cent of an erythema dose to the entire body, there has been no depression in the number of white cells. The white cell count is known to be a very sensitive index of radiation effect. Nevertheless, definite regression of some tumors has been observed with such small doses as we have administered.

X-ray Tubes at High Voltages.—Prof C C Lauritsen, of the California Institute of Technology, has discussed the working of the 900,000 volt X-ray tube with which it is hoped soon to attempt biological applications. Dr Lauritsen produced the high voltage by means of transformer as in the conventional X-ray tube operation, whereas Dr M A Tuve, of the Carnegie Institution of Washington, uses a form of Tesla coil with which higher voltages are possible. Dr Lauritsen's rays are more intense and dangerous to the worker.

Dr W D Coolidge, in discussing the difficulties encountered in designing X-ray tubes for operation at these high voltages, has said that a great reduction in both space and electrical hazard is possible by operating both the tube and the high voltage source immersed in oil. No portion of the high voltage circuit will be exposed to the air. The glass used for the tube should be free from the elongated bubbles found generally in drawn glass tubing.—*Science Service*

CANCER IN THE YOUNG

By M J SITTENFIELD, M.D., NEW YORK

THE popular conception of a definite cancer age has overshadowed the actual fact that cancer occurs quite frequently in the young. The occurrence of cancer in childhood has been distinctly underestimated and its rarity very much exaggerated, an attitude which really accounts for its scanty mention by most writers. It is my belief, however, that much more attention should be accorded this chapter of malignancy, both by the cancer student and also the clinician. For example, when isolated cases of cancer in the young are reported in the literature, it is surprising to note that these neoplasms are described usually in the terminal stage, or at a period when widespread metastases compel recognition, especially tumors which belong to certain well defined groups. Obviously a great many are overlooked, because it is the common experience that when a single neoplasm in a child is reported, within a comparatively short time a surprisingly large number of similar cases are described.

In a survey of cancer in the young, it is particularly noticeable that writers who have given much thought to this subject generally record a remarkably large number of cases.

Cushing (1) for instance, cites that out of 1,108 cases of intracranial tumors in his service at the Peter Bent Brigham Hospital, in Boston, from 1913 to 1926, 20 per cent occurred during the first two decades of life. He further states that half of these tumors should have been diagnosed at the bedside, and postulates, in his series, a definite clinical syndrome. He suggests that the recognition of certain well defined symptoms should point the way to early diagnosis.

Leavitt's report (2) of 350 cases of brain tumors, from the records of the Philadel-

phia Hospitals, states that clinically only 23 were recognized in children. He explains, however, that many brain tumors were not diagnosed clinically and believes that the larger proportion in Cushing's series was due to the greater "tumor consciousness" on the part of the examining staff at the Boston Hospital.

Tooth (3) analyzed 500 intracranial new-growth verified either at operation or post-mortem examination at the National Hospital in London, over a period of ten years, and determined that 139, or 27.8 per cent, were in individuals from one to twenty years of age.

A similar condition of affairs exists in malignant growths of the spinal cord. For example, in a collection of 251 tumors of the spinal cord from autopsy records, Schlesinger (4) found 60 tumors, or nearly one-fourth, in children under fifteen. In this series, 33 occurred before the age of nine, and 27 between the ages of nine and fifteen.

Quite in keeping with this is the frequency of neuroblastomas of the suprarenals and tumors about the kidney. The studies of Warner (5), Wollstein (6, 7), Sturtevant and Kelly (8), Kwartin and Twiss (9), Bendixen and Lamb (10), and others, indicate that nearly 20 per cent of all tumors in childhood are renal tumors. It is particularly noticeable that the greatest proportion of these tumors occur in the first five years of life, and are not so common after the fifth year.

Primary carcinoma of the liver is another group not uncommon in children, according to Rosenbusch (11), who collected 32 cases of which 20, or nearly two-thirds were in children under five years of age.

Aside from the tumors just mentioned, sarcomas of the ovary in the young are not

infrequently encountered Downes (12) reported 26 cases of ovarian tumors in children, aged less than ten years, and of these 16 were malignant tumors On the other hand, the Mayo Clinic reviewed 564 malignant tumors of the ovary operated upon from 1916 to 1926, and found only 5 in young persons less than twenty years of age Doran (14) cites one in a seven-months fetus, and one in an infant twenty-two months old Recently Hunt (15) has described a carcinoma of the ovary in an infant seventeen months old

Quite a number of carcinomas of the stomach and intestines are detailed in the literature Uhlhorn (16) gathered 69 cases of cancer of the rectum in children under fifteen So, too, newgrowths of the internal secretory glands as the thyroid, thymus, pancreas, prostate, etc., are described by Calvin (17), Slesinger (18), Lacquierre and Bouchard (19), and a host of others Sarcomatosis in the skull and chest have been reported by Lattes (20), Peacock (21), and others Parker and Stokes (22), in 1925, published reports of ten intra-ocular sarcomas in children which occurred in their own practice

From this brief outline of the occurrence of neoplasms in the young it is increasingly evident that they are not as rare as one would assume, and the reason that they are not more frequently diagnosed is due, perhaps, to a lack of concentrated effort Referring again to Cushing's series, 213 of which occurred during childhood, it would seem that, if these brain tumors in children were more carefully tabulated, other observers might find similar conditions

As a general survey, then, let us consider briefly the most frequent types of neoplasms in children in order to project and stress the outstanding features and thereby facilitate early recognition It would serve our purpose best to classify the more common types of tumors occurring in children into the following groups

- (1) Cerebro-spinal Tumors
 - (a) The intracranial tumors
 - (b) Those of the spinal cord
- (2) The malignant tumors of the suprarenal and the renal region
- (3) Malignant tumors of the bone
- (4) Miscellaneous group of carcinomas and sarcomas
- (5) The lymphomas, including the blood tumors as a supplementary group

1 CEREBRO-SPINAL TUMORS

(a) The Intracranial Tumors—In this group, the symptoms express themselves in such constant and definite manner that it would appear that early diagnosis ought not to be too difficult. For example, in a child with unexplained vomiting, headache, and unsteadiness of the extremities, without nausea or digestive disturbances, in conjunction with a perceptible enlargement of the head, the clinician should be on guard to examine the eye grounds every week or two, until the presence of a tumor in the brain has either been established or ruled out

The more common types of brain tumors in children are (a) the medulloblastomas and (b) the astrocytomas These neoplasms make up such a large proportion of brain tumors that practically three out of four of all the intracranial newgrowths in childhood fall into this group The medulloblastomas are essentially tumors of pre-adolescence, occurring as a rule in the midcerebellar or fourth ventricular region

The second type, or astrocytoma, is met with nearly twice as often as the medulloblastoma This also arises from the roof of the fourth ventricle, but differs from medulloblastoma in its comparative benignity, insofar as it grows very slowly While the astrocytomas are also tumors of the young, a great many are encountered later in life, due perhaps to their slower rate of growth

Next in importance to the gliomas in the

young are the congenital tumors of the brain. This group is made up chiefly of the adenomas. Generally they interfere seriously with the function of the pituitary body. Lately much interest has been manifested in this group of tumors.

While all of these tumors generally exist from early childhood, in only 20 of the 71 tumors in Cushing's series did the symptoms become recognizable before adolescence.

In 1890 Starr (23) reported a series of 300 brain tumors in children, and it is a matter of much speculation that, in his series, 50 per cent of the lesions were diagnosed as tuberculomas. Cushing, on the other hand, found these tumors very rare, only six cases being met with in his series, and assumes that this difference may be due to a decrease in tuberculosis in general. The infrequency of tuberculomas has been confirmed by other writers. Generally speaking, however, when they do occur the tuberculomas are more malignant than the true neoplasms.

(b) *Tumors of the Spinal Cord*.—In marked contrast to the brain tumors, the symptoms of the spinal tumors are not so clearly defined, even in tumors of the same segmental level. Lumbar puncture will often induce an increase in the sensory symptoms if they are already present, and this phenomenon is of great value as an aid to diagnosis. The lumbar manometric test appears to be of greatest significance, and Stookey (24, 25) is of the opinion that, in half of the cases, diagnosis would have been impossible without this test. He emphatically states that this should be the routine procedure in every spinal cord lesion.

Tumors of the spinal cord in children fall also into two groups: (a) the intra-medullary, and (b) the extra-dural.

Tumors of the intra-medullary group vary greatly in their symptomatology, as well as in their histopathology. Owing to the lack of a definite clinical syndrome,

many of these cases go unrecognized, as the bladder and rectal disturbances occur only late in the disease. The extra-medullary tumors belong either to the sarcoma or the fibrosarcoma type. The average age of the children in the intra-medullary group in Stookey's series was eleven years, while the extra-dural spinal tumors are usually encountered in children averaging three years.

2 MALIGNANT TUMORS OF SUPRARENAL AND RENAL REGION

The suprarenal tumors occurring in children have been recognized perhaps with greater frequency than the intracranial tumors. They occur anywhere from the age of three months up to puberty. In studying the clinical history of these tumors, one is impressed with the similarity of the subjective symptoms in this group of neoplasms.

Robert Hutchinson (26), in 1907, was the first to draw attention to these tumors which he called the "suprarenal sarcomas." The clinical and pathologic features of these cases run almost parallel, in the majority, the first symptom noticed is single or multiple swellings about the bones of the skull. Following, or sometimes preceding this, proptosis of one or both eyes is observed. In most of the children, discoloration of the eyelid on one side was the leading symptom, and in some instances this was the first one to attract attention. An abdominal tumor in one or the other loin was positive on palpation in about half of the children. Anemia also was a striking feature in every case. These tumors generally are highly malignant, and run a very rapid course, the duration in the oldest child being about six months.

A large percentage of these neoplasms occur in the first five years of life, and are relatively infrequent afterwards. From the suggestive symptoms it would seem that early recognition of these tumors ought to promise a better prognosis, providing they

are seen before the appearance of widespread metastases in the skull and other parts of the short bones. In a large majority of cases, the tumor should be recognized and of greatest diagnostic value is the ecchymosis of one eye, generally on the same side as the affected suprarenal. As these growths give rise to involvement of the orbit, Sturtevant and Kelly have made it serve a diagnostic purpose, since unilateral swelling of the orbit, in their opinion, casts definite suspicion of metastases from a suprarenal tumor.

There is another type of suprarenal tumor described by Pepper (27) which is not quite as malignant as the neuroblastoma of Hutchinson. This neoplasm gives rise to rapid and progressive distention of the abdomen, without ascites, though there is jaundice, fever, and enlargement of the liver. Pepper's tumor is made up of highly differentiated cells more closely approaching the mature type, grows more slowly, and is relatively benign, in contrast to the Hutchinson type, which is very malignant.

Wollstein described 18 primary renal neoplasms occurring in children between the ages of four months and six years. Four children with a solid type of tumor survived its surgical removal ten months or more. In other words, the prognosis is not entirely hopeless, though the operative mortality is very high.

3 MALIGNANT TUMORS OF THE BONE

Only a brief discussion of this group of bone tumors is possible at this time. This subject is being studied by a special committee of the American College of Surgeons and others, but no definite report has as yet been issued. It is of interest, however, to point to a collection of 864 bone tumors by Christensen (28), in which the age of the patient was definitely ascertained, and nearly 40 per cent were under twenty. The larger number occurred in the latter half of

the second decade. Of the 376 osteogenic sarcomas, 174, or nearly one-half, occurred before the twentieth year, of the 341 giant-cell tumors, 170, or again one-half, were in persons twenty years old or less. In his series of 84 endothelial myelomas, he found that 47 were in children and that the proportion of male to female was 2 to 1.

According to his observations, 93 per cent of all bone tumors in childhood are of one of three types: (1) Osteogenic sarcomas, 48 per cent, (2) giant-cell type, 24 per cent, (3) endothelial myelomas, 20 per cent.

Multiple myelomas have heretofore been considered a disease of adult life, but in Christensen's series, 39 per cent occurred before the twenty-first year.

4 MISCELLANEOUS GROUP OF CARCINOMAS AND SARCOMAS

Only a cursory consideration can be given to this group. From what has been said before, they arise in any part of the body and require considerable amount of skill for detection. The more important, those of the liver, stomach, intestines, rectum, thyroid, thymus, ovary, etc. have already been referred to in a general way. A diagnosis, while difficult, can be made by elimination.

5 THE LYMPHOMAS, INCLUDING THE BLOOD TUMORS AS A SUPPLEMENTARY GROUP

This group takes in the lymphomas, and, as an accessory group, the leukemias. In the opinion of many authors the analogy between leukemias and malignant neoplasms lies in the one being a tumor of the cellular elements of the blood, while the other is of the cellular elements of the fixed tissue. The leukemias, therefore, are tumors inasmuch as they present the essential features of a malignant neoplasm, i.e., unlimited proliferation, atypical character of the cells, local invasion, and metastases to other organs. The infiltrative growth by leukemic cells into various organs is a well recognized phe-

nomenon. The most common leukemias in childhood are the lymphocytic and myelogenous types, and next the chloromas.

Ramsay (29) collected 100 cases of leukemias in infancy and early childhood, 91 from the literature and 9 from his own practice, in children under eight years of age. The disease was twice as frequent before the fifth year. Here, too, the larger proportion occurred in males, and in 70 per cent the lymphocytic type predominated. He found that the average duration of the lymphocytic leukemias in children was 2 months, and that of the myelocytic type 4 3 months. Clinically, the leukemias in the young are comparable to those in adults, namely, the blood picture, the enlarged spleen, accompanied by respiratory difficulty, paroxysmal cough, with general weakness, etc. The blood picture may exhibit an increase in the white blood cells anywhere from 25,000 to 200,000 or more. Roentgenograms will often disclose a mediastinal mass or metastases elsewhere.

Maciotta (30) recently reported lymphatic leukemias occurring in all five children in a family, and in the four last born of another family of eight children.

Chloroma may be included in this group. The outstanding feature is the characteristic greenish color of the tumors, which appear chiefly in the skull, vertebrae, ribs, sternum, etc. Often the first clinical sign of the disease is the bulging of the orbit, followed by the appearance of tumors over the skull. The tumors of the orbit may simulate metastases from a suprarenal sarcoma, though here the blood picture will establish a differential diagnosis. The blood reveals an increase of the lymphocytic or myelocytic elements, the lymphocytic being the more common. The metastatic tumors are usually made up of the same type of cells as those found in the blood. The lymph glands almost without exception show wide involve-

ment. The bone marrow also shows the conspicuous greenish color.

The progress of the disease is very rapid, and manifests itself usually within the first two decades of life. Ashby and Smith (31) report three cases in boys 2½, 5, and 7 years of age, respectively, all rapidly fatal, which came under their observation in a period of six months at the Middlesex Hospital in London. Rosen and Knott (32) have recently presented two cases, one in a girl of 3 and another in a girl 9 years of age.

Under another heading, as a subgroup, are lymphosarcoma and Hodgkin's disease in childhood. They are generally so well recognized that they need no further emphasis here.

GENERAL DISCUSSION

It seems to me that this subject is of sufficient interest to attract the attention of the clinician and cancer student to the relative frequency of certain well defined tumors in the young. Unfortunately the textbooks and most writers have failed to mention that of all tumors in the brain a considerable proportion occur in the first and second decades. Cushing and his co-workers emphasize that tumors of the brain are far more common than is generally supposed. Cushing states further that tumors in the brain rank in frequency with those of the breast and uterus, or at least run a very close second. Medulloblastomas are met with often enough to be spoken of by some as the "fourth ventricle tumors of childhood." Their importance can be appreciated when we keep in mind that these intracranial tumors in children make up practically 20 per cent of all brain tumors. The symptom-complex of intracranial tumors in children, in contrast to tumors in adults, expresses itself with such remarkable constancy that if one is on the lookout for these tumors, a great many can be diagnosed at the bedside. It is reprehensible, therefore, that in one

case described by Cushing, a child was seen by fourteen different consultants and one and all discounted the fact that the head had increased in size, indicating intracranial pressure. Every type of error was committed in arriving at this obvious diagnosis. To repeat again, periodic vomiting coming on in a child without gastro-intestinal symptoms, and, added to this, increasing muscular weakness, a noticeable increase in the size of the skull, and ocular disturbances should strongly point to an intracranial neoplasm. According to what has been said before, it is highly desirable that these conditions be recognized at a much earlier period of the disease, and there is no good reason why diagnostic skill here should not attain the same high level as obtains with cancer in other organs. The recent studies on radiosensitivity, especially of the embryonal tumors, should be of particular interest. In accordance with our newer concepts that tumors in the young, made up of embryonal or lymphoid or undifferentiated cells, are highly sensitive to gamma radiation, it becomes pertinent to ask why, in this particular group of cases, the radio-active substances have received such scant attention.

Prognosis in the intracranial tumors as elsewhere in the body, depends largely upon an early diagnosis. Operative removal of the gliomas is beset with very great technical difficulties due to their anatomic topography. In the astrocytomas, however, malignancy being less rapid, operative interference is well worth attempting, as there are cases on record which remained symptom-free for six years after the removal of the tumor. Astrocytomas are commonly cystic in children and grow rather slowly. On the other hand, post-operative comfort in cases of medulloblastoma averages only about six months.

The suprarenal tumors also speak a language of their own, and this should simplify the diagnosis in the majority of cases, espe-

cially if the pediatrician or cancer specialist is on the lookout for them.

Unfortunately most of these cases come to operation only when the dissemination of secondary tumors has involved the skeletal system, and the mortality in several of the series reported was 35 per cent from the surgical procedure, and from 70 to 80 per cent from the immediate and ultimate results following operation. On the other hand, if the diagnosis is established early, excision of the tumor has been known to result in freedom from recurrence for a number of years.

Radiotherapy has so far not played much of a rôle in the treatment of those tumors in which operation was impossible on account of extreme anemia or the involvement of large blood vessels or atrophy of the unaffected kidney, and reports are as yet too meager to justify one in forming an opinion of its value.

The effects of gamma radiation in endothelial myeloma and the giant-cell type of bone sarcoma have been pretty well recognized, and deserve a definite place in the therapy of these tumors.

In the leukemias and lymphosarcomas and Hodgkin's disease in children the radio-active substances should effect their widest usefulness, for here we are dealing especially with young and immature cells. My own experience in several cases of Hodgkin's disease and lymphosarcoma in the young convinces me that in these cases, especially, radiation has a definite field of usefulness.

In conclusion, let me point out the importance of these tumors in the young by drawing attention to the statistical studies of Pearl and Bacon (33) upon the incidence of cancer and malignant tumor in the necropsy records of the Johns Hopkins Hospital. Out of 6,670 autopsies, 816 showed some form of malignant tumor, and 6 per

cent of these neoplasms were in persons under 20 years of age

X-rays to be Generated at 18,000,000 Volts

—The production of X-rays as penetrating as cosmic rays, with voltages of 18,000,000, was forecast to the American Association for the Advancement of Science when a report from Dr F Lange and Dr A Brasch, of the University of Berlin, was read by Dr Alexander Goetz, of the California Institute of Technology.

Working in a small valley between two mountain peaks in northern Italy, a place where thunderstorms occur frequently in summer and early autumn, Dr Lange and Dr Brasch emulated the famous early American scientist, Benjamin Franklin, by snatching electrical energy from the skies. With their gathering system, suspended from heavily insulated wires strung across the valley, they obtained discharges of electricity which sparked 25 feet and measured 18,000,000 volts.

Assured by these experiments on Monte Generoso that Nature would provide the high

tension electrical discharges for their experiments, Dr Lange and Dr Brasch returned to their laboratories at the University of Berlin to construct a new type X-ray tube which would withstand such powerful discharges. They succeeded in building a tube of alternate rings of rubber and metal which has been tested at 3,000,000 volts, continuing for an interval of a millionth of a second. These 3,000,000 volt X-rays are the most powerful yet produced, exceeding any so far produced in America. Electrons are so speeded in this tube that they drill holes an inch deep in a brass plate at the bottom of the tube, each electron boring its own hole.

The new X-ray tube, made of rubber and metal instead of glass, is less than a dozen feet long, despite the high voltage it withstands. It is estimated that an ordinary X-ray tube to withstand such voltages would need to be half a mile long, and therefore could not be constructed.—*Science Service*

RADIATION THERAPY OF CANCER¹

BASIC PRINCIPLES, THEIR APPLICATION AND RESULTS

By WALTER L MATTICK, M.D., BUFFALO, N.Y.

From the State Institute for the Study of Malignant Disease, Buffalo, New York
Burton T. Simpson, M.D., Director

GAMMA rays, X-rays, ultra-violet rays, sun rays, and infra-red rays are all derived from the electromagnetic spectrum. Harder X-rays and gamma rays of radium, with which therapy of cancer is chiefly concerned, are placed at the extreme short wave end, the only shorter waves are the more recently discovered cosmic rays. Therapeutically to utilize these rays properly the radiologist must be able to produce, measure, and appreciate the qualitative and quantitative reactions of such wave length groups. To this end a brief review of the action and the more essential physical measurements should be in order.

ACTION

It is generally conceded that the biologic action is dependent on the incident radiation absorbed and the law of Bergonie and Tribondeau, that young growing cells undergoing mitosis are more susceptible to the radiation of X- or gamma rays than adult cells, has been the axiom of modern cancer therapy. Another assumption of lesser importance places the cycle of cell mitosis in human cancer tissue at three-and-a-half-day intervals.

Body tissues are arranged as follows in their order of sensitivity to X- or gamma rays. Lymphatic tissue, leukocytes, testicular and ovarian tissue, basal skin layer, mucous membranes, endothelial lining of vessels, adrenals, liver, kidney, connective tissue, muscles, cartilage, and bone. Tissue of children should be respected in accordance with their age.

Among the systemic effects of radiation may be mentioned decrease of blood pressure, potassium, sodium chloride, cholesterol (1) and fatty acid content of the blood, while there may be increase in the alkali reserve, H^P , calcium content, plasma volume, total plasma proteins, and coagulability of the blood. While many of these facts seem fairly conclusive, still the final action on tissue is yet unknown.

DOSIMETRY

Methods of measurement of these rays may be stated to be either direct or indirect. The instruments most in use for the direct methods are the large galvanometer type ionization chamber of Duane and the small "thimble" electroscope type, of which there are several excellent varieties on the market. Instruments commonly used for indirect measurement are the common spark gap (125 mm spheres), voltmeter, milliammeter, and an accurate timepiece.

One of the essential measurements to define ray quality is that of the kilovolt peak, probably best determined by the standard sphere gap. Such gaps (2) should be accurately set according to temperature and pressure readings by an inside micrometer. A more complicated method is by means of the spectroscope. From this function can be derived the minimum wave length by use of the following formula:

$$\frac{12.354}{K.V. \text{ (Peak)}}$$

The next more useful measurement is that of surface intensity. By this we mean the intensity of the radiation delivered to the surface of the body expressed generally in terms of the biologic erythema, which

¹Read before the Detroit Roentgen Ray and Radium Society, May 7, 1931, at Windsor Ontario and also in part before the Buffalo Radiologic Society, March 9, 1931 at Buffalo, New York.

is ordinarily designated as 100 per cent Intensity 10 cm below the body surface compared to the surface intensity is called the depth dose. It is well known that both surface intensity and depth dose vary in accordance with changes in field size, skin target distance (S T D), peak kilovoltage, and filter thickness. Both surface intensity and depth dose measurements are made by means of a suitable ionoquantimeter of the "thimble" type and a water phantom. The intensity at the surface is measured and compared as defined above with that at 10 cm below the surface in the water phantom. Such measurements are most essential for cross-fire technic.

We must have some measurements to define the quality of the beam used in X-ray therapy. This may be expressed as half layer value, average wave length, or, as is generally done, by means of the effective wave length. Duane has defined the effective wave length as that "wave length of a monochromatic radiation that would produce the same effects (readings of the instrument employed, etc.) that the actual radiation produces." This determination is made with the same instrument used for intensity measurement and requires only the addition of a 4 mm aluminum filter for voltages up to 130 K V and 1 mm copper filter for higher voltages. In this manner is determined the percentage of transmitted radiation intensity compared to the surface intensity from which the effective wave length can be ascertained by means of a curve given by Duane (3). For deep therapy equipment at 200 K V and 0.5 mm copper filter, the effective wave length is 0.16 Å, which, according to Duane, gives more information about the quality of the radiation than can be determined in any other way by a single measurement. More recently Taylor (4), of the Bureau of Standards, has elaborated on these measurements (Fig. 1).

As a result of attempts at standardization, the International Unit, the roentgen, designated as the "r unit," has been proposed.

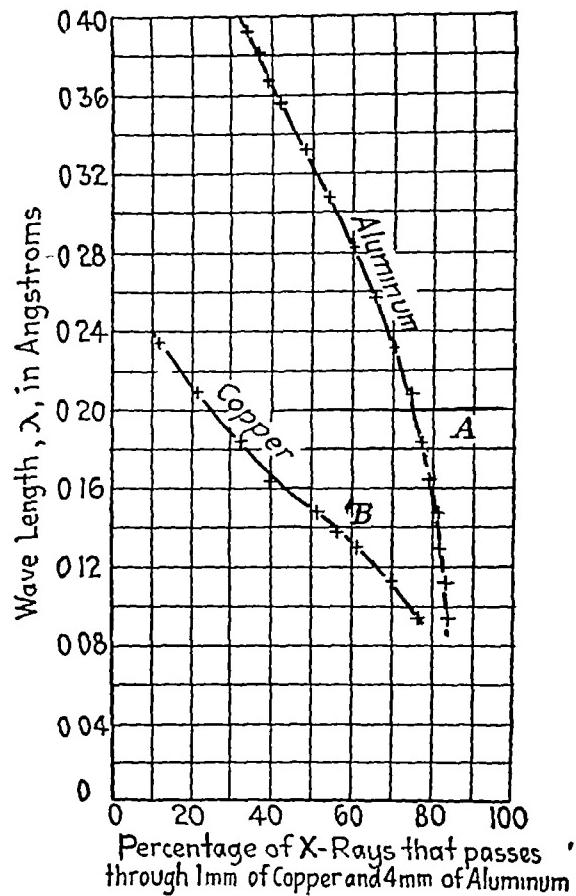

Fig. 1 Duane's curve for determining effective wave length of the X-ray. Such a curve, plus a 1 mm supplementary copper filter in addition to the usual 0.5 mm copper filter and a good ionization chamber, correctly used, is all that is necessary for determination of this quality defining factor of the X-ray beam (3).

and generally adopted. It is defined as "the quantity of radiation which, when the secondary electrons are fully utilized and the wall effect of the chamber is avoided, produces in 1 cc of atmospheric air at 0° C and 76 cm mercury pressure, such a degree of conductivity that one electrostatic unit of charge is measured at saturation current." The newer dosimeters, as referred to above, are conveniently calibrated in r. The Cleveland Clinic has given the following physical

dosage, expressed in r, as corresponding well with the biologic erythema, or 100 per cent dose, when secondary radiation is eliminated

| | |
|---------------------------|-----------------|
| Gamma rays | 1,600 r-2,000 r |
| 200 K V (Cu) | 800 r-1,500 r |
| 140 K V (Al) .. - .. | 600 r |
| 90 K V (unfiltered) | 400 r |

dose is that formulated at the Memorial Hospital under the name of "threshold erythema" (7), which represents approximately 75 per cent of the erythema in use by us. It is defined as that dose which will produce a mild reddening of the skin in 80 per cent of individuals tested, and is ap-

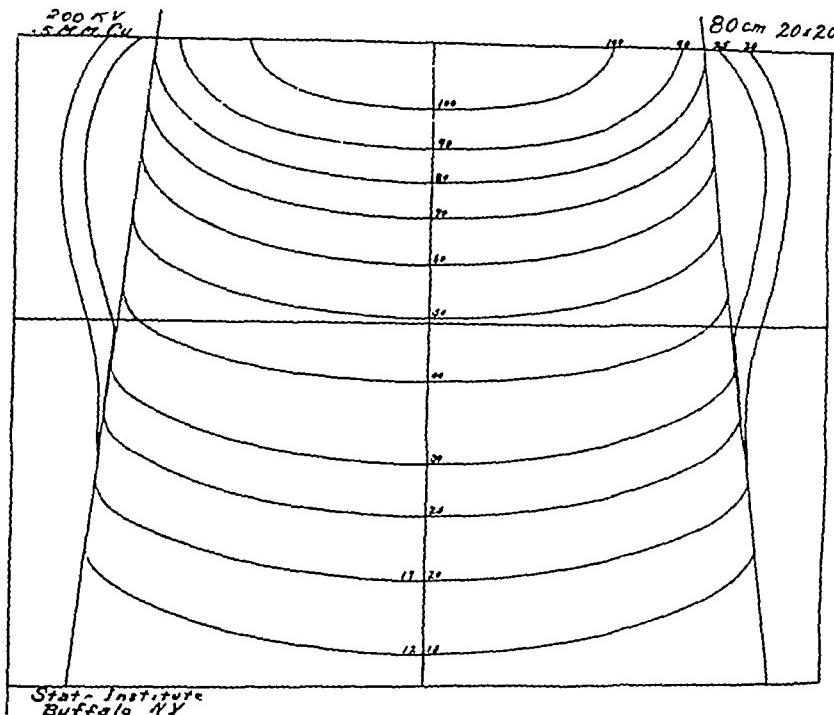

Fig 2 Isodose chart for a field 20 X 20 cm at 80 cm skin target distance (6)

In addition to the above calibrations, which every radiologist should strive to know, there should be in every laboratory a complete set of dosage curves (5), preferably of the Dessauer type, and these should be the basis of all dosage measurement, most essentially of the cross-fire multiple field technic for both radium pack and X-ray (6), in which case bolus bags (one-third china clay and two-thirds flour by weight) should be used (Figs 2-8).

Such physical measurement can now be cautiously checked by determining the biologic erythema by actual test on patients. Probably the best definition of an erythema

proximately 600 r. This reaction is generally most noticeable from about the tenth to the seventeenth day after treatment. The "threshold erythema" is in reality a scientific unit and is not to be mistaken as standard for routine dosage.

In actual technic with either X-ray or radium, most scrutinous care and attention must be paid to use of the proper filters to deliver the ray quality desired. In X-ray therapy 3 mm Al, from 0.5 mm to 3 mm copper, and 1 mm lead are used, but for routine work 0.5 mm copper is probably most efficient and economical. In radium technic a filter which will screen out ap-

proximately 99 per cent of the beta rays is generally adopted. Tables giving comparative filter thicknesses for this purpose are of easy access. Thus 0.6 mm platinum is the equivalent of 1.2 mm lead, or 1.6 mm brass, or 1.3 mm silver, or 1.5 mm monel metal, and will satisfy this requirement (8).

source of radiation, be it X-rays or gamma rays (Fig 5)

For divided dosage technic, it is necessary to have a comprehensive idea of the principle involved. Thus the erythema produced by a single massive dose of 100 per cent at 200 K.V., 0.5 mm copper, effective

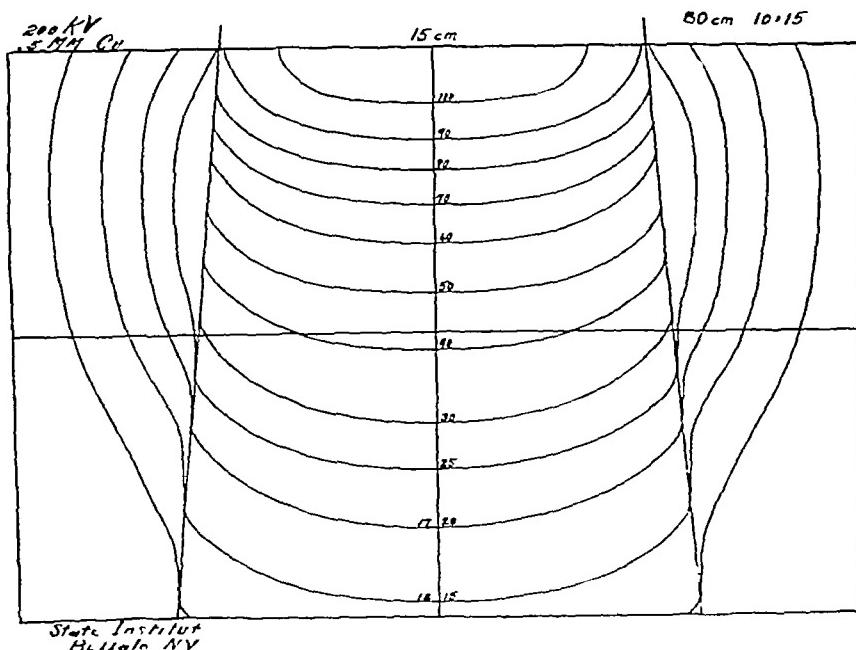

Fig 3 Isodose chart for a field 10×15 cm at 80 cm skin target distance (6)

Attention should be duly given to field size and its relation to time element for the erythema dose. Thus the time factor for an erythema at a sitting for a 400 sq cm field will be less than for smaller fields. Failure to appreciate this commonplace law has often been accompanied by serious consequences. A curve of surface intensity in percentage of the erythema, in which the human erythema is represented as 100 per cent plotted against the field area in square centimeters, is essential and has been given by Bachem (9). In this same connection, it is hardly necessary to call the attention of radiologists to the well-known inverse square law affecting the time element in relation to the skin target distance from the

0.6 Å., has been found by us (10) to correspond to that of 110 per cent over three days, 120 per cent over five days, 130 per cent over eight days, 140 per cent over 10 days, or 150 per cent over 15 days, when treatment was given every second or third day. Pfahler (11) and Hirsch (12) had previously derived such curves and, while they show minor differences, we know from the practical experience of many thousands of treatments that ours works satisfactorily. Such curves are the basis of the "saturation" principle in technic and readily demonstrate why a dose of 100 per cent delivered over a definite time interval of days and not at one sitting, will fall short of producing the biologic erythema.

All radiologists will, therefore, appreciate the benefits of standardization of dosage and calibration of X-ray equipment, for,

the former idea, which is surely worth consideration Nevertheless we still have treatment technic, divided roughly as follows, in

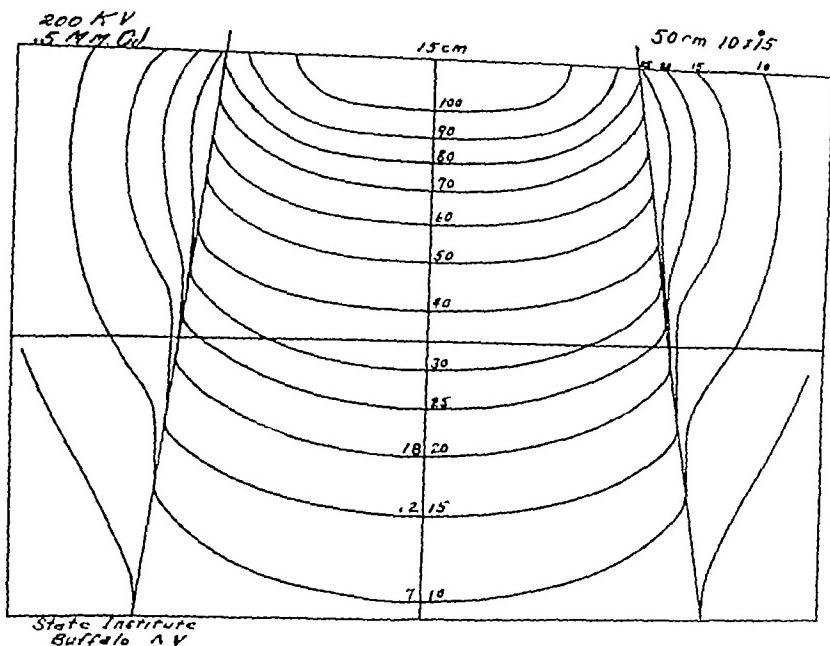

Fig. 4. Isodose chart for a field 10×15 cm at 50 cm skin target distance
(6) 200 KV, 0.5 mm copper filter, 0.16 Å
Data as shown in Tables I to IV were compiled from such isodose curves
and are constantly used in our work at the State Institute

without this, the radiologist would be unable to correlate his work with that of others or to duplicate his own results In this same sense, a close correlation of radium dosage factors expressed in erythemas or percentages thereof is equally essential Here I will refer to previous work from the Institute (5) and a more recent paper by Quimby and Martin (13), from the Memorial Hospital It is only by acquaintance with such erythema equivalents of various X-ray and radium combinations that treatments with these different agents can be intelligently given and danger avoided (Tables I-IV)

The question has often been asked if small amounts of radiation given over a long time are not preferable to large amounts over a short time Regaud and Ewing have been the chief exponents of

which each type seems to have definite indications at times for both radium and X-ray

1 Massive dose technic—unfiltered, Al or Cu

2 Divided dose technic—Al or Cu up to 1 mm (5)

3 Protracted dose technic—3 mm Cu or 1 mm Pb, low milliamperage (14)

4 Saturation dose technic—Al or Cu (11) (Fig. 6)

It is probable that, with the development of 500 KV and 2,000 KV equipment, protracted dose technic with even heavier filtration may come into vogue, or lacking this, then the present protracted dosage technic with 200 KV, 5 ma, through 2 to 3 mm Cu for from two to three hours daily, will increase in popularity Mention should also be made of the noble experiment in

continuous general body radiation being carried on at the Memorial Hospital

Here let me digress to call attention to

should train himself along these lines A basic training in pathology is also most desirable, as much of the effective treatment

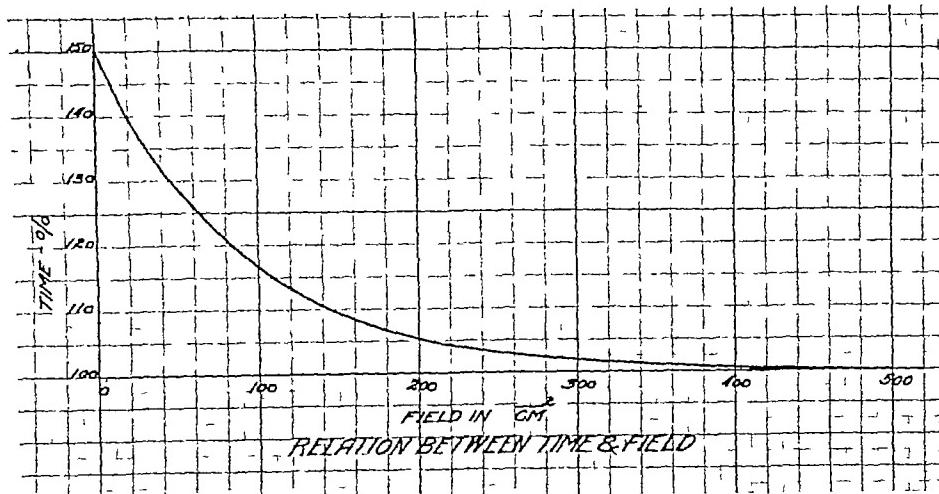

Fig 5 If a 10×15 cm field is used, approximately 10 per cent more time has to be given, as illustrated by the above curve, in order to get the same intensity of skin reaction as when the field size is over 400 square centimeters

proper protection factors The Second International Congress of Radiology (15), July, 1928, recommended a seven-hour day, a five-day week, and a month vacation yearly as the minimum for radiologic workers All treatment rooms should have the walls covered with lead 4 mm thick for voltages up to 200 K V, and thicker for higher voltages Such requirements become self-evident when we stop to reflect on the frequency of reports of ill health, and the development of aplastic anemia and lymphatic leukemia among radium and X-ray workers Some of the earliest effects are manifested by a leukopenia and relative lymphocytosis which should not be ignored

METHODS AND RESULTS

He who would properly treat cancer must recognize that there is no royal method of cure, that the triad on which dependence must be placed is early diagnosis, radiology, and surgery in various combinations Thus one aiming to treat cancer proficiently

given will depend on the actual pathologic histology presented

Time permits of but a cursory review of the methods of treating outstanding types of malignancy and the statistical results will be given as far as possible only on the basis of a five-year arrest or apparent cure of the disease, and from sources from which sufficient material has been available to make the statistics of value Here I would call attention to the thought conveyed by Professor Regaud in his report to the Cancer Sub-committee of the League of Nations in which he referred to the fact that there is as yet no general agreement on the question of correct treatment of cancer and that only by a very thorough organization of work, resulting in the production of irreproachable statistics, can such agreement be eventually reached (16)

For accurate diagnosis I would call attention to the systematic employment of biopsy whenever permissible This practice will also naturally increase the value of statis-

tics Broders' classification may be satisfactorily applied in grading the malignancy of many regional groups of cancer and is worthy of consideration from a prognostic viewpoint, especially when evaluated in conjunction with the clinical symptoms and signs.

Basal-cell epithelioma, or rodent ulcer, is one of the most common lesions. It is most often found on the face, it rarely metastasizes, and is best treated by massive doses

Here two or three erythemas of unfiltered X-radiation, depending on the thickness of the primary lesion, or a radium plaque left in place to produce a good reaction, will succeed in permanently healing most cases, unless bone or cartilage is involved. In this event, the lesion is often very refractory. A report of 340 cases from the Institute showed primary healing in 88 per cent and permanent healing in 82 per cent of the cases (17).

With squamous-cell epithelioma, or epidermoid carcinoma, which is more radio-resistant and tends to metastasize to the regional glands, results are less satisfactory. It occurs most commonly on the skin, lip, penis, clitoris, or vulva and the method of treatment will vary with the location and whether it is infiltrating or papillomatous. In the latter variety, unfiltered X-radiation, radium plaque or tube for 150 mc-hrs or more of gamma radiation, can be used on the lesion. In the infiltrating type, radon seeds of 2 mc each in 0.3 mm gold, or needles of radium with 0.6 mm platinum, should be planted in the lesion, computing on the basis of 2 mc to every 1.5 cm of pathologic tissue. The regional lymph gland areas must be treated with heavy doses of copper-filtered X-radiation or with radium and cobalt-60.

tracted technic. Frequently in epithelioma of the penis or vulva this does not result in satisfactory regression. Then electrocoagulation of the primary lesion is often resorted to, with or without block dissection of the regional glands, if the capsules are intact, and seed implantation in the gland areas, followed by further external radiation. In early penis lesions, amputation by electrothermic methods and heavy external radiation may be employed. In the lesions of both the penis and vulva, the final result is liable to be palliative only. We have seven out of 60 epitheliomas of the penis from the Institute records (18) that are permanently healed for over five years, three after radical operation and radiation, two with partial operation and radiation, and two by unfiltered radiation alone. We

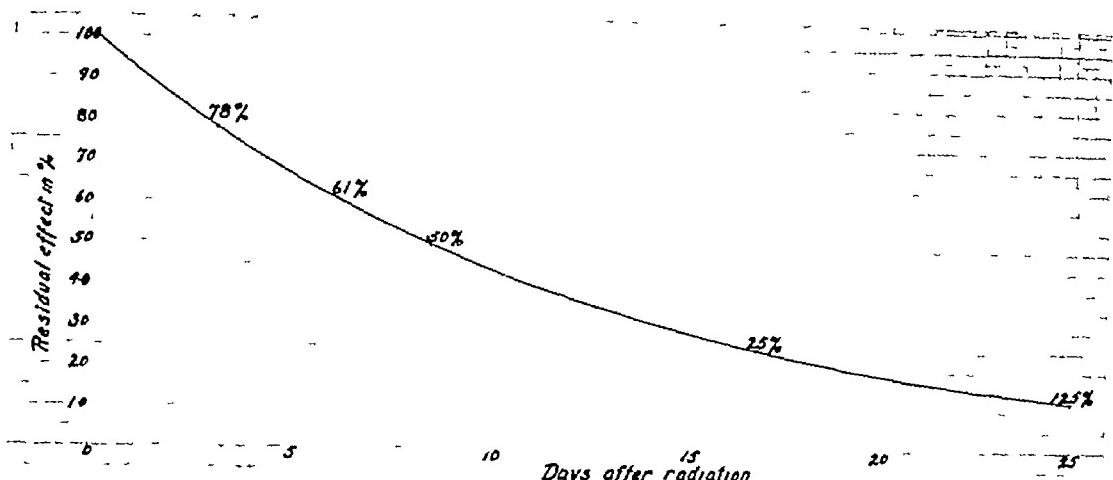

Fig. 6 Residual effect of X-rays at 200 K.V with 0.5 mm Cu filter, 0.16 A from the time of radiation over a period of 25 days (10) is observed from the skin reaction

of epithelioma of the vulva treated by radiation

Epitheliomas of the lip generally occur on the lower lip, metastasize readily to the regional glands, and may be papillomatous or infiltrating in type. They can be successfully treated by needling with radium needles of 0.6 mm platinum or 0.3 mm gold seeds, implanted on the basis of 2 mc for each 1.5 cm of tissue radiating around the periphery and under the lesion. Removal with the radioknife has also been advocated. Papillomatous lesions are often treated by unfiltered X-radiation, delivering two to four erythemas to the closely screened tumor, depending on the thickness of the individual lesion. Another good method consists in using a wax mold in which are incorporated radium tubes of 1 mm platinum, the lesion being thus radiated by a cross-fire method. Regional gland-bearing areas should always be treated with copper-filtered X-radiation or radium pack in full doses. Of lesions without glandular involvement (Group I), 44, or 68 per cent, remained healed for from five to twelve years, 92 per cent of 65 cases in the same group showed primary healing according to our Institute records (19). When the glands are involved (Group II),

in 23 cases only 13 per cent were well more than five years although 61 exhibited primary healing

Epithelioma of the tongue, floor of the mouth, alveolar process, palate, and antrum is more difficult to manage and also tends to metastasize early. Lesions of the lower jaw and floor of the mouth are prognostically less favorable than those of the upper jaw. Here, either gold seeds or platinum needles in the lesion, or a tube of gamma radiation over the primary lesion, with full dosage to the regional glands, seems generally indicated as most expedient.

Lesions of the tongue are treated, as above, with needles or seeds, and X-radiation or pack from without. Such treatments should generally produce an erythema. It is only by approaching such burning doses that therapy can produce results. Regaud has reported primary healing of tongue lesions in 75 per cent and disappearance of glands in a very small percentage of cases. Quick, at the Memorial Hospital, has reported on 140 early cases without gland involvement in which healing was secured in 85 per cent for from two months to three years. More recent experience there will show approximately 45 per cent five-year healings in cases without nodes in the neck.

Such is general radiologic experience Pfahler has reported 55 per cent of early cases without gland involvement well for

end fatally. If they are seen early, intrinsic lesions may be operated on by doing a complete laryngectomy, otherwise attempt

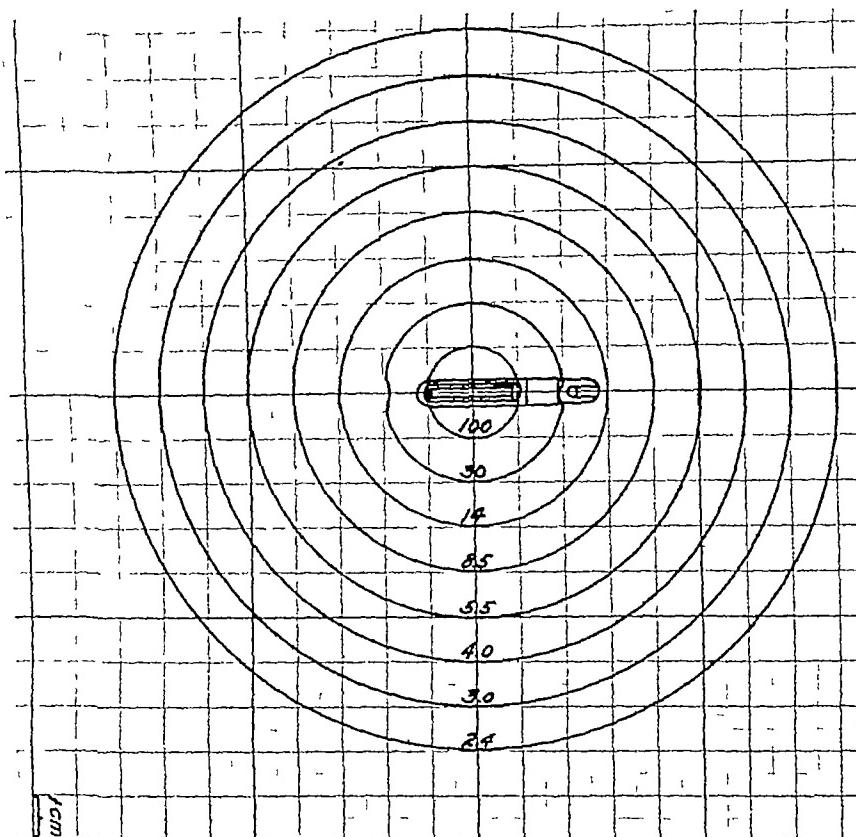

Fig 7 Isodose curve for 100 mg radium tube with 1 mm Pt filtration Active length 21.5 millimeters From paper to be published by M C Reinhard and H L Goltz

from one to fifteen years, and 40 per cent with glands well for from one to eight years

Epithelioma of the pharynx and tonsils is probably best treated by seeding, as above, and external radiation to the gland-bearing areas Quick, from the Memorial Hospital, reports 318 cases of epithelioma of the tonsil, with 14 living and well for five years A later report, to be published by Duffy, gives 38 per cent with no gland metastasis and 20 per cent of all groups clinically cured five years or more

While intrinsic lesions of the larynx are the more refractory, both types generally

should be made at seeding if possible from within or by splitting the thyroid cartilage and directly exposing and seeding the lesion Any method should be followed by external radiation, or this method may be used alone Unless preliminary tracheotomy is performed, small frequent doses making up a heavy total radiation should be given in the attempt to prevent edema of the glottis We have two cases apparently well for several years, one by laryngectomy and the other by external radiation only Regaud has reported very favorable results by external radiation, but no one else seems to be so successful in handling this lesion

Cancer of the stomach or colon, if early, is generally admitted to be best treated surgically. Post-operative treatment by ex-

When copper filtered X-radiation is administered, 80 cm S T D is used to secure the best radiation dose in the tumor and glands

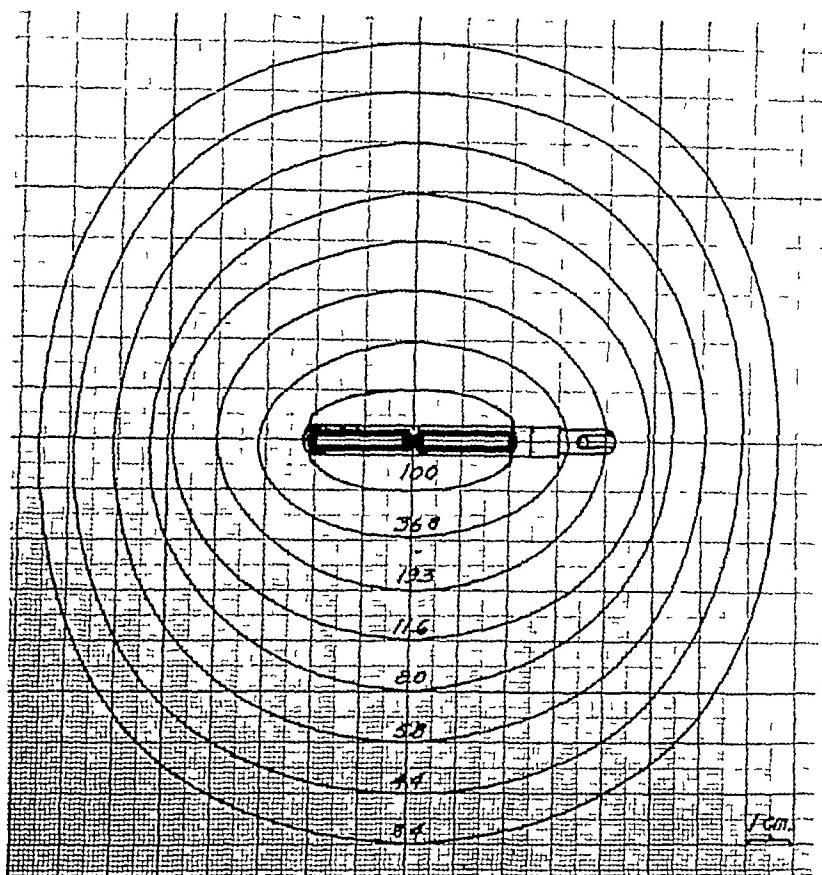

Fig 8 Isodose curve for two tubes in tandem, containing 100 mg radium in each tube with a filtration of 1 mm Pt. Active length 21.5 mm for each tube
From paper to be published by M C Reinhard and H L Goltz

ternal distant radiation, either by X-radiation or radium pack to secure a good tumor dose, should be employed. In most cases treated up to now by exclusive radiation, the results achieved have been only palliative.

Cancer of the esophagus may be dismissed by saying that there is probably no authentic cure by radiation on record. Attempt should always be made at palliation with radium seeds or tubes placed through the esophagoscope, when this is deemed feasible, supplemented by external radiation

Breast cancer should be classified in the following groups, according to Steinthal:

Group I Lesion limited to the breast and not adherent, no glandular involvement.

Group II Same as Group I with the addition of glands in the axilla or ulceration fixed to the muscles.

Group III Same as Group I with or without axillary involvement, but with widespread metastasis into the supraclavicular or mediastinal glands or bone.

Pre-operative and post-operative radiation is the method of choice in the operable

the method of Keynes is fast gaining popularity. Only time can tell the result.

The average length of life of untreated

including the breast, axilla, and supraclavicular region

Evans and Lencutia (21), in reporting

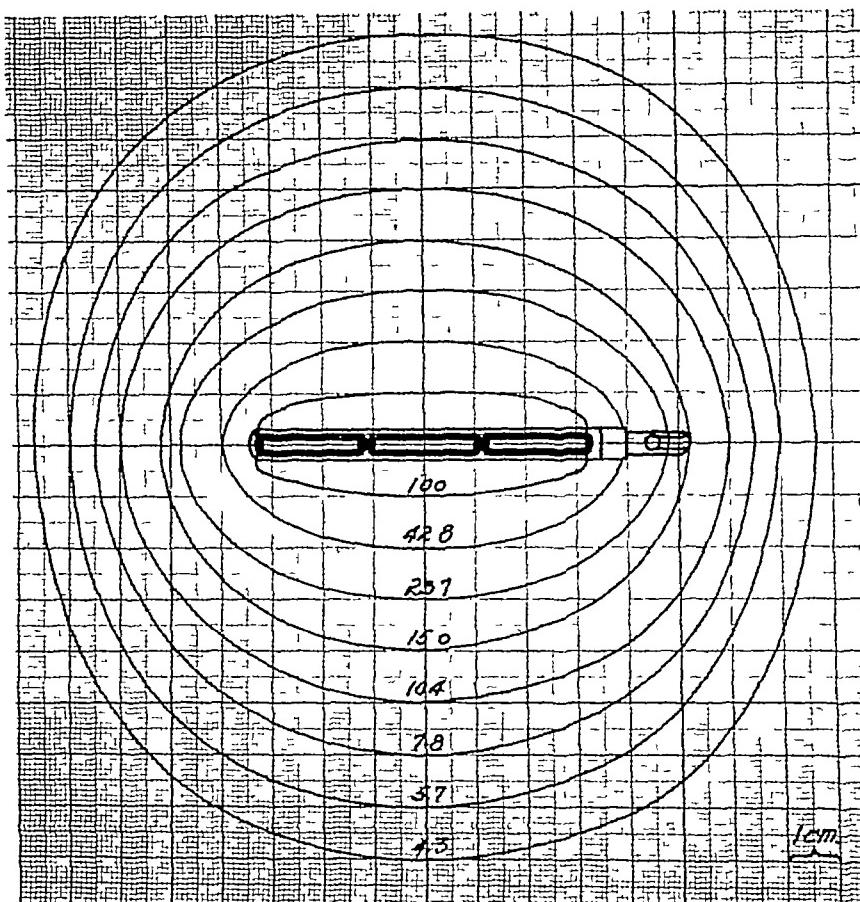

Fig 9 Isodose curve for three tubes in tandem containing 100 mg radium in each tube with a filtration of 1 mm Pt Active length 21.5 millimeters From paper to be published by M C Reinhard and H L Goltz

cases is approximately 32 months. Our treated cases from the Institute (20), based on a study of 489 patients, show five-year arrests as follows:

| | | |
|-------------|-------------|------------|
| Group I | Group II | Group III |
| 65 per cent | 23 per cent | Palliation |

These results were obtained in most cases by the combination of operation and radiation.

In these cases high voltage X-radiation consisted in radiation at from 40 to 50 cm S.T.D. divided over three or four doses giving 120 per cent over five days, 130 per cent over eight days, etc., with a large field

175 cases, give five-year arrests as 70 per cent for Group I and 46 per cent after radical operation, and radiation to the glands in the axilla. In this latter group they believe results to be doubled by radiation. B. J. Lee reporting from Memorial Hospital, shows five-year end-results of 56 per cent in relatively benign lesions, 30 per cent in moderately malignant, and 20 per cent in highly malignant lesions of the breast, with a total of 48 per cent in all groups treated by irradiation, with or without surgery. Schmitz, in reviewing 107 cases, reports 27

Cancer of the stomach or colon, if early, is generally admitted to be best treated surgically Post-operative treatment by ex-

When copper filtered X-radiation is administered, 80 cm S T D is used to secure the best radiation dose in the tumor and glands

ternal distant radiation, either by X-radiation or radium pack to secure a good tumor dose, should be employed In most cases treated up to now by exclusive radiation, the results achieved have been only palliative

Cancer of the esophagus may be dismissed by saying that there is probably no authentic cure by radiation on record Attempt should always be made at palliation with radium seeds or tubes placed through the esophagoscope, when this is deemed possible, supplemented by external radiation from without by the cross-fire method

Breast cancer should be classified in the following groups, according to Steinthal

Group I Lesion limited to the breast and not adherent, no glandular involvement

Group II Same as Group I with the addition of glands in the axilla or ulceration fixed to the muscles

Group III Same as Group I with or without axillary involvement, but with widespread metastasis into the supraclavicular or mediastinal glands or bone

Pre-operative and post-operative radiation is the method of choice in the operable groups but interstitial radiation according to

tures Of course the divided dose technic should be followed Here again results in a curative way fall short of the palliative results achieved The relief of pain in bone metastases of prostatic, as of breast, lesions

operative mortality For purposes of classification these lesions are best divided, according to Schmitz, in four groups

The general method of treatment in most clinics consists in gamma radiation by tubes

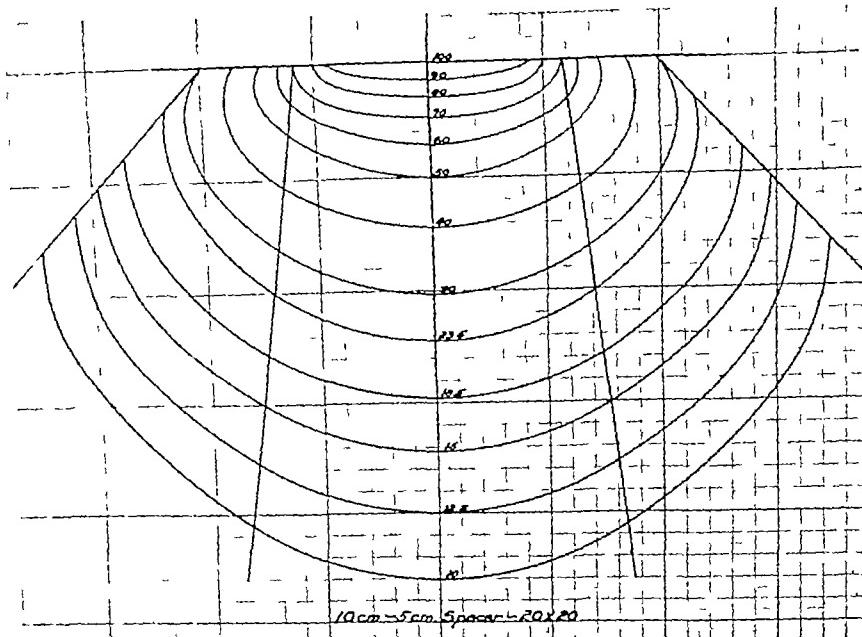

Fig 11 Isodose curve for 4 gm radium pack with 1 mm Pt filtration, 3 mm brass, RSD 15 centimeters Field size 20×20 centimeters Depth dose at 10 cm, approximately 30 per cent. Tables for practical dosage can be made for teleradium therapy as for 200 K.V., 0.5 mm Cu, X-ray (6) From paper to be published by M C Reinhard and H L Goltz

is most gratifying and in some cases seems miraculous, and full doses of high voltage X-radiation to the involved bones should be used While prostatic cancer has given only palliative results to date with radiation, the Registry of Bladder Tumors of the American Urological Association shows 14 per cent of the cases of bladder tumor alive and well five years or more Ferguson of the Memorial Hospital, reports 20 per cent five-year healings in bladder tumors

Epithelioma of the cervix uteri has been one of the triumphs of radiation Many of the largest clinics in the world to-day have discarded radical hysterectomy for this condition in favor of radiation which produces as good results with practically no

in the cervical canal for approximately from 2,000 to 3,000 mc-hrs in addition to needles of platinum or seeds of gold placed around and into the cervix and adjoining broad ligament areas This is supplemented by high voltage cross-fire X-radiation, as in the treatment of rectal and bladder lesions, calculation of combined radium and X-ray dosage being carefully made as in epithelioma of the bladder Here again we prefer an 80 cm STD on account of the better depth dose (49 per cent) This type of treatment and the calculations involved in the cross-fire method have been previously reported (6)

Probably the best statistical review of results achieved in cervical cancer has been

per cent for all groups (22), with 50 per cent in the operable groups, all treated with post-operative X-ray.

Rectal cancer has been conveniently classified surgically as involvement of the

gastro with cancer of the rectum has nearly reached its therapeutic limit, but radium treatment of this disease is as yet very young." Later results with the gold seeding technic promise a material improvement

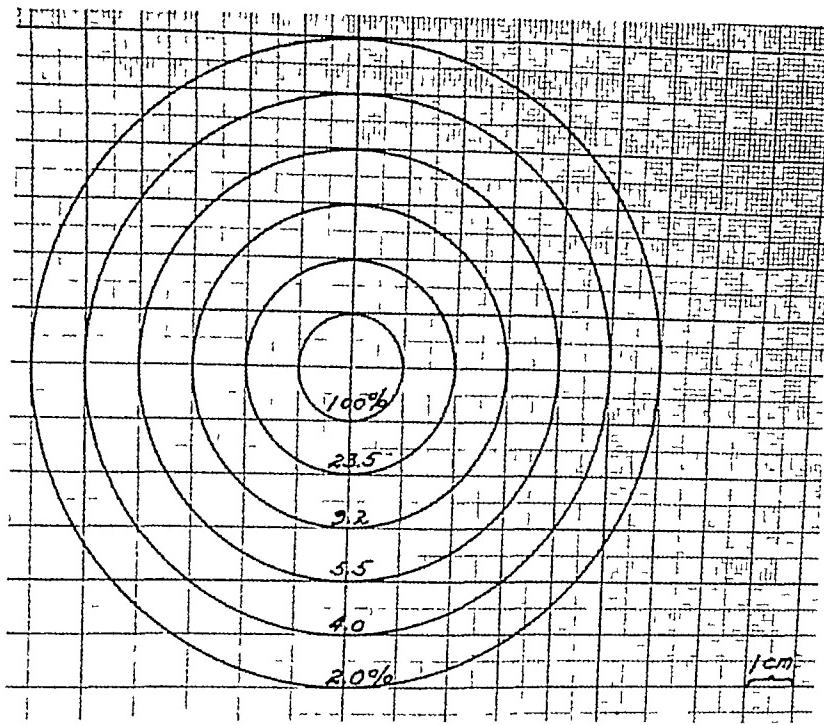

Fig 10 Isodose curve for gold interstitial seeds of 0.3 mm. wall thickness and 3 mm length. *From paper to be published by M C Reinhard and H L Goltz*

anal canal (squamous cell), rectum, and rectosigmoid (the latter two are adenocarcinoma). Under the best radical two-stage operation, D F Jones has secured five-year cures in approximately 50 per cent of the cases, with an operability of 45 per cent.

Our records (23) show 17 per cent of five-year cures in the operable group. These cases were treated with radium tubes with or without glass seeds placed in the local lesion, supplemented by high voltage X-radiation over the pelvis anteriorly and posteriorly, at 80 cm skin target distance. To quote from a recent review of 303 cases of cancer of the rectum seen at the Collis P Huntington Memorial Hospital (24), "Sur-

Furthermore, in such a difficult operation it will always be rare to have the average surgeon achieve the skill of the masters.

Epithelioma of the bladder and adenocarcinoma of the prostate are both best handled by a combination of surgical diathermy, radium implantations, and external radiation of the pelvis by cross-fire method at a long target distance (80 cm S T D) as in rectal and uterine disease. Here the external radiation, if combined with radon seeds or needles, should only supplement the latter. The dosage in all such cases should be cautiously calculated around the bladder, uterus, or rectum on account of injury to the surrounding struc-

cases and has achieved excellent results in early cases treated by removal of the primary tumor and radiation

A recent contribution by Doub on thymoma has been of interest since we have had several such cases which have been classified as lymphosarcoma. In this type of case the response to external radiation, as reported by the aforementioned writer, is often life-saving, transforming a very unfavorable case into one of apparent health in but a few days of divided X-ray or pack therapy.

Up to now our experience with primary carcinoma of the bronchus or lungs has been hopeless. Palliation of considerable extent has, however, been of common occurrence in metastatic lung involvement following a primary tumor in the prostate or thyroid. Here we are accustomed to use 80 cm S T D and an anterior and posterior field centered over the lesion, giving divided dosage to full skin tolerance.

Mixed tumors of the parotid are probably best treated by surgical removal of as much of the tumor as possible or by interstitial radiation when the former seems impractical. This should be followed by external radiation either with high voltage X-ray or the radium pack in divided dosage at preferably a long target distance. We have previously reported on a series of 54 such cases (29) with approximately 10 five-year arrests.

Mixed embryonic tumors of the kidney, hypernephroma and adenocarcinoma of this organ have given only palliation at the best, even after operation. Here divided dosage of high voltage X-ray or radium pack by the cross-fire method is the procedure of preference. Two cases of hypernephroma have lived two and three years respectively and one adenocarcinoma which recurred after operation, remained palliated for almost two years following external radiation (30).

Let us next consider one of the most in-

teresting groups of malignant processes, namely, those known under the generic term of lymphoblastomas, including Hodgkin's disease, or lymphogranuloma malignum, lymphosarcoma often designated as round-cell sarcoma as distinguished from the spindle-cell sarcoma, and the leukemias. This entire group is characterized by a comparatively high degree of radiosensitivity, the leukemic processes, including chloroma, being the most sensitive, lymphosarcoma the next, and Hodgkin's processes probably the least sensitive in this group (31, 32, 33).

The leukemic group of tumor processes is generally recognized by the typical blood picture which commonly accompanies these maladies. Both the chronic myelogenous and the lymphatic group respond nicely to radiation therapy, either X-ray or radium. Here we generally administer 30 to 50 per cent doses over the spleen or enlarged glands (31), the dosage being determined mostly by the blood picture. When the white blood count reaches approximately 20,000 cells per cu mm, radiation is discontinued temporarily until a rising count indicates further treatment. Although we have been unable to cure any of these patients, or probably even to prolong their lives, I am sure we have succeeded in keeping the patients more comfortable, and often self-supporting than could have been achieved by any other means.

There is probably no group of tumors that taxes the ingenuity of trained pathologists more than those of the lymph nodes, especially Hodgkin's and lymphosarcoma. The disconcerting fact remains that occasional sections of such tumors may be submitted to several master pathologists without securing a complete and undivided opinion as to the exact processes involved, thus testifying to the real difficulties in trying to differentiate these processes absolutely.

Here divided dosage of from 70 to 80 per cent of the skin dose delivered to the spleen or enlarged glands will generally

given by Ward and Farrar, of the Woman's Hospital (25). They report 53 per cent of five-year cures in operable Group I and Group II, with 25 per cent of five-year cures in all groups. They summarize similar

In a series of 48 operable cases of adenocarcinoma of the fundus uteri reported from this Institute (28), radiation has given permanent healings in 50 per cent of the cases for five years or more.

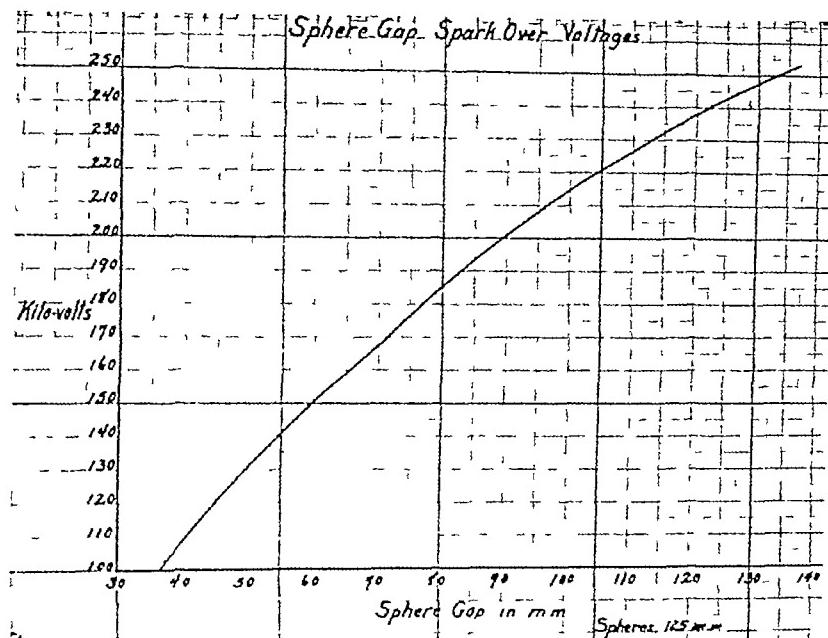

Fig. 12. The correct separation of 125 mm spheres (both insulated) at 741 mm barometric pressure and 25° C temperature is 93 mm for 200 KV peak.

To obtain the proper sphere gap separation for other temperature and pressure conditions, compute correction for temperature as 0.56 mm. for each degree above or below 25° C. If above 25° C, add; if below, subtract correction from 93 millimeters.

Next compute correction for every millimeter of pressure above or below 741 mm by multiplying by 0.21 mm for each millimeter of pressure change. If above 741, subtract; if below, add to the number obtained after correcting for temperature as above.

The result will give the proper sphere gap setting for temperature and pressure conditions desired (2).

operative results in Group I and Group II in over 3,000 cases as 43 per cent, operative mortality as 17 per cent, and operability as 43 per cent.

Our record, reviewing 374 cases (26), shows as follows:

| I | II | III | IV |
|--------|--------|--------|-------|
| 64.28% | 28.57% | 14.47% | 1.44% |

Group I and Group II combined totalled 40 per cent all well five years or more. Schmitz has given equally representative statistics (27).

Round-cell carcinoma of the testis, the seminoma or teratoma testis, is practically never seen by us in the early primary or localized stage. Even after the disease has shown evidence of metastasis, the response of this tumor to radiation is spectacular. Such metastatic masses disappear temporarily and the patient feels perfectly well until later metastasis becomes more widespread and radioresistant to subsequent treatment. More recently Ferguson has reported the presence of Prolan A in the urine of such

doses by a divided technic. In approximately 10 cases so treated, we have succeeded in bringing about a diminution in the size of the tumor, restoration of function, and often the appearance of calcification in the lesion, as demonstrated by the roentgenogram.

Melanosarcoma, or melanoma, has always been classed as a most malignant process. Our records show a five-year arrest and clinical cure in 8 out of 16 cases in which the malady was seen early, before metastasis had occurred (30). In those with dissemination of the process, palliation is all that can be expected at the best. Here radiation therapy, either pack or roentgen rays to full skin tolerance, can be given with small field and closely screened lesion by massive dose technic. The metastatic or gland-bearing areas are best treated by divided dosage methods.

As to the question of repeating the treatment, I would say that it is the consensus of opinion to treat cases with a heavy dose, repeating as seldom as absolutely necessary and not within two or three months in the average case. Too frequent repetition may lead to late tissue reaction three or more months following the last exposure. This is becoming more evident as an example of our enthusiasm to cure, especially as many of the cases of cancer are now living longer than before the advent of radiation. Reports of squamous-cell epithelioma occurring in the scar of a healed breast cancer as the result of X-radiation have come to the writer's attention. The greatest caution is necessary in radiation treatment in general and we should always remember that radiation is not an absolute specific nor does it always cure cancer.

In closing I will quote Dr. Burton T. Simpson (37): "Up to the present time, we have been working with radiation in a purely empiric way, obtaining results without a definite knowledge of its mode of

action. Should it transpire that this agent has a specific action on the cancer cell, the outlook for future results, by using this method of treatment, is very bright."

EXPLANATIONS

Tables I and IV are based on isodose curves (Figs. 2-4) measured at 200 KV with 5 mm copper filter and 0.16 Å effective wave length, and are suitable only under the above conditions.

To use the same, the diameter of the part to be treated is first determined. If two opposite fields are then applied at the extremes of the diameter, the resulting dosage can be calculated from the tables by using the figures given opposite the corresponding diameter of the part (See References 5 and 6). This method, besides possessing equal accuracy, saves time and the more cumbersome application of the isodose curves.

To translate radon dosage into approximate percentage of X-ray erythema at a distance 3 cm from the center of the tubes or a seeded area, *i.e.*, as in the application of uterine tubes or seeds. Tubes (100 gm radium or emanation) to have 1 mm Pt filtration, or its equivalent. Seeds to be made of gold tubing with 3 mm wall thickness and to be approximately 3 mm long.

For intracavitory tubes (one, two, or three in tandem) or gold seeds with filtration as above when the seeds are distributed within the inner half of the radius of the lesion (Quimby and Martin), multiply the total millicurie-hours by the factor 0.03 and the result will be the approximate percentage of the X-ray erythema 3 cm from the center. These calculations are based on isodose curves (See Figures 7 to 10).

APPROXIMATE DOSAGE FOR TELLURIUM PACKS

| (1 mm platinum and 1 mm aluminum) | | |
|-----------------------------------|-------|--|
| 6 cm | S T D | 16,000 to 20,000 mg -hrs |
| 10 cm | S T D | 30,000 to 35,000 mg -hrs |
| 15 cm | S T D | 60,000 to 70,000 mg -hrs divided into daily doses |

cause a disappearance of the process. Such patients are thus kept most comfortable but they are not cured except in a few exceptional cases of lymphosarcoma in which the disease has not spread beyond the primary seat. Thus out of 77 cases of lymphosarcoma hastily reviewed from our files, we have approximately 10 cases who have survived a five-year arrest period or better, without any manifestation of the disease. These cases were mostly those in which the disease was classified as primary or localized on admission.

While I know of no authentic cases of cure of Hodgkin's disease, it might be of interest to mention a patient treated by us who lived comfortably and worked much of the time over a period of 12 years before finally succumbing to the malady. This palliation is generally remarkable, but complete arrest of the process probably never will be secured in the present state of our knowledge.

These cases are best treated with high voltage X-radiation or radium pack, the dosage generally administered being approximately 80 per cent of the erythema (640 r), to the various groups of enlarged glands. We do not recommend the systematic treatment of all lymphatic gland areas when such glands are not enlarged unless it is impossible to see the patient for follow-up treatment at a fairly near future date.

Fibrosarcoma, or spindle-cell sarcoma, on account of its early metastasis by the blood stream, is preferably treated by radiation combined with excision, when it is primary. Here very satisfactory results have been achieved. One case, a boy with a primary spindle-cell sarcoma, was well following radiation from 1917 to 1926, then he developed a recurrence which was surgically removed, followed by radiation of the scar. He has remained well to now with no recurrences. A cursory survey of these cases from the Institute records shows arrests of five years or over in approximately 10 cases

out of 52 in which the lesion remained clinically healed (30).

Bone sarcomas furnish a most interesting and, at the same time, a pessimistic group for treatment. Roentgenograms in this group of tumors are often of more diagnostic significance than poorly chosen or insufficient biopsy material. Bloodgood thinks it is safer to radiate such tumors than to make a biopsy, if there is doubt of the pathologic diagnosis (34). The needle puncture method of securing a biopsy specimen, as recommended by Martin and Ellis, is often successful in distinguishing malignancy from benignity (35). Bloodgood recommends resection if possible for a lesion of the upper extremity, or when the growth is below the lower third of the femur, otherwise he advises a continuance of the radiation treatment. For such a lesion, long skin target distance to full skin tolerance by the divided or protracted technic is the method of choice. We have never produced more than palliation in the osteogenic sarcomas, whereas, in the Ewing sarcoma, palliation both objectively and subjectively is most marked and can be secured by lesser dosage due to the unusual radiosensitivity of this tumor. In fact, the greater radiosensitivity of the Ewing tumor serves to differentiate this endothelial group of bone tumors from the true sarcoma processes. Coley (36) has secured some remarkable results with combinations of surgery, radiation, and the use of Coley's toxin in this group.

We cannot pass without a few brief remarks on the so-called giant-cell sarcomas of bone which Bloodgood has shown to be generally of a benign nature. We have had occasion to treat by radiation many such giant-cell tumors of bone, including the solitary bone cyst, with generally a most gratifying response and lasting result, corroborating the experience of the Memorial Hospital in New York. Here the lesion should be thoroughly radiated with full skin

New Blood Test for Cancer Developed by German—A new method of detecting cancer in its early stages has been developed by Dr Hans Jacques Fuchs, member of the physiological institute of the Veterinary University of Berlin. Details will be published in a German scientific journal. So far, 2,000 cases have been successfully diagnosed by the new method, the diagnosis being confirmed by operation or dissection. The method also makes possible the determination of the presence or absence of cancer when an infectious disease occurs at the same time. Further, it is claimed that by this method the success of surgical or radiologic treatment of cancer can be controlled.

The new method depends on the digestion of serum from the blood of a suspected cancer patient with fibrin prepared from the blood of a normal person and with fibrin from the blood of a person known to have cancer. The digestion goes on for ten hours at a temperature of 104° Fahrenheit. The protein

is then removed from these samples and the amount of non-protein nitrogen present in each is determined. Depending on the amount of non-protein nitrogen present, it is possible to make a diagnosis as to whether or not the suspected case is one of cancer.

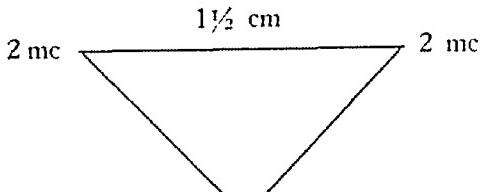

The new method is the result of five years of incessant research work during the course of which Dr Fuchs had to make a number of pieces of special apparatus in order to achieve the necessary exactness in his determinations. The method also marks the first time that a chemical determination of a serological process has been made.

A certain diagnostic test for cancer, such as this is hoped to be, will be particularly valuable because modern methods of treatment by surgery and radiation are chiefly successful only in the early stages of the disease. When cancer attacks the internal organs, it is nearly impossible to detect it in its early stages by present methods of diagnosis.—*Science Service*

1 gm of radium liberates in 1 hour 751 mc emanation or radium destroyed

1 mc radon gives the equivalent of 133.3 mc-hrs of radio-activity before it is completely decayed in its cycle of approximately 30 days

female, but, after several years of trial, we have emerged more or less disappointed with the results

Let us consider for a moment why this modality has not been all that we had hoped for in the treatment of different forms of pelvic pathology—first, as to the generator itself Many types were put on the market, some good and many bad, the main trouble being a lack of capacity Second, the electrodes were improperly constructed, the usual trouble being a lack of surface, especially in the active electrode Third, improper measurements of the heat supposed to be produced in the tissues—in reality, in the electrode only Fourth, a wrong conception of what was actually needed as to type of heat and its application for the cure of different pathologic lesions

Take, for example, gonorrhreal conditions Different authors claim that 114 degrees Fahrenheit are necessary to kill this type of bacteria The answer to this is contained in the report of Scheffey and Schmidt (1), from the Departments of Gynecology and Physical Therapy in Jefferson Medical College, in which they say "Whatever diathermy accomplishes is due to the increase in circulation brought about by local application of heat, rather than from any heat generated in the diseased tissues themselves and surely not from any destruction of bacteria by heat" Also this quotation from an article by Jeck (2) "After all, it is the heat, however applied, that turns the trick"

The first really scientific attempt to arrive at the temperature of the female pelvis has been carried out by Dr Royston and his co-workers (3) They have designed an interesting instrument and measured the temperature in a very satisfactory manner, and their work is to be highly commended Nevertheless, let me quote from Paragraph 8 in their conclusions "It is impossible to maintain this degree of heat (108 to 115 degrees) for a period of over five to eight minutes, due to the dissipation of heat by

the blood stream" This is not due to faulty technic, but to the modality used, namely, diathermy

What is needed by the average practitioner is a simple, safe, and efficient method that requires no electrical knowledge nor special, complicated technic, and which is applicable to both male and female pelvis

Feeling that much could be gained by exploring the field of heat generated from ordinary sources, and realizing the benefit that we have derived from hot water in the form of baths, douches, irrigations, the hot water bag, etc., the writer decided to investigate from this angle

Hot water applied directly to the mucous surfaces is, after a time, an irritant It is also "messy," yet it produces an ideal, even heat Water confined within a suitable container that is flexible yet separates it from contact with the mucous membrane should be ideal The container must be flexible and dilatable, so that it will conform to any and all irregularities of contour The arrangement must be such that when its bulk is introduced into the vagina or rectum it will be small, yet capable of being increased so that a maximum amount of heating surface may be brought in contact with the pelvic contents Therefore, a perfectly safe heating element must be designed, one which a novice may operate and one which cannot produce a steam burn in the event that the flexible container should break or leak

The diathermy electrodes on the market to-day are all of the rigid variety, and the surface contact is necessarily limited, the greatest amount of electrical contact obtainable being from approximately 10 to 12 square inches Due to the rigidity of the instrument, perfect contact with a prostate, for example, is impossible, while a flexible instrument will mold itself around the organ, thereby bringing the maximum amount of heat in contact with it

The problem of maintaining heat in the

SEVEN THOUSAND ÅNGSTROM UNITS PLUS¹

By RALPH C WALKER, M.D., PORTLAND, OREGON

BACK in the dim and distant past when man first made his appearance on this globe, he had no need for heat to keep himself warm and comfortable, for the earth was steaming and covered with a rank vegetation. Man had not yet learned to cook his food, for he had had no acquaintanceship with fire, and so still lived on herbs and shell fish. Terrific storms raged over the face of the earth, and the electrical discharges from the moisture-laden clouds brought terror to his primitive heart, but no fires resulted from this fascinating display, owing to the great dampness of the vegetation.

Later this condition gradually changed and man was made acquainted with the phenomenon of fire, which he worshipped, for he had grown to believe that it had been created by the gods of lightning, whose language he had partly understood in the terrible bolts. As the temperature of the atmosphere gradually decreased, man timidly approached these sacred fires and discovered that the heat was comforting to his benumbed body. Still later in the process of evolution, we are told that at one time two wild animals engaged in a death struggle accidentally fell into one of these fires and that their bodies were partly consumed. The odor of roasted flesh stirred a something in the innermost part of the cave man, and approaching, he timidly poked with his finger at the half-burned body of one of the animals. His curiosity cost him a burn and he promptly stuck the injured member into his mouth. The results were surprising, for, in addition to having cooled his finger, there lingered a delicious taste. Being more cautious next time, he procured a stick and

continued to experiment, with gratifying gastronomic reactions.

An important moment in history was recorded, for the status of the cave man immediately changed from that of the hunted to that of the hunter. The beasts were pursued and their bodies consigned to the sacred fires until they were roasted, after which they were devoured. In tending these fires men found that their bodies were not only warmed, but that their bruises and contusions were greatly benefited. Thus from antiquity comes our first lesson in the use of "seven thousand Ångstrom units plus."

The technic of conveying this modality to the body varies considerably. Primitive man probably first stood before the fire or slept in the warm ashes or on the heated ground. Later, we read, the early races placed heated stones in a pit dug in the ground, and, by pouring water on them, caused steam to be generated which was confined by means of coverings draped about the body—a forerunner of our modern steam baths.

Personally I can remember that as a child I was awakened at night by the so-called growing pains, at which time my mother would take me on her lap and, opening the door of the big "base burner," would hold me before the glowing coals thus to administer the infra-red rays to my aching limbs, with soothing results. Many of you will recall the warming pans, the jug filled with hot water, the heated flat-iron wrapped with flannel, and other contrivances for producing therapeutic heat.

With the development of high frequency currents and their adaptation for use, we thought that we had an ideal and convenient method of heating at will any portion of the body. Naturally, it should be a wonderful thing for pelvic conditions in both male and

¹Read before the Radiological Society of North America at the Sixteenth Annual Meeting at Los Angeles, Dec 1-5, 1930.

The bag was provided with an outlet and shut-off clamp, and hot water was introduced through a rubber tube from an ordinary irrigator, the height of the irrigator determining the amount of dilatation of the rubber bag. The heat was gradually increased by allowing the water to flow for a few moments out of the bag into a refuse pail, the temperature of the water in the irrigator being gradually increased to increase the heat in the bag. The time of treatment was 1 25 hour. Even with this crude instrument the results were very surprising.

I have a photostatic copy of one of their reports on the treatment of these acute and chronic gonorrhreal cases. The list comprises 35 cases, ages from six to 42 years, the average age being 24 years. Of these, 10 were fresh cases. These chronic cases had failed to respond to the usual treatment. The average number of treatments received under the new method was 10, the greatest number of treatments given was 30. By the old method, the greatest number of treatments given was 77, with an average of 28. To quote the report, which is dated Jan 3, 1928, the requirements for discharge are as follows: "No person shall be released from quarantine on account of gonococcus infection until three sets of smears of the urethra and cervix, two single and one double, a total of eight—48 hours elapsing between each set, with no douches or treatment—be taken and submitted to an approved laboratory with the report of ALL smears being free from gonococci."

The report does not state the condition of the pelvic organs, which, to those of us handling private cases, is of the utmost importance. In our practice, the cases reporting for treatment are usually of the chronic type with tubal or prostatic infection. Our custom has been to discharge the patients when they are free from all of their pathology rather than just the gonococcus as

demonstrated by the slide test. Also, not all of our cases are venereal. I can perhaps best illustrate by giving you several histories, in synopsis form.

CASE REPORTS

E F X., female, age 49 years, had previously undergone a subtotal hysterectomy for prolapse, part of one ovary being left. The appendix had been removed and the gall bladder explored and found to be full of calculi, however, it was not removed.

The patient was constipated and had been using laxatives for 15 years. She had a rectocele which she held in place by inserting her fingers into the vagina when her bowels moved. The woman suffered from severe headaches every two weeks which confined her to her bed for two or three days at a time. She had experienced hot flashes for two years preceding the present examination. She was mentally depressed and threatened to commit suicide.

This, my first case, was treated with what I now consider a very crude instrument which produced heat only. Treatments were given tri-weekly from May 29, 1929, to August 22 of that year, when she went to the beach. On her return, the patient was treated irregularly until December 20, receiving a total of 74 applications. After three treatments, the woman reported improvement and no headaches. A slight one occurred about a week later, and a little vertigo two weeks later, which was relieved by her lying down for an hour. On September 6, the patient reported that she had had no headaches, and her bowels were moving naturally twice daily. The rectocele at this time remained in place unless very heavy lifting was done, the hot flashes had disappeared and the mental depression was dissipated. In October, she did house cleaning, reporting for a few treatments then, and again in December, when nine treatments were given for the same trouble. The pa-

- pelvis may be compared to that which the heating engineer has had to meet in a draughty house. We wish to produce temperatures greater than the blood, therefore, our blood stream is acting as a cooling system. The engineer increases the number of square feet of heating surface in his radiators until the required amount of heat is obtained in the house. We must increase the number of square inches in our heating system if we are to obtain a required temperature in the pelvis and to maintain it there. Let me again call your attention to the statement of Dr. Royston and his co-workers to the effect that it was impossible to maintain the high degree of temperature for more than from five to eight minutes, due to the dissipation of heat by the blood stream. If we are to get results from heat, we must be able to keep the temperature steady for such length of time as we find necessary for the pathologic condition under treatment.

After much experimentation the speaker has designed an instrument which meets the requirements. The number of square inches of heating surface is approximately 40 for the average patient. The heater is so constructed that it cannot possibly injure the patient. The temperature of the tissues in the pelvis can be raised to 114 degrees Fahrenheit and kept there indefinitely if desired. It has been found that from 30 minutes to one hour is as long a treatment as is usually necessary. Treatments are repeated daily until a marked improvement is noted, after which tri-weekly applications are sufficient.

During the last few months, experiments have been carried on with another type of instrument having the same fundamental principles but designed to be used externally. This has many advantages, the principal one being that it pre-heats the blood stream so that a higher temperature may be maintained within the pelvis with more comfort to the patient. Experimentally it has been

found possible to raise the temperature from four to ten degrees without the patient being cognizant of the fact.

Massage has long been recognized as one of the outstanding physical assets, whether applied by the human hand, by water as in the shower bath, or by mechanical vibration. Heat and massage have always been linked together, therefore, it was but natural to add this modality to the heater. Needless to say the results have been surprisingly improved, so much so that the heating instrument alone is now seldom used except in the very acute cases. Both the internal and external instruments are fitted with these special forms of vibrators. I say special forms because one cannot use the vigorous type of vibration that is produced by the average vibrator sold.

These vibrators must be very gentle in their action so that sexual excitation may be avoided. Yet, with this mild form of vibration, infected tubes in the female and prostates in the male are induced to drain their contents with surprising ease. I have not found it necessary to carry on the usual prostatic massage so universally used. All authors have warned us of the dangers lurking in too frequent, or vigorous, prostatic massage. Would it not then be well to eliminate this phase of treatment and thereby, perhaps remove one cause of malignant degeneration? With this instrument, which molds itself to the contour of the prostate and produces a mild pressure thereon, the heat and vibration produce drainage without irritation or bruising.

The inroads made by gonorrhreal infection in the pelvis of both male and female have, for many years, held the attention of the medical profession and the public in general. Anything that will assist in combating this disease will have a definite place in our armamentarium.

About two and one-half years ago the Seattle City Hospital used a bag of rubber which was inserted into the female pelvis

The bag was provided with an outlet and shut-off clamp, and hot water was introduced through a rubber tube from an ordinary irrigator, the height of the irrigator determining the amount of dilatation of the rubber bag. The heat was gradually increased by allowing the water to flow for a few moments out of the bag into a refuse pail, the temperature of the water in the irrigator being gradually increased to increase the heat in the bag. The time of treatment was 1 25 hour. Even with this crude instrument the results were very surprising.

I have a photostatic copy of one of their reports on the treatment of these acute and chronic gonorrhreal cases. The list comprises 35 cases, ages from six to 42 years, the average age being 24 years. Of these, 10 were fresh cases. These chronic cases had failed to respond to the usual treatment. The average number of treatments received under the new method was 10, the greatest number of treatments given was 30. By the old method, the greatest number of treatments given was 77, with an average of 28. To quote the report, which is dated Jan 3, 1928, the requirements for discharge are as follows: "No person shall be released from quarantine on account of gonococcus infection until three sets of smears of the urethra and cervix, two single and one double, a total of eight—48 hours elapsing between each set, with no douches or treatment—be taken and submitted to an approved laboratory with the report of ALL smears being free from gonococci."

The report does not state the condition of the pelvic organs, which, to those of us handling private cases, is of the utmost importance. In our practice, the cases reporting for treatment are usually of the chronic type with tubal or prostatic infection. Our custom has been to discharge the patients when they are free from all of their pathology, rather than just the gonococcus as

demonstrated by the slide test. Also, not all of our cases are venereal. I can perhaps best illustrate by giving you several histories, in synopsis form.

CASE REPORTS

E F X., female age 49 years, had previously undergone a subtotal hysterectomy for prolapse, part of one ovary being left. The appendix had been removed and the gall bladder explored and found to be full of calculi, however, it was not removed.

The patient was constipated and had been using laxatives for 15 years. She had a rectocele which she held in place by inserting her fingers into the vagina when her bowels moved. The woman suffered from severe headaches every two weeks which confined her to her bed for two or three days at a time. She had experienced hot flashes for two years preceding the present examination. She was mentally depressed and threatened to commit suicide.

This, my first case, was treated with what I now consider a very crude instrument which produced heat only. Treatments were given tri-weekly from May 29, 1929, to August 22 of that year, when she went to the beach. On her return, the patient was treated irregularly until December 20, receiving a total of 74 applications. After three treatments, the woman reported improvement and no headaches. A slight one occurred about a week later, and a little vertigo two weeks later, which was relieved by her lying down for an hour. On September 6, the patient reported that she had had no headaches, and her bowels were moving naturally twice daily. The rectocele at this time remained in place unless very heavy lifting was done, the hot flashes had disappeared and the mental depression was dissipated. In October, she did house cleaning, reporting for a few treatments then, and again in December, when nine treatments were given for the same trouble. The pa-

tient has had no treatments since December, 1929, and, upon a recent examination, I found her entirely well. She reports that the rectocele is staying in place and that her bowel movements are normal.

E H Y, female, age 30 years, exhibited an old chronic gonorrhreal infection, involving both tubes. On March 1, 1929, the woman suffered an acute attack and was taken to the hospital. Inasmuch as she was flowing, the attending physician thought that attempted abortion was the cause, and so curetted the uterus. As her temperature rose to 105.5 degrees a blood transfusion was given, as well as numerous saline injections. The patient left the hospital after 10 weeks and spent eight weeks at home, where, although she gained in both weight and strength, the pain was acute in her tubes whenever she stood.

At this time, her surgeon wished to remove the tubes but she refused. She was placed on our treatment July 29, 1929. After the first one, she had a bloody, purulent discharge but her improvement was marked, and she resumed her work which kept her on her feet eight hours daily. In October her surgeon pronounced her well. At this time the tubes could not be palpated and there was no soreness in the pelvis.

H H B, male, age 32 years, had suffered from a gonorrhreal infection four years previous to the present examination. This yielded to treatment after a tempestuous course and there had been no return of symptoms. The patient, who consulted me on account of inability to perform his family duties, said that he had been drinking quite a bit of homemade beer. Examination showed the prostate to be slightly enlarged and tender, but smears made from fluid expressed from the posterior urethra showed non-specific bacteria. After the second treatment, the patient had a discharge, purulent in character, but negative for gonococci. After the tenth treatment the discharge dis-

appeared and he was able to have intercourse successfully. He was discharged after 34 treatments.

A N Z, male, age 62 years, height 5 feet, 7 inches, weight 200 pounds, striped. There was no venereal history. Hypospadias, about four years previous to the present examination, the patient found it necessary to urinate more frequently at night, attributing it to an irritable bladder due to his drinking great quantities of water. The number of urinations gradually increased to seven or eight a night. Two years previous to examination, the patient had had an acute prostatitis, but was catheterized only twice. At the time the residual urine was about seven ounces and he was told that operation was necessary. This was refused. On Oct 14, 1930, the patient suffered another attack and consulted me. I removed 36 ounces of urine from the bladder, administered urinary antiseptic, and catheterized him four times daily. Examination revealed a very large, smooth, hard, and tender prostate. Pelvic treatment was instituted at once. Within a few days the patient began to void a bit of urine. The amount rapidly increased, and the catheterizations were decreased in number as the residual urine lessened. It is very probable that the patient had had residual urine during the four years preceding. Six weeks later, the prostate had decreased very materially in size and was not tender, and the residual urine amounted to between 1.75 and 2 ounces.

The patient was not confined to his bed nor was it necessary to irrigate his bladder. Since beginning the treatment, he has continued to attend to his professional duties, has gained in strength, and now reports that he feels better than he has for several years. What the final outcome will be I cannot at this time say, but most certainly, if there be need for surgical interference, the patient will be found in a much improved physical

condition and so better able to meet the shock of an operation

SUMMARY

1 The use of seven thousand Ångstrom units plus dates back to antiquity, fires started by lightning flashes probably being the first generators to be put to use by mankind

2 The development of high frequency currents marked the modern use of this modality, but results in pelvic pathology have not been all that we had expected

3 Failure has been due to the lack of proper equipment, improper measurements of the heat produced, and a wrong conception of what was actually needed in the type of heat and its application for the cure of different pelvic lesions

4 The development of a dilatable instrument to increase the heating surface in the pelvis and to maintain constant temperature up to 114 degrees Fahrenheit over long periods of time, without danger to the patient, has been a most important step

5 The average physician needs a simple safe, and efficient apparatus, one which re-

quires no electrical knowledge or mastery of complicated technic, and which may be used to treat both male and female pelvis

6 The proper type of vibration, in addition to heat, secured results in a much shorter time than did the thermal instrument alone

7 The development of an external applicator to pre-heat the blood stream enables one to secure higher temperatures more rapidly and without discomfort to the patient

8 The results after three years of experience show that both acute and chronic pelvic inflammatory processes can be made to yield in a much shorter time than by the usual mode of treatment, and, in many cases, surgical interference is unnecessary

X-rays Relieve Baby's Stomach Obstruction—The method whereby X-ray treatment relieves obstruction of the lower opening of the stomach in newborn infants has been successfully used in 33 cases during the last five years, in only four of which it was unsuccessful

Special diets, drugs, and surgical operation to remove the obstruction have all been found effective

methods of relieving pyloric stenosis in many cases The advantage of the new method which employs X-rays is the saving of time The radiation takes effect within 24 hours if it is effective at all, whereas if medical treatment is tried it may require a week or two to be effective By that time, if it is not effective, the child may be so weakened that he cannot stand an operation, if one is considered necessary—*Science Service*

A CRITIQUE OF THE ROENTGEN SIGNS OF INFANTILE SCURVY

WITH REPORT OF THIRTEEN CASES

By KATSUJI KATO, M.D., CHICAGO

From the Children's Hospital, Los Angeles, and the Department of Pediatrics,
University of Chicago

A STUDY of infantile scurvy at present appears to have lost much of its former interest, first, because its etiology is now firmly established, and, second, because of the fact that the disease is rapidly becoming an almost extinct disorder in civilized countries. Nevertheless, the condition still exists. It is interesting to note that the cases which are presented here occurred in Southern California where "sun-kissed oranges" and other citrus fruits which contain the antiscorbutic vitamin are so abundantly produced.

The literature on infantile scurvy is now so enormous that an attempt to review it would be too tedious. But it is important to remember that the disease was first thought to occur frequently in combination with rickets (10), and was, in fact, thought to be a form of acute rickets (20). It was Barlow (4), however, who gave the first comprehensive account of the disease as an independent clinical entity, basing his observations on 31 cases of infantile scurvy. In 1898 a collective investigation of the disease was undertaken by the American Pediatric Society (2). A very extensive study of the anatomy and pathology of scurvy was made by Hojer (17) who characterized the condition as a disease of actively functioning cells throughout the body. Hess and his associates (14, 15, 16) have published numerous papers on the modern conception of the disease in its various aspects.

As the skeletal system exhibits the most characteristic changes in this disease, valuable contributions have been made chiefly in the field of roentgenologic diagnosis. The earliest work was done by Fraenkel

(9), who described (1906) the zone of hypercalcification at the ends of long bones and called it the "white line." Wimberger (29, 30) called our attention to the circular shadow surrounding the center of ossification in the epiphysis of the long bones, insisting on its specificity in scurvy. He considers this a valuable sign in differentiating scurvy from rickets. Schwartz (26) made an interesting observation of the persistence of this ring inclosing the previously rarefied epiphyseal body as a pale inset in the later epiphyseal structure. This shows a much denser shadow as a result of healing. "The coarse, dense structure of the later bony growth appears in such contrast to the washed-out appearance of the previous epiphysis that the epiphyseal structure appears to have a double contour." He also found the same insets at the carpus and tarsus. Of course, these were only in the epiphyses that had reached ossification, namely, the os capitatum and the os hamatum in the carpus, and the os calcis, the astragalus, and the cuboid in the tarsus.

Pelkan (22), basing his observations on the roentgenograms in human scurvy as well as in experimental scurvy of guinea pigs, emphasized, in the diagnosis of early scurvy, the importance of the ground-glass appearance of the shaft, due to the disappearance of trabeculae. He proposed the term "scurvy line" to take the place of the term "Trummerfeld zone."

The four stages of infantile scurvy were clearly set forth by Bromer (6) who analyzed 56 cases from the standpoint of roentgenologic diagnosis.

1. The latent, or borderline, stage in which the most constant sign is the smooth

transparent, ground-glass appearance of the shaft, the pencil-point thinning of the cortex and the edging of the epiphyseal center

2 The second stage is characterized by the appearance of the zone of decreased density just behind the dense broadened line or zone of temporary calcification at the end of the diaphyseal shadow Furthermore, the first sign of hemorrhage may appear, indicating the weakening of the zone of temporary calcification, some of its substance being pushed out by the slight trauma of the distending force of the hemorrhage

3 The third stage is that of well-developed subperiosteal hemorrhage It is in this stage that epiphyseal separations most frequently occur

4 This is the stage of absorption of hemorrhages with repair of all of the scorbutic lesions The progressive decrease in the breadth and length of the hemorrhages, with evidences of calcification, can be made out at this stage

The most recent contribution along this line was made by McLean and McIntosh (19) who made a valuable *résumé* of the frequency with which the various roentgenologic signs of scurvy occurred in 51 cases with especial emphasis on the process of healing They described multiple epiphyseal separations at vertebral ends of several ribs in one patient, which three weeks afterwards were seen to be undergoing calcification with elevation of the periosteum Although the beading of the costochondral junctions on the anterior chest wall in scurvy had been described adequately by Hess and others, this phenomenon of epiphyseal separation at the vertebral ends of the ribs was, for the first time, described by McLean and McIntosh

The 13 cases which form the basis of the present observations were all seen in the medical wards of the Children's Hospital, Los Angeles These cases are presented not as revealing any new facts about infan-

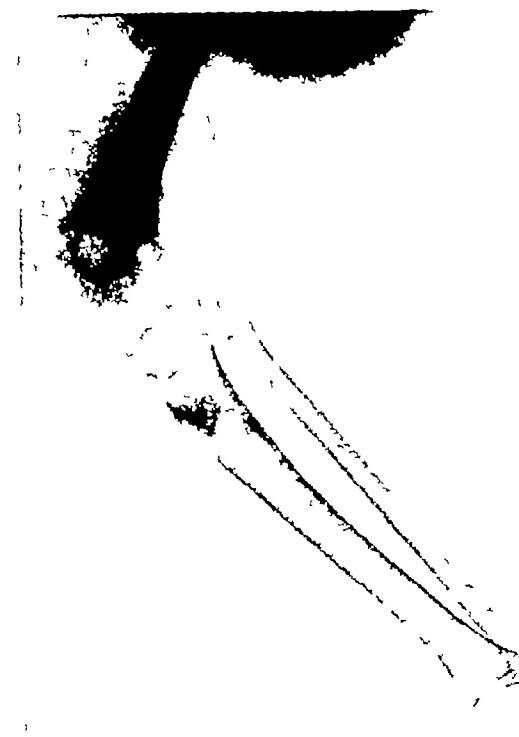

Fig 1 Lateral view of the right leg, Case E P., 11 months old, taken Nov 16, 1927

tile scurvy, but as furnishing the bases on which a critical evaluation of the roentgen signs may be made The essential features of the cases are summarized in Table I

From the summary thus tabulated of the main clinical findings in these cases, it is clear that there is a definite relation of feeding to the development of the disease Practically all are artificially fed infants, either pasteurized cow's milk or some proprietary milk or sugar preparations having been used Condensed milk, Mellin's food, malted milk, and even S M A have been mentioned in the feeding history of these patients Orange juice was not given consistently except in one case in which, however, the dose, one teaspoonful daily, was very inadequate Often mothers state that their scorbutic infants do not take the orange juice well, which apparently constitutes a sufficient excuse for not insisting on

TABLE I—SUMMARY OF THIRTEEN CASES OF INFANTILE SCURVY

| Name | Age, sex | Feeding history | Symptoms and signs | Hospital diagnosis |
|---------|-------------------|---|--|-----------------------------------|
| J O P | 1 year, male | Breast feed first few days, then S M A until 7 months Orange juice not well taken | Pain and swelling of lower extremities, loss in weight, pallor, bulging of right eye, petechial hemorrhage | Scurvy, rickets, secondary anemia |
| X. H. | 14 months, male | Pasteurized cow's milk, no sugar, no orange juice | Sore mouth and swollen gums, lost three or four teeth Cries when moved | Scurvy, rickets |
| D W | 10 months, female | Eagle Brand milk for one month, then formula with orange and prune juice (1 teaspoonful) once a day | Swollen ankles for one week, black and blue spots, nose bleed | Scurvy |
| R A | 1 year, male | Cow's milk formula from birth, 1 lump of butter daily, orange juice only occasionally | Pain in back of the neck and in both legs, bleeding from gums, four plus Wassermann test | Scurvy, rickets |
| B J B | 10 months, female | Mellin's food from birth, no orange juice or cod liver oil given | Pain in back and legs, swelling of legs, gums swollen and bleeding | Scurvy, rickets |
| A C (1) | 8 months, female | Formula with cow's milk first three weeks, then malted milk with Imperial Granum, no vegetables, cereal, orange juice, or cod liver oil given | Stiff leg for four weeks, gums blue and swollen | Scurvy |
| G P | 8 months, male | Cow's milk formula first two weeks, Eskay's food since, but with no orange juice or cod liver oil | Pain on touch | Scurvy |
| E P | 10 months, female | Cow's milk formula from birth, with nothing else | Pain in leg for seven weeks | Acute rickets, scurvy |
| B B | 9 months, female | Bottle-fed since she was three weeks old, no cereal, vegetables, or orange juice, cod liver oil (1 teaspoonful) once daily | Pain in body for three weeks, gums purple | Scurvy, abscess of upper eyelid |
| M J O | 3 months, male | Eagle Brand milk and S M A from birth | Fever and pain in body | Scurvy, acute pyelitis |
| T G | 10 months, male | Cow's milk was given for from 7 to 10 days, then Horlick's malted milk and S M A, occasionally orange juice | Pain in legs, loss of weight, swollen and bleeding gums | Scurvy |
| A C (2) | 5 months, male | Milk and strained oats, no orange juice or cod liver oil | Swelling under both eyes | Scurvy |
| D S | 1 year, male | Certified milk with dextri-maltose orange juice given first six weeks, cod liver oil for one week | Pain in legs for three weeks, red gums | Scurvy, chronic rickets |

its administration. Other vitamin requirements, especially cod liver oil, also seem to have been neglected in many cases. Solid foods have not been given adequately in the majority of the cases. The most remarkable

fault in this series lies in the infrequent use of vegetables. These cases, then, demonstrate very clearly that scurvy in infants is a result of lack in fundamental vitamin requirements, as well as of neglect in the

more liberal use of solid foods, especially the vegetables

Age incidence is also very suggestive. There is a striking agreement as to the time when the disease most frequently occurs

purplish eyelids. Loss of weight is a rather constant symptom, resulting from loss of appetite. Petechial hemorrhages on the skin are sometimes met with. With the hemorrhage along the shaft of long bones,

Fig. 2 (left) Same patient shown in Figure 1 The anteroposterior view of both legs, Dec. 2, 1927

Fig. 3 (right) Same case as shown in Figures 1 and 2, Jan 13, 1928

The majority of these patients are between 8 and 14 months, except two whose age, when scorbutic symptoms first appeared, were three and five months, respectively. From their history and the roentgenograms, they may be regarded as cases of unmistakable scurvy in its latent or early second stage.

As to the symptoms and signs, practically every case gives two typical manifestations, namely, pain on motion, particularly of the legs, and swelling and bleeding from the gums. One patient gives a history of having lost some teeth as a result of the disease. Another gives one of the most remarkable manifestations of hemorrhage, namely, exophthalmos, due to the post-orbital hemorrhage. The right eye of this patient was quite prominent with very edematous and

elevating the periosteum, there is often an appearance of swelling and edema of the extremities. Fever may, or may not, be present. In one patient with fever, there was a complicating acute pyelitis.

The blood picture in scurvy is worthy of attention. Often there is a complaint of pallor which gradually increases in severity with the progress of the disease, usually due to anemia secondary to hemorrhage. In our series, the lowest erythrocyte count was 2,180,000 with 23 per cent hemoglobin. In this patient, the blood smears showed numerous nucleated red blood cells. In many of our patients, there are other signs of anemia, such as achromasia, anisocytosis, and polychromatophilia. Poikilocytosis is practically never found. There seems to be a more or less constant leukocytosis, up to

ground-glass appearance of the medullary portion and a thinning of the cortex, well visible in all the bones shown on the film. Another point, frequently overlooked at this stage, is a suggestion, or rather a beginning,

of the lateral spur formation. The mere fact that the zone of preparatory calcification is separated from the diaphysis by means of the zone of decreased density makes the lateral ends of this line appear

21,000, with relative increase in polymorphonuclear neutrophils. In one case which showed leukopenia with a decrease in granulocytes, the outcome was fatal, indicating a loss of resistance.

possible to illustrate every case in this series with all the roentgenograms which have been made. Such films as are truly illustrative of special points of clinical value are reproduced in the accompanying figures.

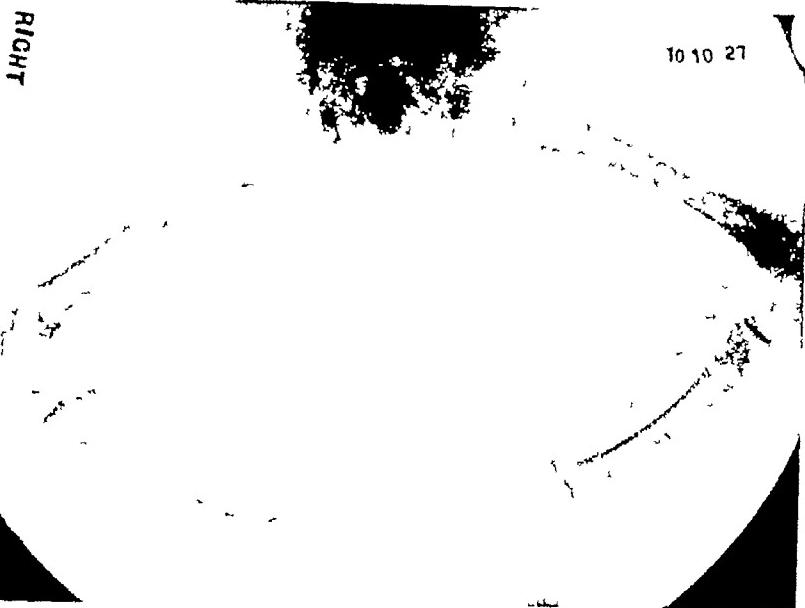

Fig 4 Lateral view of both legs of female patient, B. B., 10 months old, Oct 10, 1927

The treatment routinely adopted in the hospital consisted of the daily administration of fresh orange juice in large quantities together with an adequate dietary régime including the liberal use of solid foods. Up to eight ounces of orange juice were given to these patients each day. The course of the disease was favorable in the majority of cases, as a rule, the acute symptoms subsiding within a few days. Calcification of hemorrhages if any, commenced in about two weeks. Some cases were followed up in the Out-patient Department, and complete healing of the affected bones was proved by roentgenologic examinations many months after the attack of the disease.

In infantile scurvy, the roentgenologic study of the epiphyses of long bones is as interesting as it is valuable, from the standpoint of diagnosis and prognosis. It is im-

The three films from the patient, E. P., 11 months old, are of extreme value in following the course of subperiosteal hemorrhages in the lower extremities. According to the history, the first symptoms of the disease were noticed on Sept 25, 1927. The first roentgenogram (Fig 1), made 50 days afterward (November 16), shows a well-marked line of temporary calcification at the lower end of the femur, and the ends of both tibiae and fibulae. Immediately shaftward to this zone of increased density there is a narrow zone of decreased density, especially noticeable in the lower end of the femur and the upper end of the tibia. Thus, the film in this case shows an unmistakable Trummerfeld zone. Furthermore, there is a generalized atrophy of the shaft, though only moderate in degree, especially noticeable in the body of the fibula, as evidenced by the

TABLE II—BLOOD PICTURE IN INFANTILE SCURVY (13 CASES)

| Case | Erythrocytes | Leukocytes | Hemo-globin (Percent-age) | Differential count | | | | |

Note—The blood of patient J O P showed 32 nucleated reds in counting 200 white blood cells. In patient R. A., the blood smear showed hypochromasia and polychromatophilia. In patient M J O, the smear showed anisocytosis, achromia, and polychromatophilia. The smear of patient T G showed slight achromia and anisocytosis. The patient B J B showed very slight achromasia and polychromatophilia.

ing." The fact that such lesions are often found in scurvy is proved by the similar changes seen in the lower ends of the tibia and the fibula in our next patient. Clinically the patient showed typical symptoms of scurvy, namely, pain on motion, particularly in the back and in the legs, with swollen, blue gums. This case is of special interest in that, about two years later, a follow-up roentgenogram was made which revealed a complete healing of bone lesions, but the epiphyses at the upper ends of both tibiae showed the growth arrest line in the form of a rarefied elongated oval inset within the nucleus of ossification.

Very important roentgenologic findings in the chest film of this patient (Fig. 5), taken Oct 14, 1927, were the rounded swellings seen at the costochondral junctions of the ribs. This is the scorbutic beading of the ribs, frequently found in little patients suffering from infantile scurvy, quite analogous to the rachitic rosaries. It is of great interest that the beading of the ribs had almost completely disappeared in the next film, which was taken as a follow-up record 22 months after the previous examination.

As this phenomenon is more frequently

associated with the rachitic process than with scurvy, the two diseases have often been confused. There is still found to-day in the literature peculiar and vague combinations of terms, such as "scurvy rickets," used by some writers as synonymous with "infantile scurvy" (13). The hospital records also indicate the same confusion, as these cases are usually filed under a double classification of "scurvy" and of "rickets."

The next patient, J A P, one year old, presented a remarkable clinical symptom of exophthalmos of the right eye. Both eyelids were purplish-red in color, indicating ecchymosis in the subcutaneous tissue. There was no fever and, therefore, no evidence of this being due to any suppurative condition. The patient was exceedingly pale and anemic, the hemoglobin being 23 per cent (Sahli), with 2,180,000 red blood cells. The roentgenogram of the lower extremities (Fig. 6), made about two months after the onset of symptoms, shows bilateral dislocation of epiphyses on both sides at the lower ends of both femora, with a considerable amount of bone destruction at the metaphyses. There is a slightly noticeable beginning hemorrhage at this point, causing a

particularly prominent. This is suggestive of a spur, even though there is no actual dislocation or displacement of the hypercalcified line.

Another very constant sign at this stage

of the femur. There is no sign of hemorrhage in the lower legs.

The third film (Fig. 3), taken 27 days after the second, is equally spectacular in that the hemorrhages are now being organ-

Fig. 9 Chest and upper extremities, case of R. A., year-old male infant, April 13, 1926

is the so-called Wimberger's sign, which is the edging or rimming of the nucleus of ossification in the epiphysis by a comparatively dense, yet thin, line, its central portion having a typical ground-glass appearance. This gives a peculiar ring-like shape to the oval, or roughly spherical, center of ossification. This sign is found in all epiphyses at the ends of long bones, as well as in the small bones of the wrist and the ankle, as pointed out by Schwartz. It is interesting to note that in this film there is no suggestion of hemorrhage anywhere.

The second film (Fig. 2), taken 18 days after the first, is a very spectacular picture in that the most outstanding phenomenon is the extensive hemorrhage all along the shaft of the femur on both sides. The epiphyses appear to be dislocated, and this dislocation is sometimes called epiphyseal separation. The outer contour of the hemorrhagic mass seems to be continuous with the line of hypercalcification at the lower end

ized and there is an absorption of the hematomas as well as fairly well-marked calcification. The epiphyses still appear separated.

In the next patient, B. B., 10 months old, in whom scurvy had its onset about two months before the first film (Fig. 4) was made, we fail to find all the remarkable roentgen signs of the disease manifested in the previous case. The generalized osteoporosis of the shaft of long bones is evident, with unmistakable Wimberger's sign. The epiphyses of the lower ends of both femora appear to be jammed up against their metaphyses, which is a variety of epiphyseal separation. No hemorrhage was noted in this patient at any time. The Trummerfeld zone is distinct at the upper ends of both tibiae, while the lower ends of both tibiae reveal destructive lesions which closely resemble those found in rickets. The roentgenologist's comment on this film was "Rickets and scurvy, the latter predominat-

having made a correct diagnosis with the aid of roentgenology

THE ROENTGEN SIGNS OF INFANTILE SCURVY

Many references are found in the literature on the roentgen signs of scurvy. Beginning with the work of Fraenkel in 1904, Baetjer, Wimberger, Pelkan, Schwartz, Bromer, and finally McLean and McIntosh, have each contributed very illuminating discussions of these signs in the differential diagnosis of infantile scurvy. After a perusal of these excellent papers, the question naturally arises, "Are these signs truly pathognomonic of infantile scurvy?" A brief discussion of each of these signs may be of interest.

There are at least ten roentgenologic signs found more or less constantly in well-developed cases of infantile scurvy, which may be stated as follows:

1 A finely irregular, broadened, intensely calcified zone of preparatory calcification at the epiphyseal end of long bones, the so-called "white line" of Fraenkel.

2 A small spur at the lateral edge of the epiphysis (Pelkan).

3 A zone of rarefaction immediately back of the zone of preparatory calcification, the "scurvy line" (22), the "framework marrow" (6), or the "Gerustmark" (25).¹

4 A broad, finely irregular edge of dense shadow encircling the nucleus of ossification at the epiphysis, together with rarefaction of the central portion, "Wimberger's sign." This has been shown in the centers of ossification in the carpal and tarsal bones (26).

5 Separation of the epiphysis.

6 A ground-glass transparency of the shaft, with clouding or obliteration of the trabecular structure which is visible in normal bones.

7 A thinning of the cortical shadow, often represented merely by a narrow white line.

8 Subperiosteal hemorrhage and evidence of hemorrhage into the soft parts.

9 Subperiosteal fractures in the ends of the diaphysis.

10 Enlargement and angulation of the costochondral and of the vertebral junctions of the ribs.

The first of these signs, namely, the prominent zone of preparatory calcification, which is very striking in scorbutic bones, is, however, not absolutely characteristic. This line represents in general the results of hypercalcification which may be due to either of two causes. The arrested length growth of long bones may cause a piling up of calcium salts at the place of greatest activity, or it may be the result of a deposit of some other abnormal substances. The majority of cases showing this zone of increased density appear to be due to hypercalcification, but at present evidences are still insufficient to conclude that substances other than calcium may not be responsible for the production of this line.

Recently increasing evidence seems to be accumulating which goes to prove that similarly dense lines are produced unmistakably by such conditions as chronic lead poisoning (Vogt, Caffey, Park, etc.), and after a prolonged administration of phosphorus (28) or cod liver oil containing phosphorus (23). Viosterol, which is now being employed clinically in increasing measure, may give rise to a similar dense shadow at the metaphysis.

Lehmann speaks of "year rings" in connection with celiac disease. The lines of hypercalcification at the ends of long bones, associated with areas of distinct rarefaction in the metaphyses, have been seen on the roentgenogram of a fifteen-month-old child who received an intensive anti-rachitic treatment with phosphorized cod liver oil. A general interest now prevailing in the

¹On account of great confusion and ambiguity connected with the term "Trümmerfeldzone" it appears advisable to drop the term in the discussion of infantile scurvy, as no two authors use it with the same connotation.

line of hypercalcification to be indistinct and to appear as definitely separated. Similar changes are noted at the upper ends of both tibiae, and there is a definite hematoma on the upper end of the left tibia. The lower ends of both tibiae and fibulae also show definite changes. The generalized osteoporosis of all these bones, resulting in loss of trabeculations and thinning of the cortices, and the similar atrophy of the epiphyses with positive Wimberger's sign are most characteristic of the transition from the second to the third stage of the disease. It is also worthy of note that the fibula, particularly on the left, appears to be dislocated and its head separated from that of the tibia, due, evidently to the hemorrhage which is taking place at the metaphysis of the tibia.

It is to be added, furthermore, that this case also shows some lesions, particularly at the lower ends of both tibiae and fibulae, which closely resemble those found in rickets. The presence of these changes can be explained more satisfactorily by the generalized bone changes due to scurvy than by assuming a co-existence of rickets.

The film (Fig. 7), taken after eight days of intensive treatment in the hospital, reveals extensive hemorrhages along the shafts of both femora and both tibiae. This is a remarkable film of a very severe form of infantile scurvy, characteristic of the third stage. An interesting finding on this film is the presence of a well developed Trummerfeld zone at the upper ends of both femora, particularly well seen on the right side. Another film (Fig. 8) from this patient shows typical lateral spurs at the upper ends of both humeri, with a well marked Trummerfeld zone. The lower ends of the radii and ulnae also show typical changes. Generalized osteoporosis is evident, but no hemorrhage is noted. It is also interesting to note on this film the beading of the costochondral junctions of the ribs, quite similar to that found in the previous case. As the

film was made with the patient lying on his back, these swellings are not so clearly outlined as in the other case, but they are sufficiently clear for our recognition.

In the next patient, R. A., one year old, the film (Fig. 9), taken about two months after the first symptoms of scurvy were noted, shows extensive hemorrhages on both humeri, more marked on the right. The hemorrhage appears to be undergoing early calcification, which is the beginning of the fourth stage of infantile scurvy. The beading of the ribs is also receding, and the radius and ulna show typical changes at their distal ends. Generalized atrophy of the body of long bones and thinning of the cortex are also evident on this film.

The present series of cases illustrates fairly well the more important roentgen signs of infantile scurvy which have been accepted as pathognomonic of the disease. On the whole, the disease can be readily diagnosed without confusion when the typical clinical signs are present. This corresponds to the second stage from the standpoint of roentgenology. During the first period, in which the clinical signs are so indefinite that a correct diagnosis is impossible, roentgenology comes to the aid in establishing the diagnosis.

Pelkan is able to diagnose latent scurvy by the roentgenologic triad, consisting of (1) the broadened epiphysis (2) the dense shadow around the center of ossification of the epiphysis, and (3) the absence of trabeculations in the shaft. This is an important contribution to pediatrics as well as to roentgenology, for it is a common experience to see cases diagnosed as nutritional disturbance, in which the usual symptoms are pallor, loss of appetite, and failure to gain weight, which, in fact may be latent or borderline cases of infantile scurvy. The fact that automatically high-vitamin diet is prescribed to these patients, with favorable results, does not excuse pediatricians for not

sign, although attention was first called to it by Reyher, in 1912, and by Gott, in 1919. It was Wimberger, however, who insisted that this sign was specific in scurvy. But it has since been pointed out by several authors that this sign is by no means limited to scurvy, it may be found in such conditions as rickets, lead and phosphorus poisoning, as well as in some other forms of metabolic disturbances. Hence, it is impossible to regard this as an absolute sign in the diagnosis of scurvy. In this connection, it is also interesting to note the persistence of this rarefied area in the epiphyseal center of ossification long after recovery from the disease has taken place. This is well demonstrated in one of our patients, a roentgenogram of whom, taken 22 months after the first was made, shows a light circular area in the very core of the lower epiphyses of both femora and the upper epiphyses of both tibiae. It is to be added that McLean and McIntosh observed similar "scars" in a patient with acute lymphatic leukemia as well as in a patient with anemia of the von Jaksch type.

"Separation of the epiphysis" has been regarded by many as a term not strictly accurate in the description of the actual pathology which takes place at the ends of long bones in scurvy. It was Wimberger who proposed to substitute the term "separation of the metaphysis," for the line of cleavage is not through the epiphysis but through the metaphysis, the displaced epiphysis carrying with it the zone of preparatory calcification. Moreover, it has been particularly emphasized by McLean and McIntosh that this separation of epiphysis should include not only the cases in which the epiphyseal center is displaced laterally or anteroposteriorly, causing a distortion of alignment with the main axis of the shaft, but also those in which the dislocation takes place toward or away from the end of the bone even though there is no

actual distortion of alignment. In lateral displacement, we have the formation of lateral spurs, but in longitudinal dislocation, the abnormality is found in an undue widening of the zone of framework marrow or of rarefaction, because of the pull which is exerted by the centrifugal separation. Or it may appear as a jamming-up of the metaphysis with a narrowing, or at times almost an annihilation, of the zone of rarefaction due to the centripetal dislocation of the epiphyseal end. This phenomenon, which is very characteristic, may be regarded as one of the more reliable roentgen signs of scurvy. However, it must be remembered that, in congenital syphilis and osteogenesis imperfecta, such a separation may also take place. The distinguishing feature consists in the position of the line of preparatory calcification with reference to the epiphysis.

Ground-glass appearance of the shaft of long bones has been pointed out, particularly by Pelkan and Bromer, as being frequently found in scurvy. The latter considers this one of the roentgen signs of scurvy in its latent stage, when there are no clinical symptoms. With perfect radiation technic, the phenomenon is found to be due to the loss of trabeculation, caused by the atrophy of the spongiosa. This is very frequently found in scurvy, as our figures indicate, but McLean and McIntosh state that they were able to find this phenomenon in only one-fifth of their cases. That this is not specific for scurvy is shown by the fact that the similar appearance of the medulla of long bones is found in many other conditions, such as rickets, paralyses of many causes, and certain cases of chronic intoxication. Therefore, the emphasis placed on this phenomenon as a distinguishing feature of scurvy, in contrast with that of coarse trabeculation sometimes found in rickets, is not tenable.

The same applies to the thinning of the cortex, which is also regarded by some as

study of various conditions under which this zone may be produced will undoubtedly reveal many other factors in addition to hypercalcification. Thus, we are led to believe that this line is not a sign peculiar to scurvy. The so-called transverse lines described in detail by Eliot, Souther, and Park (8) have no relation to this line, but they are other examples of similar shadows produced under apparently normal conditions.

As to spur formation at this zone of increased density in moderately severe stages of scurvy, it is generally agreed that this may also be present in other conditions, especially rickets. The spur is said to occur in scurvy under three different conditions (1) in association with lateral separation of the epiphysis, the line of cleavage being in the zone of rarefaction, (2) as an early sign of organization and calcification of a subperiosteal hemorrhage, and (3) more rarely without any demonstrable epiphyseal separation or subperiosteal hemorrhage. In rickets, a spur may be seen on a roentgenogram, merely as a matter of contrast between the area of preparatory calcification and the swollen cartilaginous tissues. The distinguishing feature is said to consist in the fact that the lateral spur of scurvy is always at the right angle to the longitudinal shaft of the bone, while in rickets the direction of the projection is often in the direction of the joint. This, however, is not always the case, especially in view of the fact that, in scurvy, the spur is not seen as a solid and uniform projection but may assume variable forms according to the degree of hypercalcification as well as the angle from which the roentgen ray is cast. McLean and McIntosh apparently appreciate this difficulty when they remark, "Consequently the most that can be said in interpreting such a film is that there is some extension outward from the expected margin of the zone of preparatory calcification, the nature of which cannot be more precisely defined."

By far the most important roentgen sign of infantile scurvy is the zone of rarefaction, found just behind the zone of preparatory calcification at the end of the diaphysis. This has been called the scurvy line by Pelkan and the zone of framework marrow (Gerustmark) by Bromer and others. It is represented on the roentgenogram as an area of varying width immediately adjacent to the line of hypercalcification. This zone is apparently produced by a process of increased destruction of trabeculae, or, rather, a failure of the osteogenetic process. It is believed by some that the normally calcified trabeculae are replaced by the fibrous marrow in this region; this process is thought to be peculiar to scurvy. There is, however, one other condition in which this area of rarefaction is frequently present, namely, congenital syphilis. The differentiating points between these two conditions have been discussed by many authors. It must be emphasized here that, when the punched-out, rarefied areas in congenital syphilis happen to be grouped in a row just behind the line of hypercalcification, in appearance they may simulate very closely the scurvy lines. It must be admitted, however, that the presence of this scurvy line is one of the most reliable signs of infantile scurvy on a roentgenogram. Congenital syphilis is usually seen in much younger infants with clear-cut history and other signs which aid in unquestionable diagnosis. These points have been adequately discussed by Alexander and Fraenkel Hartman and Friedman report true scurvy in a seven-year-old child in whom the "Trummerfeldzone" and "Gerustmarkzone" were both lacking.

The dense edging of the periphery of the epiphyseal center of ossification and the rarefaction of its center are analogous in pathogenesis to the increased density of the metaphysis, with its concomitant area of rarefaction immediately shaftward at the end of the long bones. This phenomenon is known in the literature as Wimberger's

ued use of such terms as the "Trummerfeldzone" and "Wimberger's sign" as diagnostic of infantile scurvy leads to confusion. Pelkan's triad in the diagnosis of latent scurvy is a very valuable adjunct, but it is not absolutely characteristic. Beading of the ribs is common both to infantile scurvy and rickets. Separation of epiphyses is most frequently found in infantile scurvy, but it may also be found in other conditions. The white line of Fraenkel is the least characteristic of scurvy, for it is merely a phenomenon of hypercalcification at the end of a long bone, which is seen in many diverse pathologic conditions.

The one sign which is absolutely unique in infantile scurvy is that of subperiosteal hemorrhage during the third stage of the disease. This can be only inferred clinically upon examination of the limbs in the light of a suggestive history, but the final diagnosis must rest on roentgenology.

A conclusion such as this is not to be interpreted to mean an attempt to minimize the diagnostic value of roentgenology, but rather to emphasize the necessity of broadening the experience of both clinicians and roentgenologists in proper evaluation and interpretation of the roentgen signs of infantile scurvy.

being specific for scurvy during the early stage. But this also is not constant. Its presence alone can never be interpreted as diagnostic for scurvy, as any other condition which causes bone atrophy is likely to produce a similar phenomenon.

Subperiosteal hemorrhage is very frequently found in a severe, acute form of scurvy. It usually seems to be preceded by epiphyseal separation, as it appears to begin at the point of separation, gradually burrowing beneath the periosteum. Due to the disease process, the latter is greatly weakened. The hemorrhage, which may be so extensive as to cover the entire length of the bone involved, is clearly demonstrated in our cases. When present, periosteal hemorrhage is so characteristic that it may be regarded as one of the most reliable roentgen signs of scurvy during its third stage. As healing takes place, the hematoma gradually becomes organized and calcification sets in, with final absorption. With subperiosteal hemorrhage, there may be hemorrhage into the soft parts, but this is of rare occurrence and, for practical purposes, it may be disregarded as a sign of scurvy.

Subperiosteal fractures have been observed by McLean and McIntosh. These occur in the spongy bone at the end of the diaphysis and are usually without a definite line of cleavage, but show a collapse or buckling of the trabecular structure at that point. Fractures, however, are not frequent and constant and, therefore, cannot be regarded as specific for scurvy. When they occur, the condition must be clearly differentiated from rickets, osteogenesis imperfecta, congenital syphilis, and other conditions in which such fractures are also frequently seen.

There is one other roentgen sign of scurvy, often overlooked by some observers and frequently confused by others, namely, the beading of costochondral junctions of the

ribs. McLean and McIntosh fail to mention this sign, although they briefly mention epiphyseal separation, clearly visible as lateral displacement of the zone of preparatory calcification of the diaphysis, at the vertebral ends of several of the ribs. This is a very interesting point, and has received little attention from roentgenologists. The most characteristic changes are found, however, at the costochondral junctions of the ribs anteriorly. During the second stage of the disease, we frequently find a row of swellings, either rounded or angular, along both sides of the sternum. This, called scorbutic beading of the ribs, is quite analogous to rachitic rosaries. Barlow himself states, "The sternum, with adjacent costal cartilages and a small portion of the contiguous ribs, appear as though they had been fractured by a blow from the front and had been forced backward." Hess points out that this beading has been frequently regarded as caused by rickets, hence confusion has arisen in many cases, resulting in an erroneous diagnosis of co-existence of rickets and scurvy. Beading, however, is quite characteristic of scurvy as well as of rickets, although in scurvy it is caused by epiphyseal separation. Thus the beading may be rounded, smooth, knobby in character, or it "may have an angular feel on palpation, the junction taking on a step-like form, as if the abutting ends of the cartilage and the bone were of unequal size and not well fitted to each other." This phenomenon is well illustrated in our Figure 9, in which the sternal ends of the ribs are seen to be enlarged, with characteristic zones of preparatory calcification.

CONCLUSIONS

If the above interpretation of the various time-honored roentgen signs of infantile scurvy is at all correct, there is but one conclusion to draw. The majority of these signs are not pathognomonic. The contin-

ued use of such terms as the "Trümmerfeldzone" and "Wimberger's sign" as diagnostic of infantile scurvy leads to confusion. Pelkan's triad in the diagnosis of latent scurvy is a very valuable adjunct, but it is not absolutely characteristic. Beading of the ribs is common both to infantile scurvy and rickets. Separation of epiphyses is most frequently found in infantile scurvy, but it may also be found in other conditions. The white line of Fraenkel is the least characteristic of scurvy, for it is merely a phenomenon of hypercalcification at the end of a long bone, which is seen in many diverse pathologic conditions.

The one sign which is absolutely unique in infantile scurvy is that of subperiosteal hemorrhage during the third stage of the disease. This can be only inferred clinically, upon examination of the limbs in the light of a suggestive history, but the final diagnosis must rest on roentgenology.

A conclusion such as this is not to be interpreted to mean an attempt to minimize the diagnostic value of roentgenology, but rather to emphasize the necessity of broadening the experience of both clinicians and roentgenologists in proper evaluation and interpretation of the roentgen signs of infantile scurvy.

U S X-ray Standard Lessens Danger of Burns—The danger of burns during X-ray treatments has been greatly lessened, according to Dr Lauriston Taylor, of the U S Bureau of Standards, by the completion and final testing of apparatus designed to measure the intensity of X-ray doses

"Until now, no exact and uniform measurement of the strength of X-rays has been possible," said Dr Taylor. "Now a doctor may calibrate his apparatus to learn the intensity of his X-ray doses without the necessity of guesswork. He will not burn his patient, nor will he commit the worse crime, in cases such as cancer, of undertreating him."

According to Dr Taylor, there are two factors in X-ray treatment, the intensity and the penetrative power of the ray. The ray's penetrative power depends on the shortness of its wave length, longer waves having a burning effect. The intensity of the X-ray dose is more important, and it is this intensity which he can now measure.

For three months Dr Taylor experimented in European national standardizing laboratories, consulting foreign scientists and comparing his apparatus with theirs. Before that he labored at his instruments in the Bureau of Standards to construct a portable X-ray standard, finally building one which is so simple that he could take it with him, and so accurate and dependable that it is designated as the primary or final standard of the United States. This he compared with foreign instruments, drawing up with European scientists specifications for an international standard to remedy

international confusion. This new apparatus is the only one in the world that completely satisfies these specifications, Dr Taylor says.

Uncle Sam's X-ray yardstick is in reality a small metal chamber into which X-rays are projected in a steady, uniform beam. When the rays pass through the air in this chamber they ionize the air, that is, set loose free electrons. This causes the air to become a partial conductor of electricity, which may be measured by an electric current and meters. The strength of this current depends on the strength of the X-rays.

France, Dr Taylor said had been comparing X-rays with radium emission, but the X-ray intensity as thus measured varied with the ray's wave length. The English laboratories did not guarantee steady and uniform transmission of the ray being gauged. The American apparatus does away with both difficulties, and furnishes as nearly as possible a means for transmitting, maintaining, and measuring a ray of uniform and standard intensity independent of all other conditions. For this reason France, Egypt, and several other countries have adopted Dr Taylor's specifications outright, and other countries have drawn up specifications which at present his apparatus alone fits.

"It is now up to the Bureau," Dr Taylor said, "to find a means for gauging exactly the penetrative qualities of the various X-ray wave lengths. The intensity of a ray used in medical treatment is but half the problem. Not until we have both standards can we call our standardization work complete"—*Science Service*

THE DOLICHOCOLON

By F. D. LAROCHELLE, M.D., and E. E. SMITH, M.D., SPRINGFIELD, MASSACHUSETTS

REDUNDANCIES or elongations of the colon with loop formation have been observed by radiologists for a number of years, but it is only recently that the condition has been recognized as a definite clinical entity. The symptoms that arise from this condition are generally pronounced constipation, meteorism, and indefinite discomfort over the colon, associated with vague general symptoms such as indigestion, loss of weight, and insomnia. The patient complains of rumbling following the use of laxatives and cathartics, with only partial evacuation. The liquid intestinal contents are swept down by an exaggerated intestinal peristalsis to the elongated and dilated loop that acts as a trap and arrests the intestinal flow.

This condition has been variously described as elongation or redundancy of the colon with loop formation. Recently Chiray (1) has coined for this anomaly the term "Dolichocolon" from the Greek "*δολιγός*". The great advantage of such a term is that it can be transferred from one language to another without the necessity of translation, and the search of the literature is greatly facilitated.

It is impossible to give an exact definition of this condition, for, while the clinical features are fairly well established, the mechanism of the disease is anything but clear. While we must differentiate between elongation and dilatation of the colon, in most instances it appears that both factors are at work. Since we have become familiar with this condition, we have seen a number of patients presenting this ailment, and we can recall a number before that time whom we then classified erroneously as suffering from simple constipation.

By dolichocolon we understand an elonga-

tion of one or more segments of the colon. Another view is that this condition is due to a generalized elongation of the colon and that the redundancy and loop formation are but manifestations of an attempt of the colon as a whole to adapt itself to the abdominal cavity. Yet another view is that the condition is a form of megacolon in which the augmentation in length has been greater than the accompanying increase in caliber.

Anatomically, the dolichocolon is an elongation of the colon, most often involving one segment, usually the descending, resulting in flexures, loops, and kinks in the lumen of the gut. This may be accompanied by dilatation of the affected segment.

This condition was first recognized by pathologists, who, however, made no attempt to associate these findings with definite clinical symptoms. The work of Lane served to make diagnosticians conscious of these deformities and the advent of X-rays and the barium enema made it easy to recognize these anomalies during life.

White (2), of Boston, reports that he found this condition in from 4 to 5 per cent of patients presenting gastro-intestinal symptoms, this figure has been accepted as about the average incidence of the disease. Certain authors observed the condition more often in women than in men, but there is some doubt about this. All are agreed that it is more common in adult life and, although there may be exceptions to this, the individuals affected are usually of the viscerototic type. Our youngest patient was a 5-year-old female, the oldest, a 72-year-old man. While the condition may affect any part of the colon, it is by far more common in the sigmoid.

Numerous explanations have been offered but none is entirely satisfactory. It is prob-

U S X-ray Standard Lessens Danger of Burns—The danger of burns during X-ray treatments has been greatly lessened, according to Dr Lauriston Taylor, of the U S Bureau of Standards, by the completion and final testing of apparatus designed to measure the intensity of X-ray doses

"Until now, no exact and uniform measurement of the strength of X-rays has been possible," said Dr Taylor. "Now a doctor may calibrate his apparatus to learn the intensity of his X-ray doses without the necessity of guesswork. He will not burn his patient nor will he commit the worse crime, in cases such as cancer, of undertreating him."

According to Dr Taylor, there are two factors in X-ray treatment, the intensity and the penetrative power of the ray. The ray's penetrative power depends on the shortness of its wave length, longer waves having a burning effect. The intensity of the X-ray dose is more important, and it is this intensity which he can now measure.

For three months Dr Taylor experimented in European national standardizing laboratories, consulting foreign scientists and comparing his apparatus with theirs. Before that he labored at his instruments in the Bureau of Standards to construct a portable X-ray standard, finally building one which is so simple that he could take it with him, and so accurate and dependable that it is designated as the primary or final standard of the United States. This he compared with foreign instruments, drawing up with European scientists specifications for an international standard to remedy

international confusion. This new apparatus is the only one in the world that completely satisfies these specifications, Dr Taylor says.

Uncle Sam's X-ray yardstick is in reality a small metal chamber into which X-rays are projected in a steady, uniform beam. When the rays pass through the air in this chamber they ionize the air, that is, set loose free electrons. This causes the air to become a partial conductor of electricity, which may be measured by an electric current and meters. The strength of this current depends on the strength of the X-rays.

France, Dr Taylor said, had been comparing X-rays with radium emission, but the X-ray intensity as thus measured varied with the ray's wave length. The English laboratories did not guarantee steady and uniform transmission of the ray being gauged. The American apparatus does away with both difficulties, and furnishes as nearly as possible a means for transmitting, maintaining, and measuring a ray of uniform and standard intensity independent of all other conditions. For this reason France, Egypt, and several other countries have adopted Dr Taylor's specifications outright, and other countries have drawn up specifications which at present his apparatus alone fits.

"It is now up to the Bureau," Dr Taylor said, "to find a means for gauging exactly the penetrative qualities of the various X-ray wave lengths. The intensity of a ray used in medical treatment is but half the problem. Not until we have both standards can we call our standardization work complete"—*Science Service*

colon, it is absolutely necessary to make a general examination. If the colon is examined first, some local lesion may be found that seems to explain the symptoms. The tendency then is to stop the study, but, if this is done, one can readily overlook other anomalies that might be of greater importance. Once it is definitely established that no other pathologic condition exists, attention is focused on the colon. The anus and anal canal are examined in the usual manner, a sigmoidoscope being introduced to exclude any lesion of the ascending colon involving the mucosa. Then the colon is emptied and washed by means of colonic irrigation. It may be necessary to repeat this, as oftentimes an unusual accumulation exists that is not readily dislodged at the first attempt. A barium enema, which is usually sufficient to demonstrate the condition, is then given to fill the entire colon and plates are made. Once the condition is recognized, it is well to empty the colon by another irrigation, because, if the pathology is marked, damage, or certainly discomfort might result from retention of a large amount of barium in the elongated loop. Then the patient is given barium by mouth and another plate is made in 24 hours. This demonstrates the condition conclusively.

TREATMENT

Many patients go on for years with this condition, with no other treatment than is usually practised for ordinary constipation. However, they invariably tell us that ordinary laxatives and cathartics do not have the usual effect, more relief being afforded by an enema although the discomfort is only partly relieved by the enema. The wave of enthusiasm for surgical treatment of this condition has passed now. It should be reserved for very special cases, and then only with great circumspection. It is probable that the results from surgical treatment have fallen far short of expected results.

Fig. 3 Elongation of the descending colon, with dilatation of the sigmoid in a child five years of age

If this condition is to be permanently relieved, we must first empty the whole colon, and then restore the normal tone of the colonic walls. After emptying, suitable diet with lubricants will facilitate the passage of intestinal contents through the elongated loop, leading to a disappearance of the exaggerated reservoir function of the affected segment. There can be no doubt but that this can be accomplished by medical measures.

In the way of laxatives, oil and agar emulsions with phenolphthalein are satisfactory. If necessary, a laxative pill can be given occasionally. During the first weeks of treatment, nothing will replace colonic irri-

Fig 1. A typical dolichocolon involving the sigmoid. Note the elongated sigmoid and the gas dilatation of the rectum.

ably fair to assume that all the factors enumerated are partly true, and that the resulting condition is a composite one, with emphasis on one or more features. While some authors think that the ailment is a congenital one, others believe that it is acquired. Pauchet claims that it is due to constipation. Zorzi thinks that the condition results from a derangement of the autonomous intestinal nervous mechanism. Others emphasize diet deficiencies or endocrine derangements as etiologic factors. At this time, the question cannot be definitely answered. An important fact to remember is that, whatever the condition may be, it can be made to disappear by medical measures and this would indicate that it is largely a functional derangement if there is a definite anatomic basis.

Why is the condition most common in the sigmoid? The sigmoid flexure is normally a reservoir. Dolichocolon is very likely an exaggeration of this function, in cases in

which the dimensions of the gut have exceeded normal anatomic limits and it is unable to regain its usual caliber. In a number of patients suffering from this condition, anal spasm can readily be recognized; it is natural to assume that this may be part of a spastic condition of the whole colon.

There are two distinct types of this disease—one associated with mucous colitis and spasm, and the other dyspeptic, with loss of appetite, indigestion, loss of weight, and indefinite discomfort in the abdomen.

The two complications that have been found are pericolic abscess and intestinal obstruction, but since these are rare and present no unusual features, they are not considered here.

In patients suspected of this condition, before undertaking examination of the

A NEW FEATURE IN IODIZED OILS¹

By FREDERICK R GREENBAUM, D Sc, CHICAGO

SINCE the introduction of iodized oil in therapy by Sicard and Forestier (1), its usefulness has been established, confirmed, and generally accepted by the medical profession for roentgen diagnosis and iodine medication. Sicard and Forestier produced an iodized poppy seed oil. Other iodized oils which are also available on the market to-day are iodized sesame oil and iodized rapeseed oil. Subsequently, brominated oils were also prepared. In all these halogenated oils, the unsaturated fatty acids of the oil are chemically combined with only one halogen, such as iodine, or bromine.

In 1897, E Merck, in Darmstadt (2) patented a method for making fats containing small amounts of iodine. In this patent the fact was emphasized that the presence of chlorine caused a darkening of the oil, and decomposition occurred in a very short time. If, however, quantities of the reagents forming iodine and chlorine in amounts below the theoretic one are used, then there were obtained stable oils containing iodine in amounts of 2, 5, 10, or 15 per cent and chlorine in very small amounts. In a patent (3) assigned to Merck and Company in 1909, Seifert points out that, up to that time, the following facts were known:

1 Complete treatment of fats with "chlor-iodine" yields "chloriodine" fats not stable and not suitable for medicinal use.

2 Complete treatment of fats with hydroiodic acid or with iodine and reducing agents yields iodine fats not stable and not suitable for medicinal use.

3 Incomplete treatment of fats with chloriodine yields stable chloriodine fats suitable for medicinal use.

Incomplete treatment of fats with hydroiodic acid or with iodine and reducing agents yields stable iodine fats fit for medicinal use. However, the incomplete treatment yields only fats or oils with a low percentage of iodine and a very low chlorine content.

In 1928 two physicians (4) prepared iodine trichloride by passing chlorine gas over iodine. This they then dissolved in water and shook it with corn oil. This oil was used for their sinus work. They did not mention the iodine content of the oil nor were they aware of the fact that the chlorine was most probably also combined chemically with the oil.

THE NEW FEATURE IN IODIZED OILS

This was the status of the attempts to prepare fatty oil containing both chlorine and iodine when the problem was taken up in our research laboratories in 1929. In selecting the oil for our study, we were guided by a high iodine value, low specific gravity, low content of the free fatty acids. We also considered (5) that the unsaturated fatty acids, especially linoleic acid, of the oil are highly responsible for the irritating action of iodized oils. Poppy seed oil contains about 65 per cent of linoleic acid, while peanut oil contains only from 21.6 to 24.7 per cent. From these considerations we finally decided to use peanut oil. Peanut oil, called Oleum Arachis, also, is composed chemically of the glyceryl esters of the following fatty acids: oleic, linoleic, palmitic, stearic and arachidic. In addition, peanut oil contains in small amounts high melting fatty acids such as the normal eicosanic, docosanic, and tetracosanic acids described by Taylor (6) and Yantzen and Tiedke (7). These last investigators doubt very much the presence of

gations These empty and wash the colon, and repeated dilatation and contraction of the muscular walls combat the existing atony

While this condition is largely a local lesion, there are constitutional factors that must not be overlooked Attention should be paid to the endocrines, and a diet rich in vitamines may be indicated

Once a few cases exhibiting this condi-

tion have been recognized clinically, it will be found that it is more common than is generally known Every case of obstinate constipation may well be suspected of presenting one of these anomalies of the colon

Reports Effects of Benzene, X-rays, and Radium on Blood Formation—Radium, X-rays, benzene and its various compounds, such as arsphenamine, are all known to produce injuries to the blood-forming tissues, especially the bone marrow, in certain doses and with certain susceptible persons On the other hand, these agents are used in the treatment of blood diseases In a report to the American College of Physicians, Dr Edwin E Osgood, M D , of the University of Oregon

Medical School, reviewed the effects of these agents and the conditions under which they exert an action upon the blood-forming tissues

It was stated by Dr Osgood that serious poisoning from these substances in the industries is not uncommon but might be prevented by periodic blood examinations, elimination of the more susceptible individuals, reduction of exposure by local ventilation in benzene cases, and the use of less toxic substances—*Science Service*

gravity of 1.21, and are stable to light and heat

Table III shows the various physical properties of some vegetable oils and their halogenated products

From this table it is seen that iodized and chlorinated peanut oil has the highest relative viscosity of all halogenated oils, while the iodized and chlorinated esters of peanut oil have, with the exception of brominized olive oil, the lowest viscosity. Even the iodized and chlorinated peanut oil is suffi-

ciently heat stable to be sterilized by pasteurization

TOXICITY

Iodized and chlorinated peanut oil is non-irritating due to the fact that the iodine and the chlorine are firmly held in organic combination. The chlorine is just as firmly combined chemically as the iodine, so that no possible irritation could occur due to the presence of chlorine. The halogenated oil is also non-irritating due to the fact that the

Fig 1. Study of antrum, iodochlorol injection (Courtesy George D. Wolf, M.D., New York.)

lignoceric and isobehemic acids in peanut oil. This unique chemical composition is another reason why peanut oil was selected. No other vegetable oil offers such a wide variety of fatty acids as those contained in peanut oil, some of them being entirely specific for peanut oil only.

From a glance at Table II one will notice that peanut oil has a low specific gravity, a fairly high saponification value, and iodine value. The content of the free fatty acids in the native oils is very low. These physical properties make peanut oil a very suitable vegetable oil for the purpose of making halogenated oils.

We succeeded in introducing iodine and chlorine in peanut oil in such a fashion that the oil was saturated with halogens accord-

ing to the iodine number of peanut oil. One important feature in the manufacture of this halogenated oil is the fact that the free fatty acids are removed before and after halogenation, which removes the irritating properties and also affords remarkable stability to the halogenated oil.

This iodized and chlorinated oil, which is otherwise known as iodochlorol, contains about 27.5 per cent of iodine and 7.5 per cent of chlorine, so that the total content of halogen amounted to about 35 per cent. The action of chlorine and iodine is complementary and whether or not this results in a better shadow than produced by an oil containing iodine alone remains to be established. The halogenated oil so obtained has a brilliant yellow color, a specific gravity of 1.290 at 15.5°C., and a relative viscosity of 103, while the original peanut oil has a relative viscosity of 5.24.

ESTERS OF THIS HALOGENATED OIL

For many purposes, in fact for most purposes, this high viscosity of the halogenated oil is very desirable, but for some purposes, as in urologic work, a very low viscosity is desired. To accomplish this, we prepared the ethyl esters of peanut oil by esterifying the peanut oil with ethyl alcohol, introducing iodine and chlorine, which resulted in the formation of iodized and chlorinated esters of peanut oil, containing about 25 per cent of iodine and 7 per cent of chlorine. These esters are much more limpid than the oil, having a viscosity of 4.24, a specific

TABLE I.—FATTY ACID CONTENT OF TWO KINDS OF PEANUT OIL

Wolf (10) praises iodized oil for the study of antra and recommends its use in large institutions as a routine procedure. In the usual displacement technic, Proetz (11) obtained very satisfactory results by the use of iodized oil.

In our own researches with our iodized and chlorinated peanut oil (iodochlorol) in sinuses, X-ray plates of deep shadow, clearness, and sharpness were obtained, unexcelled by those obtained with any other contrast medium.

Figures 1 and 2 are illustrations of the study of antra by means of our iodized and chlorinated peanut oil.

In bronchography through the use of iodized oils, considerable progress has been made within recent years. The non-irritating properties of iodo-chlorol make it well adapted for this use. Wood (12) recommended the oral administration of iodized oil as an aid to the differential diagnosis of upper lobe bronchiectasis and pulmonary tuberculosis.

After several injections of iodized oil by aspiration into the lungs, Singer (13) reports satisfactory results in a case of streptothricosis. Stiehm (14) gives complete credit to the insufflation of iodized oil for successful treatment of bronchiectasis. Hygienic living, postural drainage, rest, and the systemic effect from the iodine content of the iodized oil are all possible factors. Case histories show that patients treated with iodized oils do better than those without this treatment. Eschbach (15) reports on a pulmonary gangrene cured by tracheal injection of iodized oil. Surgical intervention in such cases is difficult and dangerous. Eschbach recommends the use of iodized oil before operation is performed. According to Iglauer (16), endo-

peanut oil is highly refined before and after it is subjected to iodization and chlorination. It is, as has been established by animal experiments in our laboratories, of low toxicity and, therefore, well tolerated in large amounts. The esters of this halogenated peanut oil are likewise non-irritating and of low toxicity.

USES OF IODIZED OILS

In iodine medication, in cases in which large amounts of iodine are indicated, iodized and chlorinated peanut oil may be given in large doses, one to two teaspoonfuls, without producing any ill effects, such as iodism, etc. Iodized oils produce in general the same systemic effects as ordinary iodides, but their iodine is more slowly absorbed and excreted and they are more persistently retained in the tissues, especially in tissues rich in lipoids. The iodized oils generally pass the stomach unchanged and are saponified and absorbed in the small intestine. They are then deposited for the most part in lipoid tissues, in which they are gradually oxidized, yielding inorganic iodide, which is given off to the blood.

When a gradual long-sustained iodide action is desired, iodized oils have therapeutic advantages over ordinary iodides. Larger doses may be given than is the case in inorganic iodides without producing iodism.

In sinuses, recent investigators highly recommend the use of iodized oils for diagnosis (8, 9), pointing out that they can be injected into the various sinuses without harmful effects. Iodized peanut oil is particularly suitable in this field, because its viscosity is high and does not have to be diluted with heavy petrolatum or olive oil as is the case with other iodized oils.

In our own investigations, we have found iodized and chlorinated peanut oil (iodochlorol) very suitable for the study of monolateral and bilateral bronchiectasis, particularly if three parts of iodochlorol are mixed with one part of the iodized and chlorinated ethyl esters of peanut oil. The results obtained are shown in Figures 3 and 4.

In gynecology, considerable work has recently been done on the exploration of the fallopian tubes and the uterus for sterility investigation. The leading researches of Stein and Arens (23) have opened this field, making it accessible to almost every obstetrician and gynecologist. They devised a new radiographic table for pelvic radiography with iodized oil and pneumoperitoneum, combined the method of pneumoperitoneum with the one of iodized oil instillation (24) and obtained very satisfactory results. According to Rubin and Bendick (25), iodized oils should not be injected into the uterus without first proving, by peruterine carbon dioxide gas insufflation, that the fallopian tubes are definitely non-patent. Witwer, Cushman, and Leucutia (26) assert that hysterosalpingography by means of iodized oil is a safe and simple procedure. In a series of 152 cases, the authors observed only one accident, that of a ruptured tube which did not lead to any ill effects. The method is of great diagnostic value in developmental anomalies of the genital organs, in tubal conditions leading to sterility, in certain carefully selected cases of pregnancy, and in uterine tumors. The method is contra-indicated in recent hemorrhagic inflammatory conditions that are not completely quiescent, active infections or malignant growths involving the cervix, previous intra-uterine intervention, uterine gestation in which a therapeutic abortion is not desired, infected cervical or uterine polyps, and fever. In certain instances, the injection of iodized oil is of direct therapeutic value.

Lash (27) successfully used iodized oil in

cases of uterus bicornis, bilateral salpingitis, and pelvic peritonitis. The function of the tubes was not disturbed by the iodized oil as the patient delivered a full-term child one year after injection. Lash, however, believes that, in the presence of infections in the female generative tract, the use of iodized oils is contra-indicated, as they have no antiseptic properties.

That our own studies have given very satisfactory results with iodochlorol for the exploration of the fallopian tubes can be seen from Figure 5, obtained with our iodochlorol.

USE OF IODIZED AND CHLORINATED ESTERS OF PEANUT OIL

While intravenous pyelography has certain theoretic values, in actual practice the main reliance is still based upon retrograde pyelograms. A good pyelographic medium must have the following properties to be of service to urologists:

- 1 It should give a good shadow.
- 2 It should have a low viscosity and should be miscible with water in all proportions.
- 3 It should be of low toxicity and free from all irritation.

Our research laboratories have succeeded in developing such a medium, called iodochlorol emulsion (Searle). The active ingredient in this emulsion is the iodized and chlorinated ethyl esters of peanut oil, containing about 25 per cent of iodine and about 7 per cent of chlorine. It has a specific gravity of from 1.19 to 1.22 at 25° Centigrade. It has a relative viscosity of 4.2. This extremely low viscosity makes the iodized esters very suitable for pyelographic work, as the emulsion has a still lower viscosity. The iodized ethyl esters of peanut oil are mixed with a small amount of mineral oil and emulsified with 10 per cent potassium oleate. The emulsion also contains 0.5 per cent benzyl alcohol.

Fig 6 Normal retrograde pyelogram, iodochlorol emulsion (Courtesy Earl Ewert, M.D., Chicago)

bronchial injection is well borne by the patient, no disturbing effects being encountered. He recommends slow injection with the use of a special intubation instrument. Injection of the oil is contra-indicated in febrile or cachectic patients and in those with cardiac decompensation. Expectoration is usually increased for a few days after the introduction of the oil, a considerable portion being thus ejected. The remainder is eliminated by absorption.

Singer (17) describes the introduction of the iodized oil into the lungs by pulling the tongue out as far as possible and introducing the iodized oil with a straight cannula and a 20 c.c. syringe. Perfect films of the bronchiectatic cavities of the lungs were obtained in 25 cases. Archibald (18) pointed out the fact that iodized oils are contra-indicated in cases of tuberculosis and infections of the upper respiratory tract. In an

interesting study, Pinkerton (19) pointed out that iodized vegetable oils do not produce any reaction and do not appear to injure the lungs in any way. Their removal from the lungs seems to be accomplished entirely by expectoration. Free fatty acids in the oil produce necrosis in the lung tissue. The degree of drainage and resulting fibrosis produced by an oil in the lungs depends largely on the amount of free fatty acids originally present and on the rapidity with which hydrolysis progresses. The almost complete lack of reaction to neutral vegetable oil in the lung is probably due to the absence of enzymes capable of hydrolysing the oil.

A unique study was made by Zalewski (20), who used Finikoff's method to increase the defensive mechanism of the organism by stimulating the lipolytic and the proteolytic power of the blood. This was accomplished by intramuscular injections of iodized oil and by the peroral administration of calcium salts. Zalewski reported excellent and lasting results with this method in osteo-articular tuberculosis, tuberculosis of the epididymis, and lymph node tuberculosis.

Faulkner (21) studied the uses of iodized oil in pulmonary suppuration and found that intrabronchial injections of iodized oils permit a study of "internal drainage." Internal drainage is the spilling of pus from a diseased bronchus to the neighboring bronchi of either lung.

Soresi (22) has facilitated greatly the use of iodized oil for intratracheal injection by working out a simplified technic. He injects the iodized oil through a syringe (the oil being kept lukewarm), inserting the syringe into a special cannula tongue depressor. He anesthetizes the organs thoroughly, which avoids dripping of oil into the esophagus even if the patient moves the head.

In our own investigations, we have found iodized and chlorinated peanut oil (iodochlorol) very suitable for the study of monolateral and bilateral bronchiectasis, particularly if three parts of iodochlorol are mixed with one part of the iodized and chlorinated ethyl esters of peanut oil. The results obtained are shown in Figures 3 and 4.

In gynecology, considerable work has recently been done on the exploration of the fallopian tubes and the uterus for sterility investigation. The leading researches of Stein and Arens (23) have opened this field, making it accessible to almost every obstetrician and gynecologist. They devised a new radiographic table for pelvic radiography with iodized oil and pneumoperitoneum, combined the method of pneumoperitoneum with the one of iodized oil instillation (24) and obtained very satisfactory results. According to Rubin and Bendick (25), iodized oils should not be injected into the uterus without first proving, by peruterine carbon dioxide gas insufflation, that the fallopian tubes are definitely non-patent. Witwer, Cushman, and Leucutia (26) assert that hysterosalpingography by means of iodized oil is a safe and simple procedure. In a series of 152 cases, the authors observed only one accident, that of a ruptured tube which did not lead to any ill effects. The method is of great diagnostic value in developmental anomalies of the genital organs, in tubal conditions leading to sterility, in certain carefully selected cases of pregnancy, and in uterine tumors. The method is contra-indicated in recent hemorrhagic inflammatory conditions that are not completely quiescent, active infections or malignant growths involving the cervix, previous intra-uterine intervention, uterine gestation in which a therapeutic abortion is not desired, infected cervical or uterine polyps, and fever. In certain instances, the injection of iodized oil is of direct therapeutic value.

Lash (27) successfully used iodized oil in

cases of uterus bicornis, bilateral salpingitis, and pelvic peritonitis. The function of the tubes was not disturbed by the iodized oil as the patient delivered a full-term child one year after injection. Lash, however, believes that, in the presence of infections in the female generative tract, the use of iodized oils is contra-indicated, as they have no antiseptic properties.

That our own studies have given very satisfactory results with iodochlorol for the exploration of the fallopian tubes can be seen from Figure 5, obtained with our iodochlorol.

USE OF IODIZED AND CHLORINATED ESTERS OF PEANUT OIL

While intravenous pyelography has certain theoretic values, in actual practice the main reliance is still based upon retrograde pyelograms. A good pyelographic medium must have the following properties to be of service to urologists:

- 1 It should give a good shadow.
- 2 It should have a low viscosity and should be miscible with water in all proportions.
- 3 It should be of low toxicity and free from all irritation.

Our research laboratories have succeeded in developing such a medium, called iodochlorol emulsion (Searle). The active ingredient in this emulsion is the iodized and chlorinated ethyl esters of peanut oil, containing about 25 per cent of iodine and about 7 per cent of chlorine. It has a specific gravity of from 1.19 to 1.22 at 25° Centigrade. It has a relative viscosity of 4.2. This extremely low viscosity makes the iodized esters very suitable for pyelographic work, as the emulsion has a still lower viscosity. The iodized ethyl esters of peanut oil are mixed with a small amount of mineral oil and emulsified with 10 per cent potassium oleate. The emulsion also contains 0.5 per cent benzyl alcohol.

The use of iodized oil in emulsion form was first studied by Neuswanger (28, 29), who, as early as 1926, reported favorably on its use as a pyelographic medium. Langenbeck (30), in Germany, obtained excellent pyelograms by the use of emulsified iodized oil. No evidence of irritation or other injurious complications were obtained and it was borne without reaction of any kind. Ehrenroth (31) used the iodized oil in non-emulsified form and, while he at first reported favorable results, he encountered difficulties because he used the oil as such and not in emulsified water-miscible form.

In our own researches we found that the dichlorol emulsion gave excellent pyelograms of great density and sharpness. The emulsion was well tolerated and no irritation or reactions of any kind were obtained. The emulsion was readily eliminated a few hours after the injection into the catheter. Pyelograms were obtained with this iodochlorol emulsion, Figure 6 being typical of all of them.

ACKNOWLEDGMENT

The author is greatly indebted to the many helpful suggestions and advice of

A. Kober, Ph.D., Director of the Research Laboratories of G. D. Searle and Company. He also wishes to thank all the physicians who so kindly co-operated with him in this study.

SUMMARY

1 A new iodized peanut oil, containing approximately 27.5 per cent of iodine and 5 per cent of chlorine, and ethyl esters of the oil have been described.

2 Besides the high radiopacity due to the presence of two halogens, they possess the following properties:

(A) In sinus diagnosis, the high viscosity of the oil is an advantage.

(B) In bronchography, the non-irritating qualities of this oil and the viscosity, made controllable by adding the esters to the oil, make it particularly valuable.

(C) In gynecology, in recent studies of the exploration of the fallopian tubes, it has been found suitable.

(D) In pyelography, an emulsion of the esters was shown to have ideal properties for retrograde pyelograms.

Viosterol Found Beneficial to Radium-poisoning Victims—Almost simultaneously with the news of the twentieth death from radium poisoning among the unfortunate watch factory workers, comes the announcement of a promising method of treating the condition Viosterol, now often given children in place of cod liver oil to prevent or cure rickets, has benefited a number of victims of radium poisoning, Dr Frederick B Flinn, of Columbia University, has reported to the American Medical Association Dr Flinn does not consider that he has a cure for the condition, but merely reports a method of treatment that has given promising results

"Our experience so far suggests a method of treatment that will eliminate radium salts from the organism as well as improve the condition of the bones if continued for sufficient time," he stated "It is a matter of months and not days Care should be taken that fresh preparations are used," he cautioned

Most conspicuous among radium-poisoning victims were the dial painters in the watch factory who used to put their radium-paint brushes in their mouths to point them In this way radium entered their bodies and in about one-fifth of the cases the radium was deposited in the bones instead of being eliminated While the amounts of radium ab-

sorbed in this way were small, the activity of radium is so great that these small amounts were sufficient to destroy bones and tissues and to cause fatal illness

How to get the radium out of the body before it had caused irreparable destruction was the problem which Dr Flinn and other scientists attempted to solve Because radium is related to calcium, it was supposed that any treatment that would affect calcium might have a similar action on the radium deposits, Dr Flinn explained So he first tried treatment with an extract of the parathyroid glands, because these glands are thought to regulate the calcium of the body Parathyroid treatment had been moderately successful, when Dr Flinn suggested the use of viosterol Vitamin D, calcium utilization in the body, bone formation, and the parathyroid glands are all linked together, so viosterol, which is a potent source of Vitamin D, was a logical selection

The results of this treatment in eight cases have been good In two cases, radium was completely eliminated from the body, in the other six, the amount of radium was materially reduced Improvement in general health, such as freedom from pain, gain in weight, and improved condition of the blood, followed the treatment In most of the patients the destruction of bone was checked —*Science Service*

The use of iodized oil in emulsion form was first studied by Neuswanger (28, 29), who, as early as 1926, reported favorably on its use as a pyelographic medium Langer (30), in Germany, obtained excellent pyelograms by the use of emulsified iodized oil. No evidence of irritation or other injurious complications were obtained and it was borne without reaction of any kind. Behrenroth (31) used the iodized oil in non-emulsified form and, while he at first reported favorable results, he encountered difficulties because he used the oil as such and not in emulsified water-miscible form.

In our own researches we found that the iodochlorol emulsion gave excellent pyelograms of great density and sharpness. The emulsion was well tolerated and no irritation or reactions of any kind were obtained. The emulsion was readily eliminated a few hours after the injection into the catheter. Pyelograms were obtained with this iodochlorol emulsion, Figure 6 being typical of all of them.

In all acute cases, roentgen treatments were given every 8 to 12 hours until pain was stopped, which usually occurred after from three to five treatments were given. Relief of tenderness usually required from five to seven more treatments. The discharge in most acute cases increased in quantity for from two to four days, when it began to lessen rapidly.

The average number of treatments in acute cases was from seven to 12. Most cases were dismissed in from five to 10 days. The subacute and chronic cases required a greater number of treatments over a longer period of time.

Technic—80 K V, 5 ma, filter, 5 mm Al and 2 inches of felt next to the skin area treated, cone, 3-inch, target distance, 13 inches, time, from 6 to 7 minutes, dosage, from 30 to 35 ma-minutes.

SUMMARY

Some of the advantages of roentgenotherapy of mastoiditis are:

- (1) Treatment at once stops further invasion and destruction of mastoid cells.
- (2) Pain begins to lessen, following the first treatment.
- (3) The discharge is thinned and increased, when all pain and tenderness are relieved, the drainage stops.
- (4) No diseased areas of the mastoid cells are missed as the treatment covers the entire mastoid.
- (5) The treatment is painless.
- (6) The course of the disease is shortened.
- (7) The danger and pain attending surgical operation are avoided.

Some of the disadvantages are:

- (1) Temporary loss of hair over the area exposed to X-rays. The hair, however, comes in thicker than before in about three months.
- (2) Dermatitis of the area exposed to

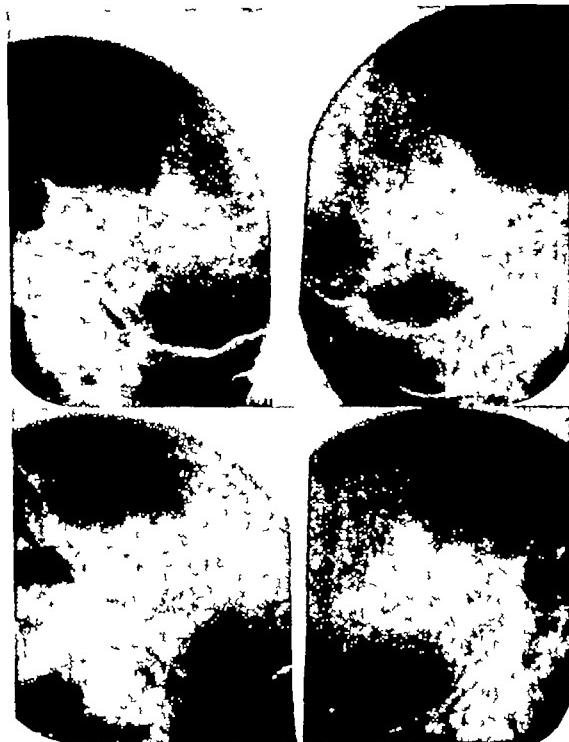

Fig 1-A (*upper*) Case 11. The film was made five days after the onset of the disease. While the left mastoid is clear, the right mastoid shows marked cloudiness of the cells of the antrum. Antral cells are filled with exudate and cell walls are faintly outlined. A condition of acute purulent mastoiditis prevails in the antral cells. The anterior wall of the sigmoid sinus is quite well outlined, which is corroborative evidence of purulent mastoiditis. Cells in the tip of the mastoid are not clouded. The cells posterior to the sigmoid sinus are definitely hazy, but the cell walls are not destroyed, indicating simple mastoiditis in this area. The superior cells of the mastoid are markedly cloudy and the cell walls are not visible, indicating acute purulent mastoiditis in this area.

Fig 1-B (*lower*) The same case, the film having been made 13 days after Figure 1-A. Cloudiness of some of the antral cells is less pronounced. The anterior wall of the sigmoid sinus is not so definitely pronounced. Cells posterior to the sigmoid sinus are less hazy, and trabecular walls are more definitely outlined. Cells of the superior mastoid area are noticeably less hazy. The condition of all the mastoid cells shown definitely demonstrates that no further invasion or destruction of trabeculae occurred after roentgenotherapy was begun.

X-rays, which, however, can be prevented by proper filtration, the application of salted butter once a day over the exposed area, and the application of a very mild high frequency current of electricity through a vacuum electrode.

TREATMENT OF MASTOIDITIS WITH X-RAYS¹

By WILLIAM L. ROSS, M.D., OMAHA, NEBRASKA

DURING the past 17 years, I have treated 41 cases of mastoiditis with X-rays. Of these, 16 acute cases were seen in children. Of the adults, 15 were acute, seven subacute, and three chronic.

The chief complaints in all were pain, tenderness to pressure over the mastoid, and discharge from the ear. The pain was generally of a deep, boring character, quite constant, accompanied at times by sharp shooting pains. These symptoms were generally preceded by an acute cold in the head, sore throat, and earache. Tenderness to pressure was generally more marked over the antrum and tip of the mastoid, but, at times, it was felt over the entire mastoid. Discharge from the ear varied from a thin, serous to a rather thick, creamy exudate.

All of the 16 children suffering from acute mastoiditis felt more or less relief from pain in the middle ear upon spontaneous rupture or paracentesis of the tympanic membrane. But pain in the mastoid continued and the discharge from the ear, in most cases was quite profuse, indicating mastoiditis.

Chief complaints in all adult cases were a constant, deep-seated, dull pain accompanied at times by sharp, shooting pain. Also, most cases complained of a swishing sound that corresponded with the heart beat. All had marked tenderness to pressure over one or more areas of the mastoid.

Symptoms.—The temperature varied from subnormal to 103° Fahrenheit. All exhibited increased pulse beat, and more or less malaise, etc. Previously 10 of the patients had been diagnosed by one or more

doctors as presenting acute mastoiditis and been advised to be operated on at once.

Of the seven cases of subacute mastoiditis, all gave a history of having had an acute attack of more or less severity from two to four months previous to examination. All complained of a deep-seated pain which varied in severity but was more or less constant. All complained of noises in the ear, and some heard the swishing sound, corresponding with the heart beat. All had tenderness to pressure over some part of the mastoid. Some had discharge from the ear. In all the hearing was impaired to varying extents. Some had a subnormal temperature and some a slight rise in temperature at some time during each 24 hours.

Of the three cases of chronic mastoiditis, all had had acute mastoiditis from four to six months previous to examination. All had complained of some pain and tenderness to deep pressure over the mastoid. Some had discharge from the ear. In all, the hearing was pronouncedly impaired.

Diagnosis.—In all cases, the diagnosis was made from the character and location of the pain, the degree of tenderness to superficial or deep pressure, and the quantity, rather than the character, of the discharge from the ear.

The extent of mastoid cells involved, the amount of exudate, and the destruction of the trabeculae were judged by a study of X-ray films of the normal and diseased mastoids. No attempt was made to differentiate the borderline medical or surgical cases.

All the foregoing cases were treated with X-rays. The technic number of treatments, and length of time during which treatment was given were varied to suit the case.

¹Read before the Radiological Society of North America, at the Seventeenth Annual Meeting, at St. Louis Nov. 30-Dec. 4, 1931.

Fig 3 Case 31 The film was made two months after the onset of disease. The right mastoid is rather small but of a pronounced pneumatic type. The anterior wall of the sinus is shown extending through the mastoid and below the tip of the mastoid. All the cells of the left mastoid are markedly cloudy. The anterior wall of the sigmoid sinus is faintly outlined. Posterior to the sigmoid sinus is a large area with varying densities of shadow, surrounded by a fairly well marked border. This area is evidently an abscess cavity, which drained into the soft tissues of the neck through a perforation of the cortex at the tip of the mastoid.

Fig 4 Case 39 The film was made about two years after the onset of mastoiditis. The left mastoid is clear with rather large pneumatic cells. The right mastoid shows marked cloudiness of the tip of the mastoid, some cloudiness of antral cells, quite marked cloudiness of a small area of superior mastoid cells, marked haziness of cells just superior to the mandibular fossa of the temporal bone, and marked cloudiness in the posterior border cells of the mastoid. This shows a wide distribution of infection of the mastoid cells with a fairly clear area of cells just anterior and posterior to the sigmoid sinus.

had had whooping cough and chicken pox. She had had measles in January, 1924.

Physical examination revealed swelling over the right mastoid. The tympanic membrane had a small opening in it and there was quite a discharge from the ear. The area over the antrum of the mastoid was tender to pressure but the tip of the mastoid was not.

The patient, who had come in from an automobile trip of 150 miles, looked sick and tired.

Temperature, 101°, respirations, 40, pulse, 120.

X-ray films showed a cloudiness of the cells in the antrum of the mastoid on the right as compared to the left.

On April 24, at 5 P.M., the patient was given an X-ray treatment over the right mastoid and that night she had less pain. On April 25 and 26, she was given two treatments each day. The pain was noticeably less following each treatment. On April 27, at 9:00 A.M., the child was free

from pain. She had slept well the preceding night. On April 27, 28, 29, and 30 she was given one treatment each day, a total of nine treatments. After April 30 no more X-ray treatments were given.

On May 2, all discharge from her ear had stopped and she felt no tenderness to deep pressure over the mastoid. She was dismissed as cured. An X-ray film was taken on May 7 which showed that infection did not extend after X-ray treatments were begun.

Case 13 July 11, 1924, G.J., age 28 years. The patient's chief complaint was of some mastoid trouble and discharge from the left ear. The patient had just come from consulting a physician who had been treating him for some time for mastoiditis and had repeatedly advised mastoid operation. G.J. came to me, he said, for treatment rather than examination and diagnosis, but I took a brief history of the present illness.

The patient had had acute mastoiditis

Fig 2-A (upper) Case 13. The film was made three months and 24 days after the onset of the disease. The right mastoid, though not complained of, is small and the cells are poorly outlined. It is not normal. The left mastoid shows marked cloudiness in the cells of the antrum. The tip of the mastoid is slightly hazy. The anterior wall of the sigmoid sinus is clearly outlined. In fact the whole lumen of the lateral and of the sigmoid sinus are quite well outlined. The cell walls overlying the sigmoid sinus are quite irregular in outline and for the most part have been destroyed and absorbed. The sinus itself is not infected. The cells posterior to the sigmoid canal are definitely filled with exudate and cell walls are destroyed. The whole picture is that of subacute, purulent mastoiditis.

Fig 2-B (lower) The same, made one month subsequent to the film above. The antral area and the area posterior to the sigmoid sinus are definitely less cloudy and show signs of absorption of the exudate. The posterior canal wall is clearly seen. The superior cells of the antrum, though small, show signs of clearing up.

CASE REPORTS

Case 1 May 3, 1914, Alice D., age 8 years. The patient had been suffering for seven days with severe pain, which began in the middle ear, spreading, in two days, to the mastoid. On the third day of the pain in the middle ear, spontaneous rupture of the tympanic membrane occurred, greatly

relieving the pain in the middle ear. Although the middle ear discharged freely, it did not relieve the pain in the mastoid. Examination revealed a marked localized swelling over the mastoid. I made a diagnosis of acute mastoiditis with subperiosteal abscess and advised mastoidotomy.

The child's aunt objected to operation and asked me to try roentgenotherapy to relieve the pain. This I promised to do, if I were permitted to lance the subperiosteal abscess which had perforated the cortex of the mastoid. The abscess was lanced and frequent irrigations of the wound and ear canal were made each day. Since the pain in the mastoid, though somewhat less, continued, I gave X-ray treatments on five consecutive days. Following each treatment the pain was noticeably less, and by the fifth day had stopped. The drainage from the wound and middle ear, although much lessened, continued. On the fifteenth day, the discharge from the middle ear had ceased and the external wound was healed. I gave one more X-ray treatment and dismissed the patient. No X-ray films were made of this case.

Case 11 April 24, 1924, L. N., aged 8 years. The chief complaint was pain in right mastoid. On April 19, the patient began suffering quite suddenly with severe pain in her right ear. Two days later, pain commenced behind her ear. Paracentesis was done on the second day, greatly relieving the pain in her middle ear but the pain in her mastoid was more marked and continuous with exacerbation. On the third day her physician asked for consultation.

On April 23, a general surgeon and an eye, ear, nose, and throat specialist were consulted. All diagnosed acute mastoiditis and advised immediate operation.

The child's personal medical history was negative except that, during the year preceding examination, she had suffered three attacks of earache, of short duration. She

his right ear canal showed occasional pneumococci and waxy material

X-ray films of the mastoids showed cloudiness of the tip of the right mastoid, of the antrum and superior cells of the mastoid, and of the cells just superior to the mandibular fossa of the temporal bone. X-ray films of the maxillary sinus showed evidence of chronic sinusitis.

X-ray treatment was begun Aug 27, 1929, and during the succeeding 14 days he was given 10 treatments. In September, 1929, he had less pain in his right mastoid and right temporal region. Tenderness to deep pressure over the mastoid and temporal region was lessened. During September he was given eight treatments, during October, 10 treatments, during November, but one treatment. During December he was given seven treatments, making 36 treatments in all. On January 1, 1930, he was free from pain in his right mastoid and right temporal region. Deep pressure over the mastoid and temporal region did not cause pain. The singing noise in his ear was not constant and was less pronounced. He was then dismissed as cured except for his maxillary sinusitis.

Case 41 Dec 13, 1930, I T, aged 10 months. Chief complaints were an abscess behind his left ear, discharge from the ear, and swelling of the left side of the face.

During the night of Nov 30, 1930, the baby suffered with earache. The following morning his ear began to discharge freely. At the end of one week the discharge was much less and a swelling was noticed just behind the left ear. December 11, twelve days from the onset of otitis media, the attending physician lanced the swelling over the mastoid and a small amount of pus exuded. On December 12 his face began to swell and his left eye was so swollen as to be shut. An eye, ear, nose, and throat specialist was consulted, who advised that the baby be operated on.

Physical examination, made on December 13, revealed a temperature of 100° F., pulse 110, respirations 40. Inspection revealed a marked swelling over the left mastoid. A closed wound was seen about the lower border of the antrum. The swelling extended above and in front of the ear. The left eyelids were badly swollen, and the left side of the face, as well as the lymph nodes of the left side of the neck, were swollen and tender.

Blood count red blood cells 3,900,000, white cells 20,000, hemoglobin 50, polymorphonuclears 60.

The abscess was lanced and a free discharge of pus followed.

X-ray films showed a cloudiness of the mastoid cells, and also the point of rupture of the abscess through the cortex of the mastoid. The diagnosis was mastoiditis with subperiosteal abscess.

This case is of particular interest in that the condition had clearly passed the medical phase of mastoiditis into that phase demanding surgery and in that we were able to demonstrate mastoid cells in a baby 10 months old.

During the first four days, eight X-ray treatments were given over the mastoid. Following the first treatment, the baby began to rest better. From Dec 13, 1930, to Jan 9, 1931, 21 X-ray treatments were given over the mastoid and three treatments over the enlarged lymph nodes of the neck. By Jan 9, 1931, the wound over the mastoid had healed, the discharge from the ear had stopped, and there was no tenderness to pressure over the mastoid. The case was dismissed as cured.

CONCLUSIONS

1. X-ray treatment is applicable in almost all phases of mastoiditis.

2. Results of X-ray treatment of mastoiditis are satisfactory to the patient and the roentgenologist.

March 20, 1924, the pain commencing suddenly in his left ear, following a head cold and sore throat. The ear discharged constantly from the latter part of March and he had experienced pain and tenderness over the left mastoid all the while. At the time of examination, the tenderness was more marked than common.

Physical examination revealed his temperature to be 100°, pulse 100, respirations 20. Localized swelling over the mastoid was marked and tenderness too acute to permit pressure examination. The blood count on July 11 showed red cells, 5,880,000, white cells, 14,400.

Films of the mastoid showed cloudiness and filling of the cells of the left mastoid anterior to, and overlying, the sigmoid sinus, also cloudiness of the tip of the mastoid, contrasting markedly with the cells of the right mastoid, which was not normal.

The diagnosis was exacerbation of subacute mastoiditis.

On July 12, he returned for treatment, receiving 12 X-ray treatments during a period of 14 days. The pain was less following each treatment and by the fourth day had stopped, but the discharge from his ear had increased.

On July 17 the white cell count was 8,400, a reduction of 6,000 white cells in six days.

Fourteen days from the beginning of treatment (July 26), he was free from all pain and tenderness over the mastoid, and the discharge had stopped. The patient was dismissed with a request to return on August 12 for X-ray films, which he did. Films made then showed marked clearing of the mastoid cells. On October 12, the patient again returned. He said he had had no further pain or discharge from the left ear and was feeling well.

Case 31 Mrs W S, age 23 years. The patient, who was referred July 2, 1928, for X-ray treatment of mastoiditis, had been suffering with varying degrees of pain in

her mastoid since May 1. On June 25, she suffered a very acute exacerbation of mastoiditis and was very ill, having a temperature of 104° F for several days.

The history of the present illness, together with the physical examination and X-ray films, compelled a diagnosis of von Bezold's abscess. Bezold's abscess, a term used to denote an abscess which has formed below the mastoid process, is caused by a subperiosteal abscess of the tip of the mastoid perforating its cortex and discharging into the soft tissues of the neck. The point of perforation at the tip of the mastoid was clearly shown in the X-ray film (Fig. 3).

X-ray treatments were begun at once and, as usual, noticeable lessening of the pain followed each treatment. During the night of July 5, after five treatments had been given, the patient slept well. By July 13, nine treatments had been given. The pain in the mastoid and discharge from her ear had stopped and the patient was referred again to her physician.

Case 39 Aug 15, 1929, Mr G, aged 57 years. Chief complaints were of pain in the right mastoid and ear, in the right side of the face, in the right temporal region, and impairment of hearing.

For two years preceding the present examination, Mr G had suffered in varying degrees with a dull, aching pain in his right mastoid. Pain was constant. He also had heard a buzzing, singing noise in the right ear. The pain in his face and temple was not constant, the character varying from dullness to sharpness. All of his pains increased when he had an acute cold.

On physical examination, he was tender to deep pressure over the tip of the mastoid and over the antrum and superior mastoid cells. He was also tender to pressure just superior to the mandibular fossa of the temporal bone. He presented an eroded, red condition of the external ear canal but no discharge from his ear. A smear from

his right ear canal showed occasional pneumococci and waxy material

X-ray films of the mastoids showed cloudiness of the tip of the right mastoid, of the antrum and superior cells of the mastoid, and of the cells just superior to the mandibular fossa of the temporal bone. X-ray films of the maxillary sinus showed evidence of chronic sinusitis.

X-ray treatment was begun Aug. 27, 1929, and during the succeeding 14 days he was given 10 treatments. In September, 1929, he had less pain in his right mastoid and right temporal region. Tenderness to deep pressure over the mastoid and temporal region was lessened. During September he was given eight treatments, during October, 10 treatments, during November, but one treatment. During December he was given seven treatments, making 36 treatments in all. On January 1, 1930, he was free from pain in his right mastoid and right temporal region. Deep pressure over the mastoid and temporal region did not cause pain. The singing noise in his ear was not constant and was less pronounced. He was then dismissed as cured except for his maxillary sinusitis.

Case 41 Dec 13, 1930, I T., aged 10 months. Chief complaints were an abscess behind his left ear, discharge from the ear, and swelling of the left side of the face.

During the night of Nov. 30, 1930, the baby suffered with earache. The following morning his ear began to discharge freely. At the end of one week the discharge was much less and a swelling was noticed just behind the left ear. December 11, twelve days from the onset of otitis media, the attending physician lanced the swelling over the mastoid and a small amount of pus exuded. On December 12 his face began to swell and his left eye was so swollen as to be shut. An eye, ear, nose, and throat specialist was consulted, who advised that the baby be operated on.

Physical examination, made on December 13, revealed a temperature of 100° F., pulse 110, respirations 40. Inspection revealed a marked swelling over the left mastoid. A closed wound was seen about the lower border of the antrum. The swelling extended above and in front of the ear. The left eyelids were badly swollen, and the left side of the face, as well as the lymph nodes of the left side of the neck, were swollen and tender.

Blood count red blood cells 3,900,000, white cells 20,000, hemoglobin 50, polymorphonuclears 60.

The abscess was lanced and a free discharge of pus followed.

X-ray films showed a cloudiness of the mastoid cells, and also the point of rupture of the abscess through the cortex of the mastoid. The diagnosis was mastoiditis with subperiosteal abscess.

This case is of particular interest in that the condition had clearly passed the medical phase of mastoiditis into that phase demanding surgery and in that we were able to demonstrate mastoid cells in a baby 10 months old.

During the first four days, eight X-ray treatments were given over the mastoid. Following the first treatment, the baby began to rest better. From Dec 13, 1930, to Jan 9, 1931, 21 X-ray treatments were given over the mastoid and three treatments over the enlarged lymph nodes of the neck. By Jan 9, 1931, the wound over the mastoid had healed, the discharge from the ear had stopped, and there was no tenderness to pressure over the mastoid. The case was dismissed as cured.

CONCLUSIONS

1. X-ray treatment is applicable in almost all phases of mastoiditis.

2. Results of X-ray treatment of mastoiditis are satisfactory to the patient and the roentgenologist.

March 20, 1924, the pain commencing suddenly in his left ear, following a head cold and sore throat. The ear discharged constantly from the latter part of March and he had experienced pain and tenderness over the left mastoid all the while. At the time of examination, the tenderness was more marked than common.

Physical examination revealed his temperature to be 100°, pulse 100, respirations 20. Localized swelling over the mastoid was marked and tenderness too acute to permit pressure examination. The blood count on July 11 showed red cells, 5,880,000, white cells, 14,400.

Films of the mastoid showed cloudiness and filling of the cells of the left mastoid anterior to, and overlying, the sigmoid sinus, also cloudiness of the tip of the mastoid, contrasting markedly with the cells of the right mastoid, which was not normal.

The diagnosis was exacerbation of subacute mastoiditis.

On July 12, he returned for treatment, receiving 12 X-ray treatments during a period of 14 days. The pain was less following each treatment and by the fourth day had stopped, but the discharge from his ear had increased.

On July 17 the white cell count was 8,400, a reduction of 6,000 white cells in six days.

Fourteen days from the beginning of treatment (July 26), he was free from all pain and tenderness over the mastoid, and the discharge had stopped. The patient was dismissed with a request to return on August 12 for X-ray films, which he did. Films made then showed marked clearing of the mastoid cells. On October 12, the patient again returned. He said he had had no further pain or discharge from the left ear and was feeling well.

Case 31 Mrs W S, age 23 years. The patient, who was referred July 2, 1928, for X-ray treatment of mastoiditis, had been suffering with varying degrees of pain in

her mastoid since May 1. On June 25, she suffered a very acute exacerbation of mastoiditis and was very ill, having a temperature of 104° F for several days.

The history of the present illness, together with the physical examination and X-ray films, compelled a diagnosis of von Bezold's abscess. Insanity a Matter of Colloid Chemistry—A permanent change in the brain means abnormal thinking, which we call insanity, says Dr Wilder D Bancroft, Professor of Chemistry at Cornell University. When we boil an egg, the white coagulates. When we dissolve rubber in benzine, the rubber is dispersed. No such extreme changes take place in the brain, but there are two types of insanity, in one of which the brain is more coagulated than usual and in the other of which it is more dispersed than usual.

If a person is suffering from the coagulation type of insanity, drugs which counteract coagulation will help the patient. This has been done successfully by administering bromides and could probably be done better by the use of thiocyanates. If a person is suffering from the dispersion type of insanity, alleviation will be obtained by giving a drug which will tend to coagulate the brain tissues.

In 1921, Berger gave cocaine to eleven patients suffering from catatonic stupor and found that the majority of them became active immediately after the first injections, though the improvement did not last more than an hour or two. In 1930, Lorenz anesthetized a similar patient with sodium amyta.

All anesthetizations involve coagulation, and the patient passed through a normal state on coming out from the anesthetic and before lapsing into the catatonic stupor. This patient was in an aroused mental state for about four hours, after which she fell into a natural sleep for five hours. Later the symptoms of mutism, muscular rigidity, and active negativism developed slowly.

Dr Langstrass, of St Elizabeth's Hospital in Washington, has reported that he has ad-

ministered carbon dioxide and oxygen in suitable proportions to a patient who had suffered from catatonic stupor for ten years. This, coupled with other treatment, has kept the patient in an apparently normal state for nearly two years, a remarkable medical triumph.

Of course, treatments of this sort will not restore brain tissue which has been eaten away by syphilis or anything of that sort, but they will enable the physician to get the coagulated tissue back into a more nearly normal state.

Over-doses of a dispersing agent should give a normal person a dispersion type of insanity, while over-doses of a coagulating agent should give the coagulation type of insanity. Naturally, there are not many data on this point because nobody wishes to make a sane person insane. When treating persons for high blood pressure, it has been found that continued administration of large doses of sodium thiocyanate gave rise to hallucinations of sight and hearing, mania, confusion, and ideas of persecution, singly or in combination. Since the patients recovered in a week after giving up the drug, these were cases of temporary insanity.

The exclusion of oxygen causes unconsciousness due to asphyxiation. When the oxygen is not cut down so much, interesting mental reactions occur. Aviators may become incapacitated temporarily when flying at high altitudes. There is a height for each aviator above which it is not safe for him to go, as he may develop mental confusion, leading to errors of performance, sometimes hallucinations of sight and hearing, and, in some cases, an uncontrollable desire to sing and whistle. This last is rather an anticlimax.—*Science Service*

RECORDS IN ROENTGEN THERAPY¹

By CARL L. GILLIES, M.D., CEDAR RAPIDS, IOWA

NO absolute, fixed rules can be laid down concerning the keeping of records in roentgen therapy. Whether the practice is hospital, clinic, or office will influence the type and general form, although certain underlying principles and minimum requirements are necessary and applicable to all kinds of practice. The necessity of making complete and accurate records cannot be over-emphasized. To insure their being kept up they should be simple and concise. It is advisable to have the records in the roentgenologist's own handwriting. This avoids the possibility of error in transcription and such an original record is of greater value than a dictated or copied one if it should have to be produced in court. A good record should include the following points:

1. A brief but adequate *clinical history* of the patient, the age, sex, and previous history, the onset and duration of the present illness, all previous medical and surgical treatment, and, in particular, all previous radiation treatment. Each disease presents its own problems and certain phases of the history must be noted as they suggest themselves. Detailed and voluminous notes of former illnesses which obviously have no bearing upon the condition under treatment can well be omitted.

2. The weight of the patient and the dimensions by actual measurement. These data are, of course, unnecessary in dermatologic practice or in cases in which the lesion is superficial.

3. The *diagnosis, size, and location* of the lesion. If it is within the body, the distance from the surface, or surfaces, through

which treatment is to be given, must be noted.

4. The *factors* employed in sufficient detail to permit the determination of the quality and intensity of the dose applied to the skin.

These factors are

- (a) *Kilovolts*
- (b) *Milliamperage*
- (c) *Anode-skin distance*
- (d) *Size of field*
- (e) *Filter material and its thickness*
- (f) *Length of exposure*

These six factors determine the size of each dose which should be recorded as

(g) *The Size of the Dose in Absolute Units*—The record should show whether the dose in r has been estimated or actually measured.

The kilovoltage and filter determine the quality or hardness which should be noted as

(h) *Quality* expressed in terms of the effective wave length or the half value layer.

(i) The *date* of each treatment is necessary so that the interval between treatments will be known and the loss of effect can be roughly estimated.

It is also necessary that the records show the dose applied to the lesion. This can be determined from the above data. In our own practice we find it satisfactory to record it as

(j) *The depth dose percentage* which is assumed to represent the percentage of each skin dose which reaches the depth of the lesion. The proportion of the beam reaching the lesion is read from distribution charts of our various standard technics. Accurate measurements of the patient, an exact localization of the lesion, and reliable distribution charts are all essential in order

¹Presented before the Radiological Society of North America at the Seventeenth Annual Meeting at St. Louis Nov. 30-Dec. 4, 1931.

MENOPAUSE FOLLOWING A SINGLE APPLICATION OF ROENTGEN RAYS TO THE HEAD

A Ridiculously Assumed Conclusion

Rulison vs Victor X-ray Corporation
(Iowa), 223 N W R 745

The Victor X-ray Corporation, through one Watson, was installing a second-hand roentgen-ray machine in a physician's office, with a view to its sale To make a demonstration, Watson requested the physician's office secretary and assistant to submit to an exposure from the machine She did so, and later, claiming to have been injured thereby, brought suit Judgment was rendered in her favor The defendant appealed to the Supreme Court of Iowa, but the judgment was affirmed

In demonstrating the roentgen-ray machine it had installed, the defendant, through its agent Watson, applied the cone to the plaintiff's head and took three films in succession, with brief intervals, at one sitting The focal point was the occipital lobe of the brain Some days later the plaintiff began to feel soreness in her head Subsequently she lost her hair from an area four inches square She became subject to a chronic condition of sick headaches, referred to in the record as "ophthalmoplegia migraine" The "muscles of accommodation of the pupil" of her right eye ceased to function, and the eyelid was affected The menopause came on, although the plaintiff was only 36 years old Watson testified that nothing occurred that would have caused a burn He estimated the dosage at 580 milliampere-seconds, concededly a normal dosage that could not result in injury The testimony on both sides, however, in-

dicated that the loss of hair was the result of a second degree roentgen burn and that it could not have occurred if less than 1,200 milliampere-seconds had been applied A technician who saw the demonstration testified that its duration was longer and the distance from the focal point shorter than were indicated by Watson She testified, too, to the heating of wires, which required an interval of stoppage to cool them and indicated a want of control of the dosage The defendant contended that there was no evidence of negligence, but the Supreme Court was of opinion that there was enough to take the question to the jury

The defendant took exception to the refusal of the trial court to withdraw from the jury all evidence concerning the plaintiff's menopause and the impairment of her vision, claiming that there was no evidence to show a causal relation between those conditions, if they existed, and the application of the roentgen rays The court pointed out, however, that Dr Heagey, a witness for the plaintiff, testified that the third cranial nerve, which controls substantially all of the muscles of the eye [sic], has its origin about the focal point toward which the roentgen rays were directed, that an overdosage of roentgen rays causes a swelling of the blood cells, which results in an obstruction of the circulation and breaks down the small veins, and that any breaking down of the circulatory system necessarily shuts off the blood supply to parts of the body dependent upon it Dr Francis W Heagey (an Omaha internist) testified, too, that although roentgen rays would not be applied to a woman's head for the purpose of producing sterility, yet an excessive dosage of roentgen rays might penetrate to more or less remote parts of the body, and

¹A part of this matter is reprinted by permission from the Journal of the American Medical Association

to estimate the sum of the depth doses with a reasonable degree of precision

5 The degree of *reaction* and date of observation should be noted

This includes both the local changes and any constitutional symptoms that may develop

6 The *results* of treatment, both immediate and late, to include follow-up notes at suitable intervals, should also be recorded

The general form of record used will depend largely upon the type of practice and whether the roentgen record is to become a part of the patient's hospital chart or is to be filed for office reference. In a clinic or hospital practice printed forms the size of

the hospital chart are convenient, separate printed blanks being used for the history, present illness, treatment record, and follow-up notes. Printed anatomical charts may be prepared upon which the location of the lesion can be marked. Filling in such separate blanks and charts is likely to be too cumbersome for the busy general roentgenologist in office practice. A printed card index system is more convenient, one side of the card being ruled vertically to provide spaces for the date of each treatment and the physical factors used. The back of the card is left blank for the history, dimensions of the patient, description and location of the lesion, and progress notes.

Waves of Electrons will Tell of Crystal Structure—Waves of electrons will soon allow the scientist to obtain a clearer picture of the internal structure of crystals than ever before possible, Dr C J Davisson has predicted to the American Association for the Advancement of Science and the American Physical Society. Very short wave lengths are available in electron waves and this results in greater power to photograph the fine crystal structure of matter. Dr Davisson is a pioneer in the use of electron waves, since he won international fame a few years ago by proving that electrons act like waves in much the same way as light and X-rays. He has also developed lenses for concentrating the beam of electrons. Since the electron is what may be termed a particle of electricity, his work bridges the previous gap between matter and electricity.

Just as shortening the wave length of light

used in illuminating a microscope allows smaller objects to be seen, use of electrons made visible by their effects on photographic plates allows physicists to study more minute structure in crystalline matter, Dr Davisson explained. The electron waves are diffracted by crystals and give rise to diffraction patterns which are quite similar to those produced by X-rays. X-ray studies have given much information on matter's structure in the past decade.

The scattering power of atoms is about a million times greater for electron waves than for X-rays. The electron waves will, therefore, give information chiefly regarding the structure of surfaces of crystals, whereas the X-rays give information about the structure of the bodies of crystals. Dr Davisson also expects that the electron waves will allow the study of layers of gas attached to the surfaces of metal crystals.—*Science Service*

ment, however, "the condition known as telangiectasis or X-ray burns," appeared on her neck. Later in 1923, she consulted a physician in New York concerning that condition, and he gave her two radium treatments for it. Because of the telangiectasis, she sued Dr. Hazen in the Supreme Court of the District of Columbia and obtained a judgment for \$15,000. He thereupon appealed to the Court of Appeals of the District.

Miss Mullen conceded that at the time of her treatment Dr. Hazen possessed the degree of skill and ability possessed by physicians of his own class, in Washington, and that the application of roentgen rays was the recognized treatment for tuberculous glands. The only question, therefore, was whether or not Dr. Hazen was negligent, and of this the Court of Appeals could find no evidence in the record. Dr. Hazen testified that he exercised his best judgment in the light of the skill and ability he possessed, and that whether he could have afforded her greater protection by prolonging the periods between the exposures of the same area was entirely and absolutely a matter of individual judgment. "It was a question," said Dr. Hazen, "based largely upon the condition of plaintiff, and I felt that the chances for the grave yard were very, very good, if the treatment were not pushed and the intervals were not made short." Several physicians, qualified as experts in the use of the roentgen rays, testified that telangiectasis "may follow X-ray treatment notwithstanding the fact that the highest degree of skill and care has been exercised in the giving of such treatment," and that there is no known method by which it can be foretold whether telangiectasis will or will not follow such treatment. These witnesses agreed that the treatments administered by Dr. Hazen as shown by the record kept by him, were proper and in accordance with the best knowledge and skill possessed

by men engaged in roentgenology in the District of Columbia at that time. As the Court of Appeals could find no evidence from which it could reasonably be concluded that Dr. Hazen did not exercise his best judgment and ability in treating Miss Mullen, or that in his treatment of her he failed to exercise the care and skill ordinarily possessed and exercised by others in the profession, the judgment of the trial court was reversed with costs, and the cause remanded.

PHYSICIAN EMPLOYED BY PLAINTIFF TO
EXAMINE HIM MAY BE COMPELLED TO
TESTIFY FOR DEFINITE ANT

Webb *et al* vs Francis J. Lewald Coal Co *et al* (Calif.), 297 P R 958

One of the plaintiffs had been examined by a physician, apparently for the purpose of enabling him to testify on behalf of her and her husband in a suit for damages for personal injuries she had sustained. At the trial, however, the plaintiffs did not produce the physician as a witness. The defendants thereupon subpoenaed him. When called to the witness stand, he refused to testify concerning his examination of the plaintiff or his conclusions from it. He contended that after a physician has made an examination for one party to a suit and his conclusions do not support the contentions of that party, and when he therefore has not been produced as a witness by that party, it would be inequitable to compel him to testify in support of the contentions of the adverse party. If it were known that a physician testified under such circumstances, patients would hesitate to come to him for examination and lawyers would hesitate to send their clients to him. The trial court ruled that the witness could not be compelled to testify. Judgment was given for the plaintiffs, and thereupon the defendants appealed to the District Court of Appeal First District, Division 1 California assigning as error,

the position in which the plaintiff was placed for the purpose of demonstrating the roentgen-ray apparatus was such as to permit the roentgen rays to penetrate the abdomen. This testimony, in the judgment of the court, was sufficient to go to the jury for determination as to whether or not the impairment of the plaintiff's vision and the early appearance of her menopause were caused in the manner claimed.

**ADMISSIBILITY OF ROENTGENOGRAMS WHEN
ADMISSION IS NOT PREJUDICIAL**

Consolidated Coach Corporation v's
Saunders (Ky.), 17 S W R
(2d) 233

Where there is no testimony to identify roentgenograms introduced in evidence as roentgenograms of the injured parts of the body that they are supposed to represent, they are inadmissible without the testimony of the person who took them. In the present case, however, two roentgenograms were made of the same injured limb. The second roentgenogram, with the exception of some minor particulars, showed the same character of injury as the first roentgenogram, to the admission of which exception was taken. The physician who took the second roentgenogram testified that his experience enabled him to swear that the roentgenogram to which exception was taken was a roentgenogram of the very same limb that was shown in the second roentgenogram, identified by him. According to this witness the same bones of the human body are differently shaped and constructed in each individual, just as are the faces of such individuals. Moreover, the plaintiff and some of her witnesses testified that the roentgenogram was taken of her limb that the doctor who took it immediately delivered it to her, and that she preserved it. But if such reasons were not sufficient to remove the objections to the introduction of the roentgenogram to the ad-

mission of which exception was taken, its admission could not be considered prejudicially material, since its only purpose was to prove the extent of the plaintiff's injuries, and the testimony was uncontradicted on that issue and no sort of earnest attack was made on the amount of the judgment.

**ROENTGENOTHERAPIST NOT HELD LIABLE
FOR TELANGIECTASIS DUE TO ROENTGEN
RAYS APPLIED FOR TUBERCULOUS
LYMPHADENITIS**

Hazen vs Mullen (Dist of Col.) 32 Fed R.
(2d) 394

The appellee, Miss Mullen, had tuberculous adenitis of the lymph glands on both sides of the neck, running down to the middle of the clavicle and into the armpits. In the absence of treatment one physician testified, the usual result would have been the breaking down of the glands and a long continued discharge through open sinuses, or a rupture of the glands into the blood vessels, with general dissemination of tuberculosis and ultimately death. A surgical operation to remove the glands would have required an incision almost from the ear down to the middle of the clavicle, with the complete cleaning out of everything in the neck on both sides, and in addition to that would have required operations on both armpits. Probably the operation would have extended from the armpits to the clavicle, in order to permit the removal of the intervening glands. While in this condition Miss Mullen consulted Dr Henry H Hazen and was treated by him by the use of roentgen rays from February, 1920, until November of the same year. One side of the neck was exposed every other week. The result was so complete a cure that a medical witness who examined Miss Mullen in 1925 testified that he could not discover any enlarged glands and would not have known that she ever had any tuberculous glands at any time.

Some time after Miss Mullen's last treat-

CASE REPORTS AND NEW DEVICES

X-RAY GENERATOR A WORKING MODEL

By H. A. TUTTLE, Assistant Director, Educational Department, Westinghouse X-ray Co., LONG ISLAND CITY, N.Y.

The first reaction of a student when beginning the study of X-ray technology is

finds himself confronted by phenomena belonging to several electric circuits which are closely related to one another. The reactions occurring within the valve and X-ray tubes must also be considered. And in addition, the problems of rectification must be understood. To complicate the matter, the

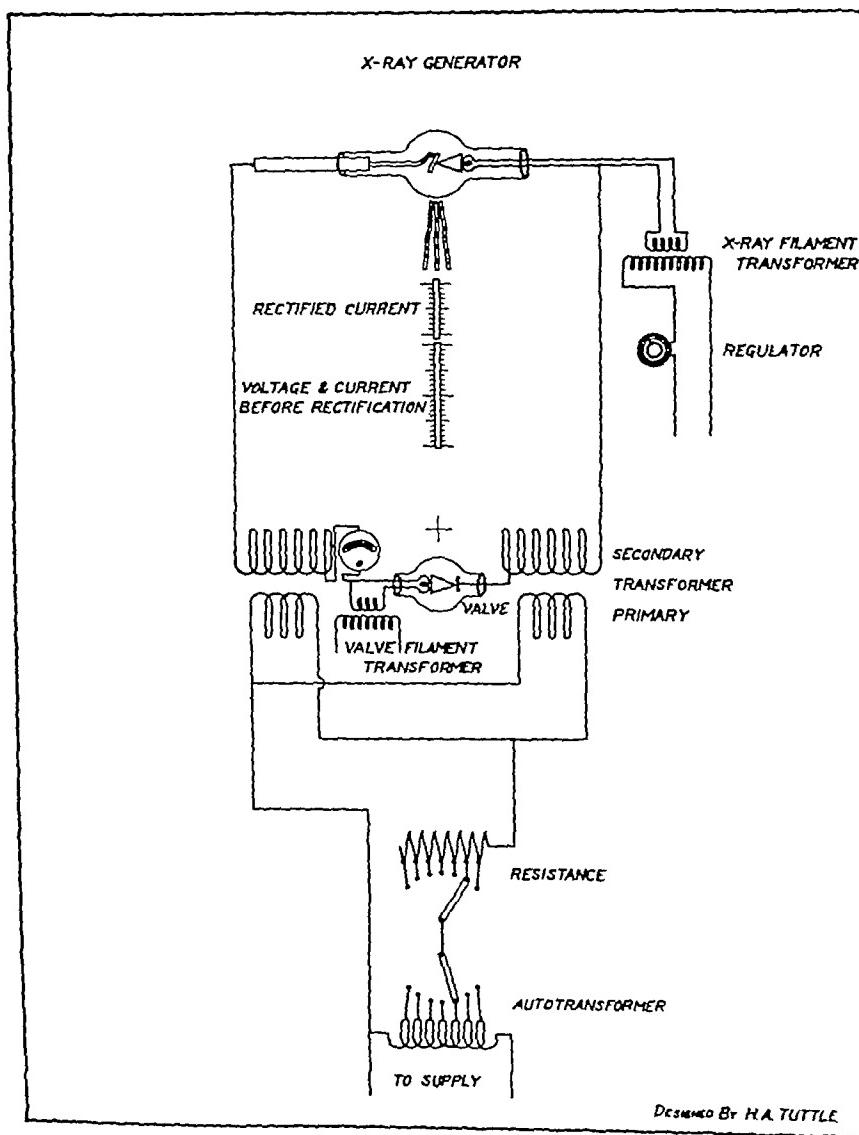

Fig. 1

usually one of bewilderment. This is especially true when he is brought into contact with the X-ray generator. He immediately

progressive, simultaneous changes occurring in all circuits and parts of the apparatus, must be correlated to one another.

among other things, the refusal of the trial court to compel the physician to testify

This ruling of the trial court, said the District Court of Appeal, in reversing the judgment of the trial court, constituted reversible error. However commendable from a professional standpoint may have been the objections of the witness, the policy of the law as declared by the California legislature required him to set aside his scruples and to testify concerning the matters that he had learned from his examination of the plaintiff. When the party examined by him brought suit, she impliedly waived her right to have the results of the examination kept secret, for Section 1881, Subdivision 4, of the California Code of Civil Procedure provides

"A licensed physician or surgeon cannot, without the consent of his patient, be examined in a civil action as to any information acquired in attending the patient, which was necessary to enable him to prescribe or act for the patient, provided, further, that where any person brings an action to recover damages for personal injuries, such action shall be deemed to constitute a consent by the person bringing such action that any physician who has prescribed for or treated said person and whose testimony is material in said action shall testify."

If the ruling of the trial court were correct, said the District Court of Appeal, that the witness could not be compelled to testify unless arrangements were made to compensate him as an expert witness, it would in effect nullify the provision of the law just stated, for then, all a physician need do if he desired to keep off the witness stand would be to demand such compensation for testifying as it would be impracticable for the defendant to pay. That, said the Court, is not the law.

"The authorities, however, all agree that, in the absence of an express contract to pay

a physician for his testimony as an expert, he is only entitled to the statutory fee. The uniform rule seems to be that a physician who has acquired knowledge of a patient or of specific facts in connection with the patient may be called upon to testify to those facts without any compensation other than the ordinary witness receives for attendance upon court. In those States recognizing the right to extra compensation for a physician who testifies as an expert it is uniformly held that, where such testimony is sought to be elicited without requiring any particular investigation on the part of the physician, he is required to testify without extra compensation"—*McClenahan vs Keves*, 188 Calif 574, 583, 206 P R 454, 458

PRIVILEGED COMMUNICATIONS WAIVER BY OFFERING TESTIMONY OF PHYSICIAN

Travelers' Building and Loan Assn vs Hawkins (Ark), 34 S W R (2d) 474

When a party to an action puts his physician on the stand to prove that the party was incompetent to make a certain contract, he thereby waives his statutory privilege of maintaining the secrecy of communications between him and his physician. The adverse party may thereafter cross-examine the physician.

COMPENSATION OF PHYSICIANS LIABILITY OF MEMBER OF FAMILY WHO SUMMONS PHYSICIAN

Benton vs Stadler (Wis), 234 N W R 739

It is a general proposition supported by many authorities that he who orders a physician to come to his home to treat a member of his family becomes responsible for payment for the physician's services unless he makes it known to the physician that he disavows responsibility.

little, if at all, by rectification. Electrons may be seen passing from filament to cathode and, simultaneously, the X-rays leaving the tube. The different curves and markings are so laid out that the phase relationships of all are correct. Note that the electron velocity within the valve is much lower than that through the X-ray tube.

A model can also be constructed to demonstrate the action of a mechanical rectifier. A third part is then necessary. This is shaped to portray the rotor of the rectifier and is placed in front of Figure 1 and is centered to Figure 2. A center bearing is then so arranged that Figures 2 and 3 revolve together. The angular position of the rotor is thereby coupled to the proper value of voltage and current.

This model can be made by a draftsman or photographic copies of all parts can be obtained. These can be mounted on cardboard, and assembled with a simple light bearing. The author used a model 3 feet by 4 feet. A smaller size is perhaps preferable, since it can be examined more easily. A size 12 X 15 inches is easy to handle and is large enough to be very understandable.

The last model which was constructed has been used successfully for over a year. All who have seen it have remarked the easy and thorough understanding obtained by a few minutes' observation.

A MOVABLE FLUOROSCOPE FOR FLUOROSCOPY AND SERIAL RADIOGRAPHY WITHOUT THE USE OF A DARK ROOM

By FRANCIS E TALTY, M.D.,
ARLINGTON, MASSACHUSETTS

In a recent survey of the literature on fluoroscopy made at the Boston Medical Library, Yale Medical Library, and the New York Academy of Medicine, I was amazed to find that little or no attempt has ever been made to do fluoroscopy by any other method

than the dark room. Dr George C Johnson (1), of Pittsburgh, in 1905 wrote an article descriptive of a device whereby he allowed a pyramid of rays to emerge from the tube. The fluoroscope consisted of an ordinary fluoroscopic screen set parallel with the line of vision. He made use of a mirror to reflect a shadow on the fluorescent screen, but his device was a hand fluoroscope, and, as such, was necessarily of limited use and fraught with all the dangers of exposure to the direct rays. Lewis Gregory Cole (2), of New York, in 1913 described a table in which he made use of a mirror, a fluorescent screen, and a stationary dark chamber. The table and dark chamber were placed against a lead-lined partition, back of which was placed a cabinet from which the table was operated. In the article descriptive of this table no mention was made of fluoroscopy outside of a dark room or cabinet. In Dr Cole's device the operator was separated from the patient, which, of course, made it impossible for him to do manual palpation in a gastro-intestinal series, or manual manipulation in case of a fracture. With the Cole table it was necessary to adjust the patient to the screen, rather than the screen to the patient. In other words, Dr Cole's screen was stationary and could be used only from one fixed point on the table, as the rest of the table was lead-lined beneath.

For several months I have been using in my office (a well lighted room), a daylight fluoroscopic device which has given me considerable satisfaction. I am not separated from the patient, can palpate while observing the shadow or can allow the surgeon to manipulate a fracture while observing the shadow. The fluoroscopic screen can be adjusted to the patient rather than the patient to the screen, as my device is beneath the table and can be moved lengthwise and crosswise with respect to the table.

While the series of cases in which I have used this device is a comparatively small

Past experience in instruction proves that charts and mechanical models are of great value to the student. But even with the best of charts, it is difficult, if not impossible, to correctly portray successive continuous changes and to refer the changes in each part of the apparatus to those of every

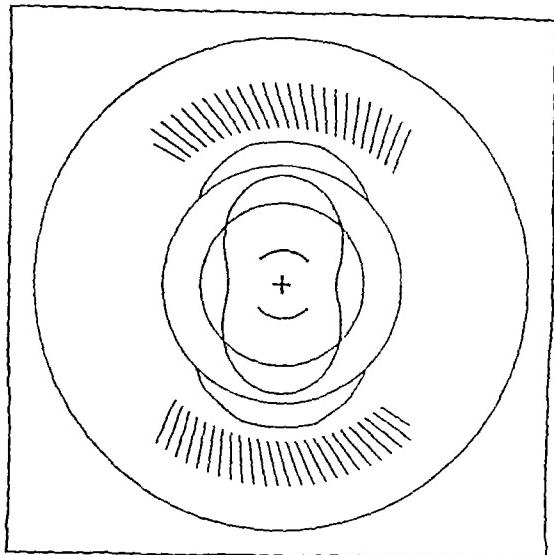

Fig. 2

other. There is only one type of chart or model that will successfully perform this function, and that is the working model.

The working model developed by the author shows first a complete diagram of all of the important electric circuits of an X-ray generator and tube as connected for operation. With a mechanical rectifier a representation of the rotating and stationary parts is given and the electric connections to them are drawn. The model illustrated was constructed for the single valve rectifier and shows the valve in its place in the circuit.

This model is made in two parts¹ (Figs. 1 and 2). The first or main chart (Fig. 1), is best made in rectangular form. It carries a complete wiring diagram of all control apparatus, the high tension transformer and rectifier, and the valve and

X-ray tubes. Several slits are cut in this chart, the use of which will be explained later.

The second part (Fig. 2) is made in the form of a circle. It is so mounted, just behind the main chart, that it can revolve easily. Continuous curves of unrectified and rectified voltages are drawn on its surface in circular form. Near the periphery a succession of dots is drawn which represents electrons. Just within the radius of the electrons is drawn a number of oblique lines. These represent X-rays. Near the center two groups of dots are drawn. These represent electrons passing through the valve.

Near the top of Figure 1, the X-ray tube is shown. Note that a triangular section between filament and target is to be cut out. The electrons drawn on Figure 2 are visible here. Three slits are to be cut in Figure 1 just below the tube and radially to the target as a center. These serve as windows to make the X-radiation, which is drawn on Figure 2, visible. Two vertical slits are to be cut just above the center of Figure 1. The upper of these reveals the curve of rectified current while the lower reveals the sine waves of voltage and current before rectification. A triangular area is also to be cut out of the valve tube as indicated. The electron stream is visible here.

We thus have a working model which indicates the complete circuits, instantaneous values of incoming and rectified voltages, the electron stream of each tube and the generated radiation. Values of these conditions may be easily compared for any phase angle. Or, if a continuous, moving picture of machine operation is desired, Figure 2 may be slowly revolved in a counter-clockwise direction. The student may then see the rising and falling values of incoming voltage through the slit just above the valve tube, and, through the slit directly above that, the changing values of rectified current. The voltage wave is changed very

¹Figures 1 and 2 are not reduced on the same scale.

placed beneath the table with the dark chamber above the table, if such an arrangement was desired.

I have described the device as used in a horizontal position, but it could also be used

chamber until it strikes the floor. The cassette adjustors are then brought together or to the distance of the width of the cassette to be used, and are then locked by turning thumb screws. On a table to the right of the

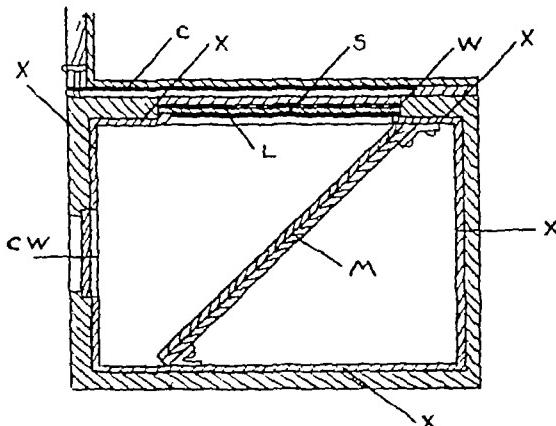

Fig. 2 Side view of dark chamber *W*, wood or plain colored glass cover over screen, *S*, fluorescent screen, *L*, lead glass on which screen is placed, *M*, mirror (angle at which it is placed can be adjusted), *CW*, lead glass chamber window, *C*, opening to insert cassette, *X*, X-ray-proof lining in chamber

in an upright or angular position by means of counter weights and perpendicular runs

It is, of course, understood that the dark chamber is connected with the tube stand, so that the tube stand and chamber move in unison. For gastro-intestinal and chest work, a device similar to the one shown in Figure 3 could be attached over the lead glass window. Thus, with the ordinary shades of the room drawn, and the use of a red light, eye accommodation could be obtained to enable one to get more detail.

How serial roentgenography is accomplished in this device is illustrated in Figure 4. Briefly explained, the operator sits in front of the dark chamber and locates the area to be roentgenographed. This localized area is then brought to the right side of the chamber and the latter made stationary by pressing down the stop at the bottom of the

operator are placed the desired number of cassettes, each numbered in the order in which it is to be inserted. With the right hand Cassette No 1 is inserted between the cassette holders and the exposure is made. No 2 is next inserted, pushing No 1 to the left side of the chamber, where it is taken by the operator's left hand, or, if a run has been provided, can slide to the floor.

A freely movable lead-lined dark chamber, having a lead-lined panel, as described extending above the chamber and the same so positioned that the patient is between the dark chamber and the tube, is, I believe, insofar as I have been able to ascertain, an original idea.

one, I feel that it is large enough to justify me in bringing the principle before the roentgenologists I submit a drawing (Fig 1) which will clearly bring out the idea, and will describe it in a brief way

the table and used in connection with a portable X-ray unit, thus making possible a portable fluoroscope for use in homes or wards The front wall of the chamber, lead-lined, is continued above the table, making a panel

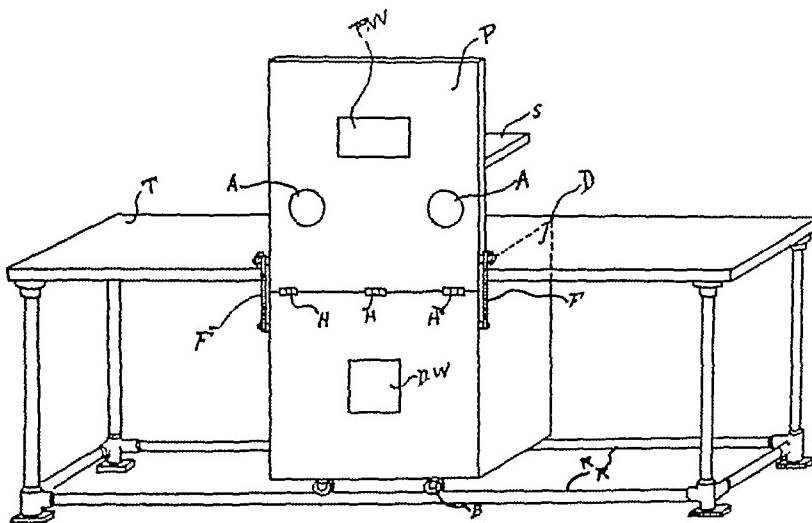

Fig 1 *T*, table top, *P*, X-ray-proof panel above table, *S*, overhanging shelf for supporting lead curtains, *PW*, panel window through which patient on table may be observed, *A*, openings through which arms of operator are thrust, *F*, fasteners for holding panel in upright position, *H*, hinges to allow panel to fold down, *DW*, dark chamber window for observing shadow in dark chamber closed by lead glass, *D*, dark chamber under table, *R*, longitudinal runs placed on transverse runs (not shown in drawing), *B*, ball bearings. The opening for the insertion of the cassette, which must be of aluminum on both sides, is not shown in this drawing, but is seen in Figure 2 (*C*)

Reduced to its simplest terms, this device consists of a freely movable lead-lined dark chamber, having a fluorescent screen placed on lead glass, backed by a colored plain glass or wood, which excludes all light from the chamber, and serves as a roof for the same In the bottom of the chamber is placed a mirror which is capable of being tilted to an angle, and this reflects the shadow from the screen In the side of the cabinet facing the operator is a lead-lined glass window which may be as large as 8×10 for observation of the shadow This dark chamber is placed beneath a wooden table on runs which allow the chamber to be freely moved lengthwise and crosswise with respect to the table If desired, the cabinet can be removed from

which when not in use can be turned down The panel has three openings, the center one closed by a lead glass window for observation of the patient on the table, and one on each side, shut off from the X-ray field by means of a lead curtain, to enable the operator to safely palpate or manipulate the part of the patient under observation

On the overhanging shelf supporting the curtain may be placed a suitable diaphragm to cut down the amount of X-ray energy striking the screen, or this diaphragm could be placed on the roof of the dark chamber and lead curtains attached to the cone, in this way eliminating the overhanging shelf The tube in this device is placed above the table, rather than beneath, but could be

amination a bony fragment in the foot. A rather large fragment of bone was demonstrated slightly posterior to the fifth metatarsophalangeal articulation and extending mesially into the plantar tissues. On the original film, the serrated margin of the fish bone is well demonstrated, the density of the

fragment being practically that of the bones of the foot. The fragment was readily removed and the patient returned to his usual duties in ten days.

A TRIPLE BONE LESION¹

By I S TROSTLER, M.D., F.A.C.R., F.A.C.P.,
CHICAGO

In November, 1930, G. M., a rather thick-set Russian man, 42 years of age, was sent to me by a general practitioner for examination of the right hip region. The patient, who walked with a slight limp on the right, was wearing a shoe with the right sole about one inch thick and the heel about one and one-half inches high.

He stated that, since childhood, his right leg had been shorter than the left, but that, until a few months before coming for the present examination, he had had no pain in the joint or hip region. During the four and one-half months preceding the roentgen examination the right hip joint had become progressively stiffer and more painful. When I saw him, he had less than 25 per cent of the normal motion in the joint. Abduction was particularly limited.

There was no history of injury or unusual illness.

A roentgenogram of both hips and the pelvis showed a slight atrophy of the entire right half of the pelvis. The left hip joint,

THE RADIOGRAPHIC DETECTION OF THE CATFISH SPUR AS A FOREIGN BODY

By W R BROOKSHER, JR., A B, M D,
FORT SMITH, ARKANSAS

The recent case report of Taft,¹ in which a catfish spur was demonstrated in the soft tissues of the foot, prompts the report of a similar case, examined by me in 1923. In my case, the bony fragment is of sufficient size to permit of illustration, it is of further interest due to the period the spur remained in the foot without producing symptoms.

A young man, engaged in spring baseball training at Bradenton, Florida, during March, 1923, was in bathing on March 1

supervening infection. He thought at the time that a fin of the fish had broken off in his foot but no attempt was made to determine its presence. He returned to his usual training duties at the end of the period of hospitalization, experiencing no difficulty with the foot, despite the fact that it was subjected to unusual stress in his pitching.

At the conclusion of the training period, the young man went to the Syracuse, N Y, baseball club where he remained for a period of about ten days, working regularly. To quote his statement, he was "in good form." He was sent to the Fort Smith, Arkansas, club on June 10, 1923. Shortly after his arrival he began to complain of pains in the injured foot. He consulted me and the history of the injury as given suggested the possibility of locating by roentgenologic ex-

slowly disappeared in a way that is said to be characteristic of this condition. With greater and more efficient pulmonary aeration, this doughnut-shaped shadow separated into smaller and smaller areas of more or less circular mottlings as time went on. It was noticed that the part of the atelectatic area closest to the mediastinum was the last to disappear. The area of lessened density in the center of the circular shadow may be accounted for by the fact that a bronchus filled with air seems to enter from the right hilar region to the middle of the atelectatic area.

The diagnosis of congenital atelectasis is made more frequently by the X-ray examination and the symptoms than by the physical findings. In the differential diagnosis among bronchopneumonia, miliary tuberculosis, pulmonary neoplasms, obstructive atelectasis, enlarged thymus, congenital syphilis, and eventration of the abdominal contents into the chest, recourse must be had to the history, symptoms, physical examination, and the clinical course of the condition as well as to the roentgen-ray films, which may have to be taken serially.

Considerable areas of atelectasis escape detection by any means but the X-ray. Films should be taken both during inspiration and expiration, preferably at the end of each phase, to rule out what may appear to be atelectatic areas occurring at the end of expiration. In infancy, expiration is much more complete than in adult life.

The prognosis as regards life depends on how early the diagnosis is made, the underlying cause, the extent of the atelectasis, the time of the institution of treatment, and the type of the treatment. Recent developments lend strong support to the frequent occurrence of pneumonia in cases of atelectasis (1).

It is good prophylaxis for as many in-

Fig 1 Doughnut-shaped shadow in the right pulmonary field of an infant chest interpreted as due to congenital atelectasis

Fig 2 Same case, five days after birth. Barium in the stomach and the proximal small bowel to indicate their normal position. This film shows more clearly the air-containing branch bronchus which enters the central clear area of the doughnut-shaped density.

left acetabulum, and upper fourth of the left femur were normal. The right hip joint showed erosion or absorption of the cartilage of the joint surfaces. The space between the head of the femur and the acetabulum was reduced and decidedly at variance with the normal. There was an osseous extension outward from the upper outer border of this acetabulum. The right acetabulum was wider and rougher on its inner articular aspect than is normal and did not present the normal smooth outline. The head of the right femur presented a mushroomed outline, with shortening of the femoral neck and reduction of the density of the head, neck, and both trochanters. The femur was abducted and Shenton's line destroyed.

In the intertrochanteric region, an oblong or oval area of rarefaction, with a denser border or edge, was seen. This, to all appearances, was the remains of an abscess of the bone. Below this area (in the upper third), the shaft of this bone appeared to be normal.

SUMMARY

Summarizing the above findings, it is my opinion that—

1 There was Perthes' disease in early childhood,

2 There was a Brodie's abscess in the intertrochanteric region of the right femur,

3 There was at the time of the roentgenographic examination, an infectious arthritis in the right hip joint, with an effort at fixation, resulting in abduction for the purpose of lessening the tension within the joint.

CONGENITAL ATELECTASIS DISCUSSION AND CASE PRESENTATION

By M BRAVERMAN, M.D., and
S BROWN, M.D.

From the Department of Roentgenology, Jewish Hospital, CINCINNATI, OHIO

It frequently occurs that the persistence of the fetal pulmonary state, which is physi-

ological to a limited degree during the first few days of life, can be diagnosed only with the roentgen ray, due to a lack of symptoms or signs. The condition may be either partial or complete, unilateral or bilateral.

Congenital atelectasis occurs more frequently in premature and feeble babies. Other causes are birth injury to the central nervous system, narcotization, inhaled meconium or amniotic fluid, and prolonged or difficult labor.

Atelectasis most often involves the paravertebral and central portions of the lungs, especially the areas close to the hilus. The expanded areas are seen at the periphery. This is undoubtedly due to the fact that the periphery of the lung is the most mobile.

Considerable degrees of atelectasis may be found at necropsy in an infant who, in life, presented few or no symptoms. Examination of the chest may present nothing definite except poor resonance throughout. Auscultation may sometimes reveal medium coarse râles or, more often, fine crackles or showers of fine crackles, especially when the infant is made to breathe deeply.

Recently it was our privilege, through the kindness of Dr L Friedman, to study the chest of an infant, Baby D, who was born of healthy parents at the Jewish Hospital November 18, 1930. A moderate degree of cyanosis was present for the first twelve hours following a prolonged and difficult delivery by version of a breech. The child, twenty-four hours post-delivery and presenting no symptoms or signs, was found to have a doughnut-shaped shadow (Figs 1 and 2) in the right pulmonary field close to the heart on an anteroposterior view and overlying it on a lateral view. During the period of about four months, when the gradual disappearance of this shadow could be watched by serial X-rays, the child did not present any symptoms or physical signs. This singular roentgen-ray finding, interpreted by us as congenital atelectasis, has

sclerosis around the margin of the described lesion (Fig 1) A tentative diagnosis of bone abscess or bone cyst was made On March 3, 1931, the patient was operated upon through a lateral incision The cortical bone covering the site of the cavity seen in the roentgenogram was removed with a chisel The surrounding bone was hard, and the cavity was filled with a gelatinous material, slightly pearly gray in color This material had broken through the cortex on the plantar surface, but there was no invasion of the soft tissue The material was curetted out and a specimen sent to the laboratory for diagnosis The hard sclerotic bone was cut away to leave no over-hanging edges and the wound was closed (Fig 2)

The microscopic examination revealed several types of growth (Fig 3) Numerous areas were composed of perivascular endothelial cells, occasionally multinucleated giant cells were seen There was also imperfectly formed cartilage All of the sections examined approached, in certain areas, the picture of a myxosarcoma While the histologic appearance suggested a rather slow-growing tumor of a low grade of malignancy, it was nevertheless an osteogenic sarcoma The diagnosis was chondromyxosarcoma

Forty-eight hours after the operation X-ray deep therapy was started in prefer-

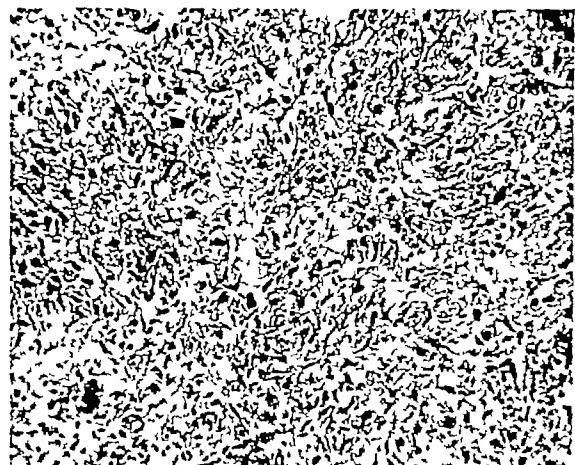

Fig 3 Photomicrograph of removed tissue (100 diameters)

ence to radical surgery From March 5 to April 10, 1931, a total of 1200 r (surface dose) was applied over the incision, using a field of 6.5×6.5 sq cm, 50 cm FSD, and an effective wave length (Duane) of 0.16 Ångstrom unit The changes in the bone at the site of the former lesion are well demonstrated in Figures 4 and 5 The last roentgenogram (Nov 16, 1931) revealed a circumscribed area in the os calcis, slightly less dense than the surrounding bone The sclerosis around the margin, as described at the first examination, was still present It was noted, however, that the bone structure was apparently nearly homogeneous It may also be mentioned here

CHONDROMYXOSARCOMA OF THE OS CALCIS

By ERNST A. POHLE, M.D., PH.D., and WILLIAM D. STOVALL, M.D., University of Wisconsin Medical School, MADISON, Wisconsin

On Feb 25, 1931, S.Y., white, female, aged 12 years, was admitted to the orthopedic service, University Hospital, with the complaint of pain in the left heel. She had not been able to use it in walking for the two weeks preceding her admission to the

hospital. The diagnosis of the referring physician was osteomyelitis.

It appeared that, in January, 1930, she had slipped on ice and hurt her left foot, the skin, however, was not broken. The parents thought she had a sprained ankle and applied hot dressings. She continued to walk, using her heel as little as possible. In September, 1930, the pain increased and the heel became slightly swollen. Cold seemed to aggravate the pain. In January, 1931, a physician was consulted, roentgenograms were taken, and a diagnosis of osteomyelitis made.

The general physical examination was essentially negative. The temperature varied between 97.8° and 100° Fahrenheit. There was swelling, with tenderness at the lateral aspect of the left heel but no limitation in motion and the patient walked normally. The roentgenograms of the foot, taken on Feb 25, 1931, showed a sharply circumscribed, circular, punched-out area about 1.5 cm in diameter on the medial margin of the plantar surface of the os calcis. This had broken through the cortex. There seemed to be no bone atrophy but moderate

Fig 1 Left foot, Feb 26, 1931

ence to radical surgery From March 5 to April 10 1931, a total of 1200 r (surface dose) was applied over the incision, using a field of 6.5×6.5 sq cm, 50 cm F S D, and an effective wave length (Duane) of 0.16 Ångstrom unit The changes in the bone at the site of the former lesion are well demonstrated in Figures 4 and 5 The last roentgenogram (Nov 16, 1931) revealed a circumscribed area in the os calcis, slightly less dense than the surrounding bone The sclerosis around the margin, as described at the first examination, was still present It was noted, however, that the bone structure was apparently nearly homogeneous It may also be mentioned here

that X-ray therapy did not interfere with the healing of the incision

The patient is now enjoying good health and can walk freely. Roentgen examination of the chest has failed to show any abnormalities. This patient is returning once a month for re-examination.¹

We have reported this case for two reasons. In the first place it is interesting from the diagnostic standpoint because it demonstrates the difficulties encountered in such cases, and, secondly, because we feel that X-ray deep therapy has been of definite benefit in clearing up the local lesion.

A CASE OF CARCINOMA OF THE THYMUS

By J. J. COLLINS, M.D., Radiologist, the John D. Archbold Memorial Hospital, THOMASVILLE, GEORGIA

A case of thymic tumor is reported in which the clinical diagnosis was cellulitis of the neck, with sinus thrombosis, the roentgen diagnosis was abscess or tumor of the upper mediastinum, and the pathologic diagnosis, made postmortem, was carcinoma of the thymus, with metastases to the lungs, liver, and mesenteric lymph glands.

Anamnesis.—The patient, colored, male, aged 28, was admitted to the John D. Archbold Memorial Hospital on Aug. 25, 1930, and died on Aug. 28, 1930. The past history was unimportant. The present illness began five weeks previous to admission with sore throat, toothache, fever, and general malaise. Several days later swelling of the neck was noted which soon became progressively more marked. Edema of the eyelids appeared and later marked difficulty in breathing and swallowing was noted. For three or four days previous to admission nothing could be swallowed except small amounts of fluid.

Physical Examination.—Temperature 101 degrees F., pulse 120, respiration 30. The patient was a well-nourished, well-de-

veloped colored male. Respiration was labored, the neck markedly swollen, the face and eyelids edematous, and there was a bilateral exophthalmos.

The swelling of the neck was uniformly hard and smooth, nothing suggesting enlarged glands in this or any other area was found. No dilatation or prominence of the superficial vessels was discernible. A bloody mucus discharge exuded from the mouth and nose. There were coarse râles and exaggerated breath sounds throughout both lungs. There was a wide area of dullness over the upper mediastinum. No edema of the arms or thorax was noted.

Laboratory Findings.—White blood cells, 9,150, polymorphonuclear leukocytes, 80 per cent, eosinophiles, 2 per cent, transitional cells, 4 per cent, lymphocytes, 14 per cent. Red blood cells, 3,350,000. Hemoglobin, 60 per cent. The blood sugar and non-protein nitrogen were within normal limits. The urine, which contained a few granular casts, had a specific gravity of 1.035. The Kahn test was negative.

Roentgen Report.—Examination of the chest was made August 26, 1930. A single film only was made because of the semicomatose condition of the patient. There was a large dense mass, 11 cm in width, in the upper mediastinal area, extending laterally on both sides beyond the mediastinum. The upper border extended above the sternoclavicular articulations and the lower border fused with the heart shadow. The lateral borders were well defined and regular. There was definitely a diminished aeration of the upper lobe of the right lung but no other evidence of pathology. Considering the history and course of the illness it was thought that the condition was mediastinal abscess rather than tumor.

The patient died on his fourth day in the hospital. The salient points of the postmortem examination were: The neck was markedly swollen and the face and eyelids edematous. There was a marked bilateral

¹In April 1932 the patient was still well.

exophthalmos. None of the superficial glands was palpable. The pericardial and pleural cavities contained no increased amount of fluid. A large mass, shaped like an inverted pyramid, filled the upper mediastinum. This was of grayish color and cartilaginous consistency. There was no infiltration of the lungs, sternum, or surrounding structures, but there was a very definite compression of the lungs, trachea, and vessels of the mediastinum. No thrombi or erosions were found in any of the vessels. The pleural surfaces of the lungs showed numerous small, avascular, grayish nodules. The liver contained multiple small, grayish, necrotic areas. Cultures from these were sterile. In the abdominal cavity there were three enlarged mesenteric glands. No pathology was found in the brain.

Sections from the tumor and metastatic areas were examined by Mary J. Erickson, M.D., and a diagnosis of an undifferentiated cell carcinoma was made. Sections were submitted to the late Dr. Warthin whose report was as follows:

The greater part of this neoplasm is necrotic. The living areas present the appearance of an undifferentiated cell carcinoma, very medullary in areas. It may be a so-called thymoma of carcinomatous type. It is distinctly epithelial in type and not lymphoblastic.

In 1930, Doub (1), in reviewing the literature of thymic tumors, found that approximately a hundred cases of all types had been reported. To this number may be added five other cases reported by him. Of these cases of thymic tumor approximately 20 were carcinomas, the remainder being for the most part sarcomas.

Brannan (2), in 1926, reviewing the literature of carcinoma of the thymus, stated

Fig. 1 Upper mediastinal tumor with clear-cut borders. There is no evidence of invasion.

that 19 authentic cases had been reported. This number included a case reported by him and one by Foot in that year.

The case of carcinoma of the thymus here reported is one which did not present the usual local invasion of surrounding structures but did present the pyramidal form and the compression of the vessels of the mediastinum described by Brannan. Metastases to pleura, liver, and mesenteric glands had also occurred. The course of the disease, following the initial symptoms, progressed rapidly to a fatal termination. There were no palpable glandular enlargements to suggest the diagnosis of tumor or to afford biopsy specimens.

that X-ray therapy did not interfere with the healing of the incision

The patient is now enjoying good health and can walk freely. Roentgen examination of the chest has failed to show any abnormalities. This patient is returning once a month for re-examination.¹

We have reported this case for two reasons. In the first place it is interesting from the diagnostic standpoint because it demonstrates the difficulties encountered in such cases, and, secondly, because we feel that X-ray deep therapy has been of definite benefit in clearing up the local lesion.

A CASE OF CARCINOMA OF THE THYMUS

By J. J. COLLINS, M.D., Radiologist, the John D. Archbold Memorial Hospital, Thomasville, Georgia

A case of thymic tumor is reported in which the clinical diagnosis was cellulitis of the neck, with sinus thrombosis, the roentgen diagnosis was abscess or tumor of the upper mediastinum, and the pathologic diagnosis, made postmortem, was carcinoma of the thymus, with metastases to the lungs, liver, and mesenteric lymph glands.

OBJECTIVES IN RADIOLOGY¹

Radiology, the newest member of the medical family, is still experiencing the growing pains incidental to reaching a useful maturity. Most of us have watched its development from the time of the old static machine, which, if it was capable of impressing faintly the bones of the hand on a photographic plate, was considered a wonderful thing. With the development of increased power through the use of larger induction coils and the introduction of the transformer came the realization, and sadly so, to many of the pioneers, that somehow these rays had a decided effect on tissue cells. This, in turn, led to further study to determine to what extent these rays might be used to affect tissue cells deliberately, particularly in the various malignant diseases. The introduction of the Coolidge tube and further refinements in apparatus, such as the movable grid, double intensifying screens, and films of greater speed, led finally to diagnostic endeavor to interpret pathology in the soft tissues as presented by the use of contrast media of various kinds for outlining the gastro-intestinal tract, visualizing the gall bladder, the kidney pelvis, ureters, and bladder, and tracing the outlines of cavities and sinuses. All of this within a period of three and a half decades! Is it any wonder

that the application of radiology should to-day find itself in a more or less chaotic situation? On the one hand we have the few sincere men striving to place radiology where it belongs, on the other we have the multitude trying to make interest charges on equipment sold to them by enterprising salesmen. In the first instance the object is humanitarian and scientific, in the second, purely economic.

What is the greatest objective in radiology? Service. Service to hospitals, service to their staffs, and, most important of all, intelligent service to the patient, who, in this case, is the ultimate consumer. The patient is entitled to the best service and opinion possible at all times and I am happy to say that, for the most part, he is getting them; else applied radiology would soon pass into disrepute.

The larger hospitals throughout the country, practically without exception, employ full-time directors for their X-ray departments. But what about the bulwark of the Nation's health defense, the hundreds of smaller hospitals that cannot afford to employ full-time directors? We cannot expect a small hospital to operate its X-ray department at a financial loss, neither should any hospital expect income from its X-ray department to offset losses from elsewhere within the institution. The reputation for thoroughness which a hospital might acquire through an efficient X-ray department, and the additional number of patients who might, for that reason, use the hospital should be a full reward. Apparently, then, the only solution for adequate service within the means of the small hospital, for the present at least, lies in some sort of part-time arrangement with a competent and recognized roentgenologist.

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting at St. Louis, Nov. 30-Dec. 4, 1931

In an effort to determine the value of a roentgenologist to a small hospital, and to evaluate this in tangible terms, a 65-bed hospital was chosen. Prior to the early part of 1930, the procedure in the hospital² selected for this study was quite similar to that of many others of approximately the same size. That is, the hospital employed a technician and the referring physician interpreted the film. All of the X-ray records and films from 1925 to January 1, 1931, were carefully examined in order to contrast the work done before a part-time roentgenologist was employed with the work done after this arrangement had been made. The outstanding features of this survey will follow, and I might add that the roentgenologic supervision in this hospital is that of another than myself, and, therefore, the conclusions drawn are unbiased.

The equipment, which was installed new in 1925, is capable of doing as high-grade work as can be done anywhere. It is still in use, so no corrections need be made for change of equipment.

The following comments will give a general idea of the character of work done in this hospital in 1925 and 1926. Radiographs of bony structures, including lumbar and dorsal spines, were uniformly good. However, no lateral projections of the spine were found. Stereoscopic views were limited to the skull and, in a few instances, to the pelvis, and did not include any of the smaller regions, for example, the shoulders. Films falling into the gastro-intestinal classification contained a few flat films of the abdomen. In cases in which contrast media were used the films were limited for the most part to one or two, all being taken in the standing position. Films of the gall-bladder region were all without contrast media, in only one case could the gall bladder be visualized. Kidney films in general were unsatisfactory as far as being informative

was concerned. Only one case had had retrograde pyelography and in that only the ureter was visualized. Chest films were satisfactory throughout except that they were not taken stereoscopically.

In 1927, films of the gastro-intestinal tract showed some improvement in that a greater number of films were used in each case and the contrast meal was followed into the colon. Several of these examinations were made in the horizontal position with, of course, increased detail and interpretative possibilities. Some of the gall-bladder examinations during this year were made with oral dye in capsule form, frequently the capsules in the colon were more prominent than the object of their use.

The years 1928 and 1929 continued to show improvement, especially in gastro-intestinal work. Gall-bladder films were capable of more conclusive interpretation and films of this region following intravenous dye were found. Chest films were more often taken stereoscopically. In all of these years, films of the opposite extremity or side for comparison in checking a doubtful finding or a congenital anomaly were conspicuously absent. A few interesting films were found but no effort had been made to take additional films in other positions or to follow them up with subsequent exposures. What a wealth of interesting material must lie buried in the hospital files of the country! No written reports accompany any of the cases examined during these years except that in one or two instances the individual physician may have referred the films to a roentgenologist for some special reason of his own. Taking into consideration that there was no one to make suggestions for proper procedure the work done was very satisfactory as far as it went and no criticism is intended.

Early in 1930, a roentgenologist was employed to supervise the X-ray Department and to visit the hospital one day a week.

This, in turn, led to further study to determine to what extent these rays might be used to affect tissue cells deliberately, particularly in the various malignant diseases. The introduction of the Coolidge tube and further refinements in apparatus, such as the movable grid, double intensifying screens, and films of greater speed, led finally to diagnostic endeavor to interpret pathology in the soft tissues as presented by the use of contrast media of various kinds for outlining the gastro-intestinal tract, visualizing the gall bladder, the kidney pelvis, ureters, and bladder, and tracing the outlines of cavities and sinuses. All of this within a period of three and a half decades! Is it any wonder

that the application of radiology should to-day find itself in a more or less chaotic situation? On the one hand we have the few sincere men striving to place radiology where it belongs, on the other we have the multitude trying to make interest charges on equipment sold to them by enterprising salesmen. In the first instance the object is humanitarian and scientific, in the second, purely economic.

What is the greatest objective in radiology? Service Service to hospitals, service to their staffs, and, most important of all, intelligent service to the patient, who, in this case, is the ultimate consumer. The patient is entitled to the best service and opinion possible at all times and I am happy to say that, for the most part, he is getting them else applied radiology would soon pass into disrepute.

The larger hospitals throughout the country, practically without exception, employ full-time directors for their X-ray departments. But what about the bulwark of the Nation's health defense, the hundreds of smaller hospitals that cannot afford to employ full-time directors? We cannot expect a small hospital to operate its X-ray department at a financial loss, neither should any hospital expect income from its X-ray department to offset losses from elsewhere within the institution. The reputation for thoroughness which a hospital might acquire through an efficient X-ray department, and the additional number of patients who might for that reason, use the hospital should be a full reward. Apparently, then, the only solution for adequate service within the means of the small hospital, for the present at least, lies in some sort of part-time arrangement with a competent and recognized roentgenologist.

¹Read before the Radiological Society of North America at the Seventeenth Annual Meeting at St Louis Nov 30-Dec. 4, 1931

"radiographic study", perhaps the latter is better. Films are only a means to an opinion and in the final analysis the opinion is the entity for which the patient pays.

Another important objective should be to make yourselves consultants in every sense of the word. For the most part a roentgenologist seems content to sit at the viewing box and report what he sees in the shadows. Would it not be better to be seen more often at the bedside of the patient? It will give the patient a good impression and he will feel that everything possible is being done, it will be helpful to the attending physician, suggestions to him of another angle from which to attack his problem will often be appreciated. In this way the roentgenologist can order the exposures necessary for the best results instead of accepting whatever projections the attending man may think necessary. In any event, insist on a history of all obscure or doubtful cases, or at least a synopsis of the outstanding objective and subjective symptoms. Patients are glad to have X-ray examinations made, they are comprehensible to them and, therefore, received by them with confidence. See to it that the character of your work continues to merit this confidence.

What of the future? Forecasts are always hazardous but interesting. Could anyone have predicted twenty years ago what the present gives in all the branches of radiology and to what extent radiology is being used to-day in the fields of diagnosis and therapy? A few years ago, surgery was the only accepted method of treatment in malignant conditions, to-day irradiation shares equally with surgery in importance. Perhaps the future, through better facilities and better technic in application, will find irradiation the only accepted method of treating cancer. Who knows? There will be less surgery done in the next decade, everything else being equal, for, as refinements in apparatus and methods are perfected, roent-

genologists will keep pace with increased skill in interpretation. The net result will be less necessity for undertaking surgical procedures on an exploratory basis. Irradiation is already displacing surgery in the treatment of some cancerous conditions, notably in the female pelvis and in malignancies about the tongue, mouth, and face. Eradication of cancer is a gargantuan task, neither the surgeon nor the radiologist can afford to ignore the other, and each must have implicit confidence in the pathologist. With the establishment of cancer clinics throughout the country, under responsible guidance, the future holds much hope. In this work as in all of the problems of the future, radiology can be depended upon to contribute its full share in an ever increasing sphere of usefulness.

COMMUNICATIONS

FLORIDA RADIOLOGICAL SOCIETY

The regular annual meeting of the Florida Radiological Society was held in Sarasota, Florida, on May 2, 1932, at the Sarasota Terrace Hotel. Lester W Cunningham, M D, of Jacksonville, President of the Society, presided. Informal presentations of case reports and demonstrations of interesting roentgenograms were featured at the morning and afternoon sessions.

The following officers were elected, to serve until the spring meeting, 1933. *President*, Orion O Feaster, M D, St Anthony's Hospital, St Petersburg, Florida; *Vice-president*, Frederick K Herpel, M D, Good Samaritan Hospital, West Palm Beach, Florida; *Secretary-Treasurer*, W McL Shaw, M D, 418 St James Bldg, Jacksonville, Florida.

He is still retained in this capacity. It is interesting to report that this hospital was approved as a fully standardized hospital at the fall meeting of the American College of Surgeons. It must follow, therefore, that a part-time service of the proper kind is satisfactory. A comparison of the films and the general management of the department for 1930 with those of the preceding years should show some differences.

In the first place, each case carries with it a written report of the shadow features presented in the films, over the signature of the roentgenologist in charge. Secondly, fluoroscopic procedures have a more definite value. Thirdly, the number of cases of soft-tissue examinations, such as kidney and gall bladder, have increased in number, the latter 100 per cent over the preceding year. Fourthly, films of the opposite side for comparison are almost a matter of routine. Fifthly, the X-ray findings and interpretations are accepted with more confidence by the members of the staff. And, lastly, opportunity is had for proper therapeutic procedures.

Let us now look at the situation from the financial side. The gross income from this X-ray Department in 1925 was \$1,286.50. This amount was a little more than doubled in 1926, due principally to the fact that 1925 was only an eight-month year in this department. The gain each year following was irregularly upward but only at a rate of two or three hundred dollars each year. The gross income for 1929 was \$3,033.50, approximately \$100 less than in 1928. For the year 1930, when roentgenologic service was had for the last ten months, the gross income was \$4,583.00, an increase of 50 per cent. In the present year, 1931, the gross income to October 1 is \$3,507.00, not a bad showing in this period of world-wide mental depression. This does not mean that the hospital is any better off financially so far as its X-ray Department is concerned. In fact, its net income is less

than in the period prior to 1930, but it is rendering a better service to its patients and a better service to its staff. After all, that is the ultimate function of any hospital, and no hospital management should feel that it can afford not to provide the best in its radiology department.

The exact nature of the financial arrangement between the hospital and the radiologist is immaterial so long as the relationship is harmonious and neither one feels that the other is getting the better of it. No arrangement can be satisfactory under which the cost of an X-ray examination to the hospital is in the balance. Then only the most obvious conditions will call for a radiologic examination, and other cases in which this examination is of more importance and the indications less obvious will not receive the full benefit of their hospital stay. Probably a straight salary on a part-time basis, adjusted from time to time on the value of the work done, is conducive to the best general results and will lead ultimately to a larger volume of work than an arrangement under which the cost is considered each time.

Patients are human and have the traits with which Nature endowed them. I refer particularly to that of possession. The question of ownership of films is quite generally conceded to lie with the individual or hospital making the exposures, but a film is something tangible and understandable to a degree by the patient. Therefore, it is not surprising that he should feel that he has an interest in the film and that it should be available to him in shopping around a bit. Imagine a patient going from doctor to doctor with a ureameter in one hand and a sedimentation glass in the other. It is all a matter of education and roentgenologists, themselves, are largely to blame for this situation. How often do we not hear, "We'll take a film of this and see what you have." Make it one of your objectives to dignify your profession. Always refer to this kind of work as an "X-ray examination," or a

"radiographic study", perhaps the latter is better. Films are only a means to an opinion and in the final analysis the opinion is the entity for which the patient pays.

Another important objective should be to make yourselves consultants in every sense of the word. For the most part a roentgenologist seems content to sit at the viewing box and report what he sees in the shadows. Would it not be better to be seen more often at the bedside of the patient? It will give the patient a good impression and he will feel that everything possible is being done, it will be helpful to the attending physician, suggestions to him of another angle from which to attack his problem will often be appreciated. In this way the roentgenologist can order the exposures necessary for the best results instead of accepting whatever projections the attending man may think necessary. In any event, insist on a history of all obscure or doubtful cases, or at least a synopsis of the outstanding objective and subjective symptoms. Patients are glad to have X-ray examinations made, they are comprehensible to them and, therefore, received by them with confidence. See to it that the character of your work continues to merit this confidence.

Tours to Russia—Conrad K. Gale, M.D., 225 West 86th St., New York City, has asked RADIOLOGY to announce that an invitation has been extended to American physicians and surgeons by the medical associations of Leningrad, Moscow, and other cities of Soviet Russia, to visit their hospitals, clinics, research laboratories and similar institutions.

This is the first occasion ever offered the American physicians to inspect officially these most interesting phases of Russian medical life.

The group of American physicians, which is now forming, will sail this summer. Those interested can get full information from Compass Tours, 55 West 42nd Street, New York City.

Our attention has been called to a paper by I. S. Trostler, M.D. in the April, 1932, issue of the *Illinois Medical Journal*, page 343. The title is "The Commercial Roentgen Laboratory—Some Good Reasons why they should not be Tolerated or Patronized," and such of our readers as are interested in this timely—in this country, at least—question may read the paper with interest.

BOOK REVIEWS

UNITED STATES ARMY X-RAY MANUAL Authorized by the Surgeon-General of the Army. Second Edition, rewritten and edited by Lt. Col. H. C. PILLSBURY, M.C., U.S.A. Pages 482, with 228 illustrations, 12 mo, flexible leatherette. Published by Paul B. Hoeber, Inc., New York, 1932. Price, \$5.00.

This book has been sufficiently modified from the Manual intended primarily for the student of military medicine to permit it now to be classed as a suitable text-book for the instruction of medical students anywhere. There are still a few pages devoted to military matters, but, after all, there is no strict difference between the practice of roentgen-

ology in military and in civil life. The problems of physics and of diagnostic internal medicine, of fractures and bone tumors are common to civil and military life. No space has been given to therapy. The text is carefully prepared. The illustrations are numerous and well chosen, and the book is a commendable introductory work for those who wish to take up the study of roentgenology.

JAMES T. CASE, M.D.

SURGICAL PATHOLOGY OF THE GENITO-URINARY ORGANS By ARTHUR E. HERTZLER, M.D., Surgeon to the Agnes Hertzler Memorial Hospital, Halstead, Kansas, Professor of Surgery, University of Kansas. A volume of 286 pages and 222 illustrations. Published by J. B. Lippincott Co., Philadelphia, 1931. Price, \$5.00.

This monograph is one of a series of monographs which Dr. Hertzler is writing on surgical pathology. The subject matter of this volume is disposed of in three parts, namely, diseases of the external genitalia in the male, diseases of the prostate and the bladder, and diseases of the kidney and ureter. The descriptive nature of the discussions and the excellent illustrations of gross specimens and the photomicrographs hold the reader's interest from the beginning to the end. The bibliographies, one at the end of each chapter, denote a critical review of the subject and add much to the value of the book as a reference volume.

The author has successfully and efficiently performed his task of presenting the subject from the viewpoint of the general surgeon, freed as much as possible from the complications of the specialists. Rarely does one encounter pathologic descriptions and classification of tumors so simplified. The emphasis which he has placed on the similarity of the embryonal tumors as found in the testicle and kidney is commendable.

For tumors of the testicle he has adopted the classification proposed by Hinman because it clarifies the subject for the surgeon. This includes seminomas and embryomas. The seminomas are so named because the cells are

made up pretty much of one type, frequently lobulated, especially in the less malignant ones. He states it is the most common testicular tumor and is distinctly one of adult life. Those of this group which seem to develop from seminiferous tubules, he feels, are merely those which least deviate from the normal. These tumors metastasize early, and usually before the primary tumor is noted have already extended to the lungs, retroperitoneal and supraclavicular nodes. The prognosis has been much improved with the advent of the X-ray, since the cells of this group are radiosensitive. Embryomas (teratomas) from the other group are composed of more maturely formed tissues, such as cartilage, muscle, glandular structures, etc. He regards a tissue which is a *biologic impossibility* as originating from a teratoma of the testicle.

Disease of the prostate is considered under three general heads: its inflammations, its hypertrophies, and its malignancies. The importance of accurate evaluation of all the factors influencing prostatic obstruction is stressed, since not infrequently the prostate is accused of producing symptoms totally unrelated to it. The secondary results of enlarged prostates such as hypertrophied bladder wall, the formation of cellules and diverticula, the cystitis incident to catheterization, and, finally, pyelonephritis are well described. A pathologic explanation of the causes of failure after prostatectomy, aside from a wrong diagnosis, is stone formation. The author feels this is more common when the prostatic bed is packed with gauze to control bleeding, and that a blood clot furnishes excellent nuclei for the formation of stones. The failure to remove enough capsule and excessive scar formation in the prostatic bed are noted. In dealing with carcinoma of the prostate the reader's attention is directed to the characteristic hard and nodular feeling of the gland which is the earliest and most reliable of all signs of malignancy. The pathogenesis and the pathology are logically reviewed.

The two types of papillomas of the bladder, the villous which he considers more or less benign, and the broad-based, usually malignant, are considered separately. He states that

the points of differentiation are in the arrangement of the villi and epithelium of the stalk, and the surgical pathologist should not offer an opinion as to its identity without an examination of the stalk. Epitheliomas and sarcoma of the bladder are considered separately also.

The chapter on urolithiasis covers this subject in an excellent manner. The author has gone into the etiology of calculi, with many remarks regarding their distinctive characters. The photographs of the various types of stones and the secondary changes produced in the bladder, ureters, and kidneys are excellent. Infections of the kidney are divided in the primary and secondary groups under the primary infections of the kidney. Brewer's kidney is discussed at great length. Brewer's kidney represents an acute lesion due to embolism from regions elsewhere in the body which produce infarcts, with resultant intense reactions of the entire body. Some of these are sufficiently infectious to produce abscesses, but the author feels that a great majority of these subsides spontaneously, due to some bactericidal factor in the kidney similar to that known to be present in the liver. He presents photographs of kidneys showing the resultant scars of these infarcts which have undoubtedly occurred a matter of years before the kidney was sufficiently involved to require surgical removal.

Essential hematuria is regarded as due to an unlocalized focal renal infection. Secondary infections of the kidney such as result from stones, prostatic obstruction, tumors, etc., are regarded as ascending infections and caused by the colon bacillus. The author agrees with Burns and Swartz on this point.

In dealing with tuberculosis of the kidney the author points out that the kidney, next to the lung, is the commonest site of tuberculosis, and that, on account of the accessibility of the kidney to the surgeon, there has been too much tendency on his part to regard kidney tuberculosis from the operative standpoint only. Careful differentiation between the acute and chronic forms of tuberculosis is discussed. The lesions of chronic tuberculosis of the kidney are divided into four groups:

(1) tuberculous ulceration of the apices of the pyramids, (2) chronic disseminated tuberculosis, (3) cheesy-cavernous forms, (4) mixed infections

Under cystic disease of the kidney are grouped together such conditions as solitary cysts, cysts associated with chronic nephritis, congenital polycystic disease, a number of very rare cysts and hydronephrosis. Hydronephrosis was placed in this group merely as a matter of convenience to him for its discussion. The various theories underlying polycystic disease of the kidney are briefly but carefully reviewed.

The author presents an admirable classification for tumors of the kidney. This classification includes the more common tumors, while those which are considered rare are grouped separately and are referred to principally in the bibliography. The classification of the more common tumors of the kidney is First, adenocarcinomas which are derived from the kidney tubules, remaining more or less spherical but gradually invading the surrounding kidney tissue, second, hypernephromas (fetal adenomas). This latter is the commonest group of kidney tumors. The author objects to having these tumors designated as carcinomas, since there is nothing in their structure or life history to suggest a confusion with carcinomas. The third group in the classification includes teratomas of infancy and childhood—the embryonal tumors of the kidney usually designated as sarcomas. These are characterized by their diversified cell structure, the author stating that the variety of cell structure and arrangement is not equaled by any other tissue. They grow rapidly, usually running their course in from six months to three years. The fourth group includes tumors of the renal pelvis and ureters. Tumors of the renal pelvis are of two types, the papillary and the squamous. The pathogenesis of these two types of tumors is fully described.

Every phase of the book is well prepared and interestingly presented. It should be recommended to genito-urinary surgeons, surgeons in general, and students of surgical pathology.

ATLAS DE RADIOGRAPHIE OSSEUSE II—
PATHOLOGIE (SQUELETTE PATHOLOGIQUE)
1 Lésions traumatiques, by G. HARET, A. DARIAUX, Electro-radiologistes des Hôpitaux de Paris, and JEAN QUÉNU, Professeur agrégé à la Faculte de Médecine Chirurgien des Hôpitaux de Paris 2 Lésions non-traumatiques, by ETIENNE SORREL, Chirurgien de l'Hôpital Troussseau, Ancien Chirurgien en chef Hôp. Mme de Berck, and MME SORREL-DEJERINE, Ancien Interne des Hôpitaux de Paris Two volumes of 344 pages, 897 figures, of which 519 are radiographs and 378 drawings Published by Masson et Cie, Paris, 1931 Price, 310 francs for the two volumes

This atlas in two volumes presents a most interesting review of the subject. It will have a distinct value in a reference library. The one drawback, which applies to all similar attempts, is the necessary limitation of the number of illustrations, but the choice of these has been made wisely, resulting in a wide range of subject material presented clearly and comprehensively.

Diagrammatic sketches accompanying the majority of the illustrations elucidate the anatomico-pathologic changes from the normal and add considerably to the value of the books as reference volumes. This applies particularly to the first volume on fractures and dislocations, the accompanying sketches are very helpful in interpreting the roentgenographic reproductions of various types of fracture and the resultant deformities.

The limitations are more apparent in the second volume, but one is surprised by the number of subjects touched on and the excellence of the reproductions, allowing many subjects to be well presented by a single illustration. Tuberculosis of bone and joint, including the spine, is particularly well illustrated. Characteristic examples of syphilitic bone lesions are well chosen. Bone tumors are limited in number but the types have been particularly well chosen to show the pathognomonic characteristics of each. Various types of the arthropathies, the arthropathies associated with central nervous system syphilis and syringo-

myelia, osteitis deformans, von Recklinghausen's disease, multiple congenital exostoses, epiphysitis in the spine, rickets, achondroplasia, osteochondritis juvenilis and the coxa varas of adolescence are all well illustrated.

A most interesting group of congenital anomalies and congenital absence of bones is presented. Excellent illustrations of various

grades of osteomyelitis and melorheostosis, hydatid cyst of the ilium, osteochondritis dissecans and osteochondromatosis round out a volume which will be most useful in determining the nature of the rare lesions periodically met with in the routine of a roentgenologic practice.

ABSCESS

Subphrenic Abscess D C Elkin Jour Am Med Assn., Oct 31, 1931, XCVII, 1279-1283

A study of subphrenic abscess is largely anatomic, since the pus is localized in well-defined areas. Barnard completely described the subphrenic spaces and divided the subdiaphragmatic area into five regions. The author discusses each of these in detail. Infection spreads along anatomic lines to well-mapped subphrenic areas. A knowledge of these areas is necessary for diagnosis and proper drainage.

The greatest help in diagnosis is roentgen examination. The diaphragm is elevated, fixed, and frequently deformed. If gas is present, it can be easily seen. Pneumoperitoneum may be of great value in determining the presence of adhesions between the diaphragm and the liver.

The only favorable outcome without operation is perforation into a bronchus, however, without operation, practically all patients die. With operation, the mortality is approximately 50 per cent. The transpleural operation, done in two stages, is advocated as the safest and most direct approach for abscess above the liver.

BONE (THERAPY)

Fractures of the Calcaneus. The Subcutaneous Circular Metallic Suture in Those of Postero-superior Angle. Enrique Finocchietto and Marcelo Fitte La Prensa Med Argentum, Nov 30, 1931, XVIII, 831-835

Since fractures of the postero-superior angle of the greater tuberosity of the calcaneus, also known as Boer's or Destot's fracture, are so difficult to reduce and the results so unsatisfactory, the authors introduce a method which they consider excellent. They review the methods advocated and their pitfalls, and believe that the method described by them gives an assurance of reduction, there being no such long immobilization, besides

Their method is as follows. After due antisepsis of the ankle, a mark is made on its external surface which corresponds to the point where the superior border of the calcaneus ought to be after correction. Through this point, which is more or less half way between the posterior border of the malleolus and the posterior cutaneous surface of the Achilles tendon, a curved Doyen needle is introduced. It is first passed upward and then horizontally in a tangential line to the superior surface of the displaced calcaneous fragment, coming out on the anterior surface just opposite to the point of introduction. When the eye of the needle comes out, a wire is attached and the needle pulled out so that it will go through the same route as before. Then the needle is in-

troduced through the internal surface, following an imaginary line running tangentially to the posterior part of the internal surface of the calcaneus, coming out at the ankle. The needle is then carried upward, following close to the calcaneus and coming out where the wire was left before. The wire is then attached and the same course followed. A semi-circle has thus been followed. The next step is to carry the needle in a similar manner but through the external surface of the ankle. The wire is then pulled through the same tract and finally returned to the point at which the needle was originally introduced, thus forming a complete circle. The reduction is performed by twisting the ends of the wire, which is cut close to the skin, the incised point being covered with gauze. The foot is then immobilized for two weeks by means of plaster of Paris. The authors then present two cases with radiographs before and after reduction, which showed excellent results.

N G GONZALEZ, M.D.

BONE DISEASES (DIAGNOSIS)

Charcot's Disease of the Hip Joint, Report of a Case. Curtis A Hunsaker Med Bull Veterans' Administration, February, 1932, VIII, 155, 156

This is a case report of an ex-service man, 30 years of age, who complained of dizziness, blurring of vision, and occasional sharp pains in and about the right hip joint. He had contracted syphilis, in 1918, and had received antisyphilitic treatment for a period of ten months. At the time of admission, the physical condition of the patient was generally good, except for a speech defect and loss of reaction to light by the pupils. Spinal and blood Wassermann examinations were positive. Examination of the right hip joint revealed very little swelling and no evidence of inflammation.

The patient soon began to walk with a decided limp and, as the disease progressed, complained less of the sharp, stabbing pains. He also showed a definite change in his mental condition, having periods of depression and a general emotional let-down.

The destruction of the joint was slow and insidious but eventually amounted to an almost complete disintegration of the hip joint. The head of the femur was almost completely destroyed and the acetabular cavity was widened and showed much disintegration.

This case was believed to represent the osteosclerotic type of the disease, in which there is an increased hardening and density of the bone substance. The author emphasizes the value of the assistance of modern laboratories in distinguishing this case of Charcot's joint from some form of rheumatism or clinical arthritis.

J N AND M D

A Case of Necrosis of the Epiphysis after Healed Fracture of the Neck of the Femur Rolf Euren Acta Chirurgica Scandinavica, Dec 3, 1931, LXIX, 8-20

This is the report of a case of partial necrosis of the epiphysis in a boy, 13 years of age, following fracture of the neck of the femur, which had seemingly healed and was functioning well, as shown by clinical and roentgenologic examinations.

For more than eight months after the accident signs of consistent necrosis were visible in the upper lateral portion of the epiphysis, followed by resorption and softening in the part affected, together with fragmentation and bowing due to weight-bearing. Regenerative processes gradually led to healing, with a resultant *coxa plana* deformation of the head, on the other hand, the articular cartilage seems not at any time to have suffered noteworthy pathologic changes.

Analogous to the healing of medial fractures of the neck in persons of advanced age, the author believes that a more or less complete necrosis of the epiphysis started in the present case, as a direct result of the fracture. Insufficient nutrition, due to original vascular lesions in the capsule, in the course of the following restitution led to lasting pathologic changes, of which the location and aspect were affected by mechanical factors and by the distribution of the blood vessels in the bone.

In accordance with this view of the case, the author emphasizes the necessity for extending the period of treatment in cases of fracture of the neck of the femur in children.

W W WHITELock, PhD

Multiple Manifestations of Subchondral Necrosis (Osteochondropathia Juvenilis, Osteochondritis Epiphysitis) W C Martin and Hugo Röcsler Am Jour Roentgenol and Rad Ther, December, 1931, XXVI, 861-867

With two-year follow-up studies, the case of a girl, eleven years of age, is presented, who showed multiple areas of subchondral bone disease in the femoral heads (resembling bilateral Perthes-Calve-Legg's disease), the eleventh dorsal vertebra (Calvé's disease), the carpal scaphoid (Preisler's disease), the metacarpals and metatarsals (Köhler-Freiberg's disease) and also in the astragali and clavicles. Symptoms and physical findings were limited to the back and hips, and the only active therapy consisted in a spine fusion operation at the level of dorsal kyphosis. The disease is considered by the writers not to be one of endocrine disturbance or disturbance in calcium metabolism but rather a specific epiphyseal disease. Because of the tendency toward spontaneous healing palliative measures only are indicated until the disease becomes stationary.

J E. HABBE, MD

Slipping of the Upper Femoral Epiphysis A Study of Seventy Cases Albert B Ferguson and M Beckett Howorth Jour Am Med Assn, Dec 19, 1931, XCVII, 1867-1872

This is a study of seventy cases of a condition occurring between the ages of 8 and 17 years, described in the literature as epiphyseal fracture, separation or slipping, epiphyseal *coxa vara*, adolescent rickets, pathologic fracture, and femoral osteochondritis of adolescence. It is a disease characterized by weakening of the epiphyseal disc at the femoral head, permitting subsequent displacement of the head in the neck. It has been suggested that the disease is due to trauma, static forces, rickets, osteomalacia, infection, and endocrine imbalance. The pathologic features are sclerosis, thickening and avascularity of the soft tissues about the neck, with absence of any primary disease of the bone or cartilage. Four stages are described: Preslipping, slipping, quiescent and residual. Definite symptoms, physical signs, and roentgenographic evidence of the disease are always present in the preslipping stage. Early diagnosis is essential for the best results. Adequate rest for the hip is the most important factor.

CANCER (DIAGNOSIS)

The Present Status of Cancer Research M Borst. München med Wchnschr, Oct 9, 1931, LXXVIII, 1745-1750, also October 16, LXXVIII, 1785-1790

In a very precise manner this excellent German pathologist reviews the past and present of cancer research. It cannot be denied that cancer is on the increase, although very slowly. At present animal experimentation appears to prevail in the research of cancer. The theories of Cohnheim, Ribbert, and Virchow are considered from the standpoint of the modern clinician, who can add to them the theory of the pre-cancerous condition.

At the present the thought that cancer may be produced by parasites has been laid aside. To produce a cancer a certain disposition for it must exist in the patient. It must be admitted that, although a tremendous amount of scientific work has been done, it is not known yet how a cancer cell originates from a normal cell. It seems that internal secretion can take part in this. Cancer resistance, the opposite side to disposition, is the power which does not permit healthy tissue to accept a transplanted cancer to grow. It may be influenced by change in living conditions, by disturbing the inner secretory functions, or by extraordinary physiologic conditions, such as pregnancy. The growing of human cancer tissue has not been very successful.

CANCER (THERAPY)

The Degeneration of the Chemistry of the Cancer Cell S Edlbacher Strahlentherapie, Dec 12, 1931, XLII 929-938

Following a discussion of the recent advances in our knowledge of the chemical processes in the cancer cell, the author comes to the conclusion that the solution of the cancer problem may be found by further research in metabolism

ERNST A POHLE, M D, Ph D

The Organization of the Fight against Cancer Ferdinand Blumenthal Strahlentherapie, Dec. 12, 1931, XLII, 809-820

This article has been written as an introduction to the volume dedicated to the Samariterhaus (Heidelberg) on its twenty-fifth anniversary. In this institute R. Werner has carried out his well recognized work on cancer. The author outlines in detail all problems involved in the organization of the fight against cancer. He emphasizes the advantage resulting from the connection of tumor clinics with universities. No hard and fast rules can be given at the present time, only one fact stands out. Without the full co-operation of the profession at large the cancer problem cannot be solved.

ERNST A POHLE, M D, Ph D

Radiotherapy in Carcinoma of the Cervix Uteri Hermann Wintz München med Wchnschr, Nov 13, 1931, LXXVIII, 1935-1937

Radiotherapy has shown excellent results in the treatment of cancer of the portio. Even in cancer of the corpus the results of radiotherapy are equal to those of operation. However, the results in adenocarcinoma of the cervix are still poor. Unfortunately, there are no statistics about the results of surgery. While the anatomic arrangement of the lymphatics leading to the portio and corpus is such that the disease remains localized for a long time, cancer of the cervix almost always spreads early into the parametria. Döderlein and others have proven that the cancer has already infiltrated the parametria long before the infiltration can be palpated.

Between January, 1916, and July, 1926, 32 cases of true carcinoma of the cervix were treated by the author. Of these, 15, or 47 per cent, are cured. In 25 of the cases an additional intra-uterine application of radium was given, besides the typical roentgen treatment of Seitz and Wintz. As the adenocarcinoma of the cervix is from 20 to 25 per cent less radiosensitive than the basal-cell carcinoma of the portio, the total dose has to be increased to 125

per cent, or 1,000 r units. The entire dose must be applied within three days. This will be followed by a severe reaction, with tenesmus and bloody stools. The increase in dosage from 110 to 125 per cent has brought about results which are at least equal to those of surgery. Both types of carcinoma are equal as to their radiosensitivity. However, the early spreading of the cancer in cervix cases will lower the five-year results considerably.

In conclusion, radiotherapy is to be given preference in the treatment of adenocarcinoma of the cervix. Radiation will reach the distant metastases in the lower pelvis much better than the knife.

E A MAY, M D

The Importance of Surgical Treatment in the Fight against Cancer H v Haberer Strahlentherapie, Dec 12, 1931, XLII, 840-857

The well-known surgeon, who now holds the chair of Surgery at the University of Cologne, offers a very interesting account of his own impressions concerning the rôle of surgery in the treatment of malignant diseases. He emphasizes throughout the article the importance of early diagnosis. Among 10,035 major operations of his own, 1,277 were for malignant disease and less than 50 per cent of the latter could be operated on radically. All others could be treated only palliatively.

The author is rather skeptical about the value of pre- and post-operative irradiation in cancer of the breast. However, he admits the splendid results of irradiation in certain cases and stresses the importance of co-operation between surgeon and radiologist. In his opinion, the high mortality of major and difficult operations, as, for instance, in cancer of the sigmoid, is justified because without assuming this risk 100 per cent of the patients would die.

ERNST A POHLE, M D, Ph D

Methods and Results of the Fight against Cancer in Gynecology Robert Schröder Strahlentherapie, Dec 12, 1931, XLII, 858-869

This is a general discussion of the treatment of gynecologic cancer. In his own clinic the author observed, between the years 1923 and 1930, 585 patients with cancer of the cervix, 64 patients with cancer of the fundus, 62 with cancer of the ovaries, 30 with cancer of the vagina, and 97 with cancer of the vulva. About 68 per cent of carcinomas of the cervix occurred between the ages of 35 and 55 years. Definite relations between the histologic picture of the growth and prognosis could not be established in his cases.

Early diagnosis and treatment are of paramount importance. The mortality of Wertheim's operation

yet. The treatment of cancer is surgical and radiologic, serum treatment having failed

E. A. MAY, MD

Character and Cause of Cancer in the Light of Pathologic Anatomy and Experimental Pathology
A Dietrich Strahlentherapie, Dec 12, 1931, XLII, 913-928

This is a critical review of the outstanding accomplishments in the scientific search for the cause and nature of cancer. The recent work of Warburg dealing with the metabolism of the cancer cell is considered an important step in the right direction.

ERNST A. POHLE, MD, PhD

Metastases to the Bone from Cancer Editorial
Jour Am Med Assn, Oct 31, 1931, XCVII, 1304, 1305

With the introduction of the roentgen ray, greater accuracy in studying the incidence of bony metastases in the skeleton became possible. Copeland combined the roentgenographic and microscopic study in his series. The bones in which metastases most frequently were found in carcinomas of the breast were the spine, pelvis, femur, skull, ribs, and humerus. There were two types of metastatic lesions shown by the X-rays, a destructive lesion and a bone-forming process. Bloodgood has differentiated multiple myeloma by the punched-out areas of destruction. Bence-Jones bodies in the urine favor the diagnosis of multiple myeloma. A single focus occurred in only one-fourth of the cases and the majority of these were in the vertebrae or femur. Treated by the roentgen ray, patients may expect relief from pain and often a few months of comparatively comfortable living. In hypernephroma little attempt at the formation of new bone within the area of destruction was found. Irradiation alone offers as much for the prolongation of life as does surgical intervention alone or surgery combined with radiation. Osseous lesions in cancer of the prostate were most frequent in the pelvic bones, vertebrae, and femur. Roentgenograms showed the lesion to be of an osteoplastic nature with a marked increase in the formation of bone. Malignant disease of the testicle, carcinoma of the uterus, ovarian malignant disease, carcinoma of the stomach, carcinoma of the lung, and melanoma showing metastases to bone are analyzed. Copeland found evidence indicating that both an embolic and a lymphatic mode of involvement occurred.

CHARLES G. SUTHERLAND, MD

Schatzki Strahlentherapie, Dec 12, 1931, XLII, 821-839

This most interesting general review does not lend itself to abstracting since it covers such a wide subject. The ripe personal experience of the authors manifests itself throughout the article and many illustrative cases are quoted to support their standpoint. It is almost pathetic that they have to reach the conclusions "It is not the inadequacy of our diagnostic facilities that prevents us from improving our present results in the treatment of cancer but the sad fact that there are no marked early symptoms of cancer, except in very rare instances."

ERNST A. POHLE, MD, PhD

Sexual Physiologic Studies Hypophysis and Malignancy M. Borst, A. Döderlein, and D. Gostimirovic. München med Wochenschr, Dec 11, 1931, LXXVIII, 2108-2113

This article concerns the behavior and clinical value of the excretion of prolactin in women radiated for cancer of the genital organs. Prolactin is the sex hormone of the anterior lobe of the hypophyseal gland. In cancer cases, especially those of the female genital organs, the excretion of prolactin is increased, but the hormone is evidently produced in the anterior part of the hypophysis and not in the cancer tissue.

In cancer of the female genitalia, prolactin is found in the urine in 63 to 66 per cent. This figure increases after the first radiation and reaches 100 per cent after the second one. Even after an interval of six years, prolactin may be found in 50 per cent of the cured cases.

ERNST A. MAY, MD

A Clinical Study of Etiology of Gastric and Esophageal Carcinoma Lloyd F. Craver Am Jour Cancer, January, 1932, XVI, 68-102

The author investigates in detail histories personally obtained from 36 patients with cancer of the stomach and 18 patients showing cancer of the esophagus. There were no control cases, however.

He concludes that there is a definite difference between the predominant etiologic factors in carcinoma of the stomach and carcinoma of the esophagus. In the former, poor teeth, lack of teeth, gastro-intestinal diseases, heat of ingested food and drink, irregularity of meals, lack of water, seasoning, cathartic drugs, rapid eating, tobacco, and alcohol seem to have some importance in the order named.

In the case of cancer of the esophagus the following factors seem important in the order named: tobacco, alcohol, lack of water, poor teeth, lack of teeth, and cathartic drugs.

JOHN R. CARTI, MD

Early Symptoms of Cancer P. Morawitz and R.

afterward The treatment should cover the entire lower abdomen

The after-care of cancer cases consists of the restitution of the patients to health, so that they are able to work Every case must be followed up and examined at regular intervals Recurrent cases should receive only radiation Hopeless cases should receive relief from pain and suffering as much as is possible

E A MAY, MD

CHEST (DIAGNOSIS)

Case Reports of Congenital and Acquired Bronchiectases (Cystic Lungs) Thomas Canigiani Röntgenpraxis, Dec 15, 1931, III, 1116-1120

The pathologists have described cysts and cavities of the lungs rather frequently as congenital anomalies Clinical and roentgenologic observations have not been made very often during the life of the patient Three such cases are described in detail

Clinically, chronic tuberculosis is usually suspected Roentgenologically, it seems impossible to distinguish between congenital and acquired bronchiectases, the history in such cases being of great importance If there is no lung structure within the cyst, one may suspect a congenital anomaly The differential diagnosis from echinococcal cysts is not often required

H W HEPKE, MD

Latent and Transient Exudative Serosities as the Cause of Cryptotuberculous Fever Collatino Cantieri Riv di Patol e Clin della Tuberculosis, November, 1931, V, 990-992

The concept of exudative pleuritis or peritonitis is generally that of a disease with a long course, whether of more or less acute nature or of slow and disguised form

The author demonstrates the existence of certain exudative tuberculous serosities, as the anatomic basis of a febrile process, for a time cryptogenetic, which have as a characteristic a marked lack of physical and general signs and a particularly short course, hence a very rapid reabsorption of the exudation There is no pain, no subjective disturbance which might direct attention to the thorax or the abdomen, in both of which all signs of a strong effusion are lacking

These morbid manifestations, however, possess a great practical significance as indicative of tuberculous infection Study of the case calls for explorative puncture, but with an especially fine and delicate technic, since we are dealing with a liquid through which the point of the needle may easily pass unnoticed, unless the hand is highly skilled

Roentgenologic examination is unable to tell us anything in certain cases, a few days after an explorative puncture of the thorax, with positive findings and with a liquid directly inflammatory It re-

veals to us the pleura completely free, the diaphragm mobile, no trace remaining of the morbid process evolved in that region

W W WHITELOCK, PhD

Case Reports of Free Fibrin Balls (Blood Fibrin Balls) in the Pleural Cavity Georg Grundner Röntgenpraxis, Jan 1, 1932, IV, 36-40

The author has been able to find 19 cases of free fibrin bodies in the literature He reports two new cases The general opinion is that these balls originate from fibrin, which comes from the exudate or from blood, by the thoracic paracentesis It was possible in one of these cases to remove these bodies from the pleural cavity during a thoracotomy for an empyema The histologic examination in this case showed the presence of fibrin, which must have originated from blood Introduction of a needle in the thorax should, therefore, be done very carefully

H W HEPKE, MD

A Review of Pneumoconiosis Further Roentgenological and Pathological Studies Henry K. Pancoast and Eugene P Pendergrass Am Jour Roentgenol and Rad Ther, October, 1931, XXVI, 556-614

Pneumoconiosis must now be looked on as a more or less necessary risk in the progress of civilization Since the roentgenologic examination is the most accurate and satisfactory method of detecting it from the earliest to the most advanced stages, it is essential that roentgenologists be familiar with all phases of the disease

The continuance of the term "pneumoconiosis" is advocated, for while silica is usually the active fibrosing agent, other agents are capable of directly causing fibrosis Others, such as coal and clay dust, tend to retard the action of silica, while some alkalies may enhance its action Certain very unusual features in the fibrosis occurring in asbestos workers have caused the term "pulmonary asbestosis" to be widely used

It has not yet been established as to just how much silica dust is necessary in the lungs in order to produce actual silicosis, however, investigations by the U S Public Health Service have shown that 10,000,000 particles containing about 35 per cent free silica per cubic foot of air could be tolerated over a long period without great injury to the lungs

Concerning pathology, the consensus of opinion is still in favor of the "dust cells" being of endothelial origin and being derived from the walls of the capillaries and lymphatics, which are in intimate relationship with the alveolar epithelium From the alveoli these "dust cells" migrate to the lymphoid deposits, pass then to the larger lymphoid deposits, and then to the pulmonary lymph nodes, some being stopped at each of these way-stations along the

in his 176 cases amounted to 19 per cent, with a five-year cure of 40 per cent. Radium has become a strong competitor of surgery. From 60 to 100 mg of radium, heavily filtered, are placed near the tumor, and $3 \times 2,000$ mg-hr at 8-, 14-, and 21-day intervals are applied. The five-year cure reaches from 35 to 40 per cent, but one must not forget that about 10 per cent of the inoperable cases can also be saved. The value of radiation therapy is further clearly demonstrated in the treatment of recurrences following operation.

ERNST A. POHLE, M.D., Ph.D.

Cancer Therapy in Gynecology. F. von Mikulicz-Radecki. München med Wehnschr, Nov 20, 1931, LXXVIII, 1993-1999.

The modern fight against cancer consists of three stages. The early discovery and proper diagnosis of the case, the actual treatment, and the after-treatment and after-care of the patient. The results in cancer therapy depend at present mostly on the early diagnosis.

In Germany, several districts have already made remarkable progress in propaganda and instruction of the population, especially physicians, as to the early signs of cancer. Every woman suffering from hemorrhages must be examined by palpation and inspection. Every suspicious condition must be considered as being possibly carcinomatous. A section should not be made by the practitioner but by the specialist who is to treat the case afterward. Rational treatment should follow the section immediately. Absolutely condemned are any such incomplete measures as scraping out the crater of the portio, imputation of a cauliflower tumor, simple vaginal extirpation of the uterus in carcinoma of the cervix, electrocoagulation of a cervical carcinoma alone, or simple excision of a cancer of the vulva or urethra. All these measures are only palliative, not radical, and darken the outlook of further radical treatment and ultimate cure.

The problem is more serious than any statistics show, as a high percentage of the cases do not enter a hospital and are not reported. The author requests that cancer patients be referred to special institutions, which are fully equipped to take care of them. Since statistics have proven that radiotherapy in the treatment of female genital cancer is at least equal to operation, most of the cases receive radiotherapy, for the inoperable ones can also be treated with a chance of cure. However, there are those who advocate the combination therapy. The operable patients receive a pre-operative radium or roentgen treatment, which may reduce the size and extension of the growth. This is followed by radical operation. After the patient has sufficiently recovered, post-operative roentgen treatment is given.

Another method is the so-called selective therapy. Since only cases which are very good operative risks

undergo operation, every one with mild or severe complications from the heart, lungs, kidneys, thyroid, etc., is referred for radiation. This reduces the operative mortality and thus increases the relative number of cures. Cases which six weeks after radiation do not show a good improvement are also subjected to operation.

A further method is to select the cases from the histologic viewpoint, however, this is still very difficult. In cancer of the neck of the cervix the operative method shows an absolute cure of 19, or 1 per cent, and a relative cure of 35, or 6 per cent. The comparative results in radiotherapy are 17, or 4 per cent, and 42, or 7 per cent, in operative and borderline cases, and 11, or 1 per cent, in inoperable cases. The combination treatment at the Berlin clinic shows an absolute cure in 36 per cent and a relative cure of 49, or 2 per cent, in operable and 16 per cent in inoperable cases. All cases of Group 1 of Döderlein, also all early adenocarcinomas, are operated on, except those with even light contraindications. Also, all cases below 35 years of age are radiated. If six weeks after radiation these cases do not show marked improvement, an operation is indicated. The method of operation is the vaginal radical operation as developed by Stoeckel. Cases of Groups 2 and 3 receive first an intrauterine and intravaginal radium dose of from 2,500 to 3,000 milligram-hours. If after six weeks the cancer appears to be operable, operation is performed, if not, a second radium application plus a course of X-ray treatments are given with 100 per cent over the entire lower pelvis. All cases operated on receive prophylactic X-ray treatment.

Cauterization or electrocoagulation of a cancer of the cervix is to be avoided, as a beneficial action has never been seen and the cancer cells left behind seem to be more virulent than before.

In cancer of the corpus uteri, the results are better than in cancer of the cervix. Here the ratio of the collective statistics among the methods of operation, radiotherapy, and the combination of the two in absolute cures is, respectively, 42, or 8 per cent, 42, or 7 per cent (Wintz), and 48 or 1 per cent. This again shows the superiority of the combination method.

As in cancer of the vagina both methods give poor results, the author suggests surgery and post-operative treatments in operable cases. The same holds true in cancer of the vulva. In cancer of the urethra, radium is to be preferred to operation, perhaps combined with extirpation of the inguinal glands, radiation to follow. Cancer of the tubes is very rare and is diagnosed only at operation. The method of total extirpation and post-operative radiation is recommended. Most cases of cancer of the ovaries come under medical observation after having reached an inoperable condition. Still operable and borderline cases should be operated on and radiated.

bestos particles At any rate they are considered absolutely characteristic of pulmonary asbestosis

Röntgenographically, the findings, while rather unusual, cannot be considered characteristic. In several groups of cases studied the evidence of fibrosis was found first on the left side, although other workers have not confirmed this finding. Characteristically, the interstitial fibrosis seems predominant and often one is apt to underestimate the degree of disability unless careful roentgenoscopic observations are made which may demonstrate a surprising degree of restriction. Even in the later stages the interstitial fibrosis may predominate. Without adequate protection the prognosis is considered grave, although no definite tendency to susceptibility to tuberculosis in the presence of asbestosis has been yet established

J E HABBE, MD

Some Forms of Chronic Bronchitis Mariano R Castex La Prensa Med Argentina, Dec. 10, 1931, XVIII, 879-887

Though the knowledge on this subject is familiar to everyone, it is of great importance because of its common occurrence and also because of its complications, such as bronchiectasis, pulmonary emphysema, fibrosclerosis, adenocellulitis of the mediastinum, myocardial insufficiency, etc. The microbiologic study often reveals the causative bacteria, and thus the successful treatment is instituted. Some cases are due to amebiasis, and emetine promptly cures them. Others are due to infections of the tonsils and disappear after their removal. A third type of chronic bronchitis is due to infection of the maxillary sinuses.

The author presents four cases, together with their corresponding radiographs, which showed improvement following a maxillary sinus drainage. Other factors relating to the etiology are familial tendencies, the influence of certain diseases, such as syphilis, tuberculosis and gastro-intestinal disturbances, and the absence of Vitamin A in the diet.

N G GONZALEZ, MD

Bronchoscopy as an Aid in the Diagnosis of Obscure Pulmonary Disorders Edward A Looper Jour Am Med Assn, Oct 31, 1931, XCVII, 1287-1291

The present trend of the bronchoscopic art is to bring additional help to the internist in the investigation of the larynx, trachea, and bronchial tree. The surgeon can often obtain much helpful information from endoscopic examinations. In lung abscess co-operation between bronchoscopist and surgeon will insure the best results. In various parts of the country a great opportunity exists for bronchoscopic investigations in sanatoriums, special clinics are suggested to take advantage of this opportunity. In chronic cases the decision of some

unrecognized or complicating condition may rest largely on bronchoscopic examination

Bronchoscopic examination may reveal a local cause for repeated attacks of hemoptysis. Used with iodized oil injection or pneumography, it is also helpful in outlining lung abscesses, atelectasis, new-growths, and bronchial stenosis. A series of cases are reviewed to show the application of the above mentioned points

CHARLES G SUTHERLAND, MD

Advantages of Intubation Method of Introducing Iodized Oil for Bronchography in Children Samuel Iglauder Jour Am Med Assn, Nov 21, 1931, XCVII, 1517-1521

Bronchography should be employed more frequently in children, for many chronic pulmonary diseases, particularly bronchitis, pneumonitis, bronchiectasis, and lung abscess very often originate during the early years of life. It is contra-indicated in the presence of high fever, dyspnea, or recent hemoptysis, in cardiac decompensation, and in cachectic individuals.

In the intubation method a modified, all-metal O'Dwyer intubation tube is used. The modification consists in the addition of a second small bore tube soldered into a longitudinal groove in the posterior wall of the original intubation tube, thus creating a double-barreled tube, with one channel to provide for breathing and a second channel to convey the oil. The intubation tube is introduced by touch.

To obtund the cough reflex about 4 cc. of a procaine solution is slowly injected through the rubber tubing into the trachea and bronchi. With the patient in the upright position behind a fluoroscopic screen, iodized poppy-seed oil, 40 per cent (Iopiodol), is injected under fluoroscopic control. The injection of any alveoli should be avoided. From 10 to 20 cc. is usually sufficient. It is advisable not to remove the intubation tube before the roentgenograms are made, as the extraction of the tube excites a cough reflex which tends to scatter the oil within the lungs.

CHARLES G SUTHERLAND, MD

CHEST (GENERAL)

The Bronchial Bifurcation in Mitral Lesions C Donovan, A Battro, and Gazotti La Prensa Med Argentina, Dec 10, 1931, XVIII, 905-913

The authors begin their paper by giving the normal anatomy of the bronchi and emphasize the fact that the right bronchus runs vertically while the left one runs horizontally. Due to the relation of the left bronchus to the left auricle, anything affecting the size of the latter is going to affect the direction of the former. Mitral stenosis and mitral insufficiency provoke a dilatation of the left auricle. Several authors, such as Vaquez and Bordet, Steel,

route of pulmonary lymphatic drainage and producing lymphatic obstruction and subsequent fibrosis

More recent views on the termination of the dust cells are that at some point or another these cells die and liberate their silica particles, the liberated silica being the important factor in producing the end-result of fibrosis. At certain points along the lymphatic channels there may be sufficient clogging, so that some of the cells break through the walls of the blocked vessels and set up a fibrosis reaction in the interstitial lung tissues. With blockage of the hilum-ward lymph flow, a backflow toward the subpleural lymphatics takes place, resulting in peripheral nodulation and thickening of the pleura and adhesions. While, theoretically, removal of the dust hazards from an individual developing pneumoconiosis should be followed by a certain amount of clearing of the lung by elimination of some of the dust particles from the pulmonary lymphatics, the authors believe that once established silicosis is progressive, and any improvement following cessation of dusty work is apparent rather than real. All extensive studies of silicosis show that workers who develop the condition with any degree of rapidity are predisposed to respiratory infections, especially bronchitis, pneumonia, and tuberculosis. Tuberculosis affects particularly those in whom silicosis develops most rapidly, hence it can be controlled to a certain extent by measures directed against the rapid development of silicosis.

Spontaneous pneumothorax is a not infrequent accident in the course of the development of pneumoconiosis and is almost always in the upper lobe. Pleural effusion, as a direct complication in the course of pneumoconiosis, has never been encountered by these writers.

Roentgenologic studies to be complete must include both roentgenoscopy and stereoscopic roentgenography, the former procedure being especially important in determining respiratory capacity. The commonly used roentgenologic classification of involvement is first, second, and third stage. The first stage, which, in the belief of the writers, should have no definite medico-legal status for awarding compensation, shows a definite increase in the prominence and extent of the hilar shadows, increased prominence and thickening of the trunk shadows, and greater prominence of the linear markings of the peripheral zone. It is emphasized that this appearance is not characteristic of pneumoconiosis but may be simulated by passive congestion, acute or chronic respiratory infections, chronic, bronchial catarrh, and bronchiectasis.

The second stage, which is the most characteristic of the three, is indicated roentgenographically by the presence of small rounded densities, varying in size from a pin head to a pea, distributed throughout both lungs but most numerous about the lung roots and least frequent in the apical regions and

bases. Theoretically, these appearances should be superimposed upon the first stage appearances, but often the latter are absent, either being obscured by emphysema or being in some measure resolved, if peripheral lymph block occurred early.

The third stage of the disease shows a diffuse fibrosis predominating, which may be in the form of large coalescing nodules, more or less diffuse fibrosis, or massive fibrotic areas resembling extensive consolidations. Diaphragmatic excursions are usually greatly restricted or absent.

The writers believe that the time has come for the adoption of a more satisfactory classification of this disease process on a pathologic basis which will include the typical and the variants and be applicable to both clinical and roentgenologic studies for all industries and occupations. Their classification is in five groups as follows:

- (1) Peribronchial-perivasculary lymph node predominance
 - (a) rapid
 - (b) slow
- (2) Early interstitial predominance (interference with diaphragmatic movement)
 - (a) with nodular appearance
 - (b) without nodular appearance
 - (c) rapid or slow
- (3) Late or advanced interstitial predominance
- (4) Nodular predominance
 - (a) non-progressive
 - (b) progressive
- (5) Advanced diffuse or terminal fibrosis
 - (a) conglomerate nodular type
 - (b) interstitial type
 - (c) massive fibrosis type

In the latter part of the article certain dusty industries are considered individually, those included being coal mining, the asbestos industry, the abrasive industry, hard rock mining, the sandstone industry, the granite industry, the slate industry, iron mining, the cement industry, and vitreous enamel painting. Particular attention is given to the asbestos hazard and to the roentgenologic appearances of what has been termed "asbestosis".

The harmful products of the asbestos factories are almost entirely silicates, chiefly hydrate magnesium silicate. "Asbestos bodies" occurring in a number of different forms and found on necropsy examination in the lungs of patients dying of asbestosis, are one of the most remarkable features of this form of pneumoconiosis. The most characteristic form is found in the alveoli and bronchioles and in fibrous and necrotic areas. They are from 20 to 100 microns in length and are often dumb-bell shaped. They are golden yellow or brownish in color. Theories as to the nature of these bodies are that they are osmotic silica infarcts, particles of ferruginous quartz, or some colloidal product of the original as-

of dust containing iron particles even in great quantities does not apparently lead to any pathologic changes in the lung tissue, except to cause a pigmentation. It is the presence of the silica in the dust which produces fibrosis. The *modus* of invasion and the pathologic sequences produced by the entrance of silica-dust into the lungs are described. The anatomic and clinical pictures and roentgenograms were thoroughly investigated.

The author examined roentgenologically 140 men who were employed as workers in iron mines in the Ukraine. They were all drillers, and the dust content of the air was high (from 12,000 to 13,000 dust particles per cubic centimeter). Eighty-two of the 140 men were found to have a fibrosis in the first stage (their average working time had been 151 years), 40 were found to have a fibrosis of the second stage (their average working time was 182 years). A third-stage fibrosis could be found only among some who had been invalids and were no longer employed. Four such men had worked for an average of 357 years.

The roentgenologic appearance of the silicosiderosis cannot be differentiated from the pure silicosis. The fibrosis must be explained by the action of silica, the iron might even give a certain amount of protection. Three types of lung siderosis must be distinguished: (1) Siderosis of metal grinders (silico-siderosis gravis), (2) siderosis of workers in iron mines (silico-siderosis leesus), (3) siderosis of glass polishers (siderosis pura or chromatica).

H W HEFKE, M D

Yeast Infection of the Lungs T R. Healy and L. B. Morrison Am Jour Roentgenol and Rad Ther, September, 1931, XXVI, 408-413

Fungi may attack any organ or system of the body and are most common in the integumentary system, while the nervous system is least frequently involved. The exact mode of development of the infection in the human being is not certain, although, undoubtedly, breaks in the skin favor entry. In other cases, inhalation of dust containing the mold may be the portal of entry. Since the geographic distribution of these fungi is wide, yet the frequency of the disease is not great, it is reasonable to assume that man possesses a considerable degree of natural immunity.

Symptoms of fungus infection in the lungs may vary from that of mild bronchitis to that of advanced phthisis. Cases may go on to spontaneous cure or terminate fatally. The diagnostic triad of absence of tubercle bacilli in the sputum, apparent discrepancy between the roentgen evidence of extensive disease and the clinical appearance of fair health, and of the presence of yeast cells in the sputum is stressed by the writers. Five cases are reported, all showing *Blastomycetes imperfecti* in the

sputum, and are illustrated with the chest roentgenogram of each.

CHEST (THERAPY)

Treatment of Cavities in the Vertex of the Lung by Apicolysis and Packing Alejandro J Pavlovsky and Antonio A Cetrangolo La Prensa Med Argentina, Jan 10, 1932, XVIII, 1049-1068.

Recently in Central Europe there have been many articles on this subject. The authors state that since about 5 per cent of pulmonary tuberculosis cases are surgical, this treatment ought to be applied to a selected number of those cases. They review the literature and state that the poor results obtained with this method were finally overcome by the use of a special mixture of paraffin first introduced by Baer, in 1913. The authors believe that the ideal indication for such a procedure is a cavity process of long standing, well limited, the rest of the lung being normal, and the other lung uninvolved.

All the cases on which the authors have practised this treatment have had the following: (1) General dietetic, hygienic, and climatic therapy, (2) sanocrysin, (3) unsuccessful attempts at pneumothorax, and (4) phrenicectomy. The authors explain why this treatment is more agreeable and more successful than thoracoplasty. Their method consists of a posterior incision, resection of 3 cm of the third rib, freeing of the parietal pleura, breaking all the adhesions, and packing with Baer's paraffin mixture, following which the wound is closed.

They conclude their article by presenting eight cases with complete radiographs before and after operation. Judging by the histories of those eight cases, their main difficulty is in introducing enough Baer's paraffin mixture.

N G GONZALEZ, M D

CIRCULATORY DISTURBANCES

Bleeding of Benign Origin Leo Kessel Jour Am Med Assn, Oct 10, 1931, XCVII, 1058-1060

Acute bleeding arouses at least three grave suspicions: a blood dyscrasia, the ulceration of a malignant neoplasm, or a chronic inflammatory process, particularly tuberculosis.

This report of a series of interesting cases deals with a group of patients in whom serious organic disease was excluded, yet presenting a history of hemorrhage. Bronchoscopy revealed in one a plexus of dilated veins at the base of the tongue, in another a broncholith, with a piece of nut shell as a kernel, filled the right lower bronchus with a mass of granulation tissue which bled easily. Lupus of the trachea was the cause of another hemoptysis of three years' duration. Benign tumors of the bronchus accounted for two, and multiple telangiectasis

Peterson, Gäbert, and others have studied the radiologic changes of mitral stenosis

The authors go into detail in regard to the changes in mitral stenosis, particularly in reference to the exaggerated aperture of the bronchial bifurcation. They conclude their paper by presenting a chart of fourteen cases, with the diagnoses, angle of bronchial divergence, and deformity of esophagus

N G GONZALEZ, M D

Pulmonary Conditions under Strain (Certain Radiologic Modifications in the Lungs of Athletes in Breathing Pauses before, during, and after the Strain) Gioacchino Arnone Riv di Patol e Clin della Tubercolosi, Jan 31, 1932, VI, 57, 58

This report is in response to a resolution of the Italian Fascist Society for Scientific Study of Tuberculosis drawn up at its session of May 29, 1931, calling for extension of the system of individual charts of the respiratory system, not alone to schoolchildren and workmen, but also to those engaged in sports, for prophylactic, eugenic, and medico-legal purposes. The report was made at the session of the Society at Palermo, on July 10, 1931.

On the basis of radiograms made in breathing pauses in the case of individuals engaged in various sports, and studied in conjunction with the cardiac tonus before, during, and after the strain, the following conclusions were reached:

Shadow of the Hilus—This is seen to be fuller and more extended than normal in repose. During the strain it is more ample, and its tissue stands out more clearly, owing to the greater transparency of the lung. After the strain, the return to normal occurs within from 7 to 40 minutes, according to the degree of relaxation and to heart conditions.

Pulmonary Trauma—During repose it is clearly evident in the median zone, becoming more so during the strain, owing to the clearing up of the pulmonary field. The tuberculae are more distinctly visible being more separated, owing to greater aeration of the lungs. After the strain the trauma is compact, as in repose.

Nodular Shadows—In repose, these are very numerous, both on the right and left, in the lung as well as in the hilus, so as to simulate a lymphatic tuberculosis with numerous nodules of infiltration of the median pulmonary regions. During the strain some of the nodules are less evident or even imperceptible, others are more evident, either because enlarged and denser, or owing to the greater aeration of the lung. After the strain the shadows become as during repose.

The nodular shadows are of two kinds (1) Nodular shadows of irregular outline scattered in the pulmonary field and in proximity to the hilus, which disappear or become modified during the strain, (2) nodular shadows of regular outline, in-

tensely opaque, often accompanied by ring-shaped shadows of approximately the same caliber, which increase in volume during the strain. The former are due to circumscribed vascular ectasia, or to crossing of vessels, the latter are due to infiltrated vessels.

One of the nodular shadows, accompanied by the shadow of the bronchus, on being examined and measured, was seen to increase during the strain by 1.5 mm. in vascular caliber and by 2 mm. in bronchial caliber.

Explanation of the data placed in evidence is closely connected with study of the heart and vessels, of their tonus and normal function during the strain.

Limiting ourselves for the moment to the radiologic observation of respiration of the lung, it may be stated that in the lung of the athlete during a pause in the period of strain there appear shadows of the hilus and lung, due to a vascular network more vigorous than under normal conditions, in a state of functional equilibrium.

W W WHITELOCK, Ph D

The Postpneumonic Lung A Critical Review
Alan L Hart Am Jour Roentgenol and Rad Ther, September, 1931, XXVI, 371-396

Following an acute pneumonic process, any one of three conditions may occur: Absorption of exudate, with return to normal of lung tissue, organization of exudate, with fibrosis and development of non-tuberculous infections, suppuration, with possible abscess formation or other sequelæ. Such pneumonias as the influenzal, with or without streptococcal invasion (Friedländer's), and the bronchopneumonias following measles and pertussis, in which the connective tissue framework of the lung, the walls of the bronchial tree, and blood and lymph vessels are most seriously damaged, are most prone to chronic lung changes. The resulting fibrosis, if diffuse, may cause considerable impairment of function. Serial roentgenologic studies afford the best means of following the course of these chronic lung changes when resolution does not take place promptly.

An excellent chart, giving briefly the gross and microscopic pathology in the various component parts of the lung, with frequency of development of suppuration in the lobar and several types of bronchopneumonias, is a valuable aid to roentgenologists. It enables them to interpret the roentgen changes in terms of pathology in those cases in which prompt and complete resolution fails to occur.

J E HABBE, M D

Siderosis of the Lungs N A Podkaminsky Röntgenpraxis, Dec 1, 1931, III, 1071-1084

The dust from iron contains mainly either iron or silica in different combinations. The inhalation

of dust containing iron particles even in great quantities does not apparently lead to any pathologic changes in the lung tissue, except to cause a pigmentation. It is the presence of the silica in the dust which produces fibrosis. The *modus* of invasion and the pathologic sequences produced by the entrance of silica-dust into the lungs are described. The anatomic and clinical pictures and roentgenograms were thoroughly investigated.

The author examined roentgenologically 140 men who were employed as workers in iron mines in the Ukraine. They were all drillers, and the dust content of the air was high (from 12,000 to 13,000 dust particles per cubic centimeter). Eighty-two of the 140 men were found to have a fibrosis in the first stage (their average working time had been 15.1 years), 40 were found to have a fibrosis of the second stage (their average working time was 18.2 years). A third-stage fibrosis could be found only among some who had been invalids and were no longer employed. Four such men had worked for an average of 35.7 years.

The roentgenologic appearance of the silicosiderosis cannot be differentiated from the pure silicosis. The fibrosis must be explained by the action of silica, the iron might even give a certain amount of protection. Three types of lung siderosis must be distinguished: (1) Siderosis of metal grinders (silico-siderosis gravis), (2) siderosis of workers in iron mines (silico-siderosis lesus), (3) siderosis of glass polishers (siderosis pura or chromatica).

CHEST (THERAPY)

Treatment of Cavities in the Vertex of the Lung by Apicotomy and Packing Alejandro J Pavlovsky and Antonio A Cetrangolo La Prensa Med Argentina, Jan 10, 1932, XVIII, 1049-1068

Recently in Central Europe there have been many articles on this subject. The authors state that since about 5 per cent of pulmonary tuberculosis cases are surgical, this treatment ought to be applied to a selected number of those cases. They review the literature and state that the poor results obtained with this method were finally overcome by the use of a special mixture of paraffin first introduced by Baer, in 1913. The authors believe that the ideal indication for such a procedure is a cavity process of long standing, well limited, the rest of the lung being normal, and the other lung uninvolved.

All the cases on which the authors have practised this treatment have had the following: (1) General dietetic, hygienic, and climatic therapy, (2) sanocrysins, (3) unsuccessful attempts at pneumothorax, and (4) phrenicectomy. The authors explain why this treatment is more agreeable and more successful than thoracoplasty. Their method consists of a posterior incision, resection of 3 cm of the third rib, freeing of the parietal pleura, breaking all the adhesions, and packing with Baer's paraffin mixture, following which the wound is closed.

They conclude their article by presenting eight cases with complete radiographs before and after operation. Judging by the histories of those eight cases, their main difficulty is in introducing enough Baer's paraffin mixture.

CIRCULATORY DISTURBANCES

Bleeding of Benign Origin Leo Kessel Jour Am Med Assn, Oct. 10, 1931, XCIVII, 1058-1060

Acute bleeding arouses at least three grave suspicions: a blood dyscrasia, the ulceration of a malignant neoplasm, or a chronic inflammatory process, particularly tuberculosis.

This report of a series of interesting cases deals with a group of patients in whom serious organic disease was excluded, yet presenting a history of hemorrhage. Bronchoscopy revealed in one a plexus of dilated veins at the base of the tongue, in another a broncholith, with a piece of nut shell as a kernel, filled the right lower bronchus with a mass of granulation tissue which bled easily. Lupus of the trachea was the cause of another hemoptysis of three years' duration. Benign tumors of the bronchus accounted for two, and multiple telangiectasias

involving the nose, tongue, and lips accounted for another. In one case laryngoscopy revealed a cavernous angioma in the left vocal cord, while in another melena resulted from a small nevus in the anal ring, again, it was associated with a rash over the hands and back, typical of erythema nodosum.

In discussing this paper, Smithies stressed bleeding related to the menstrual cycle or menopause. He mentioned occupations in close relationship with some of the volatile hydrocarbons, leading to saturation of the blood to a degree adequate to produce leaking in the vessels followed by seepage from the capillary bed.

CONTRAST MEDIA

Hepatosplenography Hans L. Popper and Erwin Klein. *Münchener med. Wochenschr.*, Oct. 23, 1931, LXXVIII, 1829, 1830.

The visualization of liver and spleen by the X-ray is of great aid to the clinician. Radt and Oka have accomplished this by intravenous injection of a colloidal thorium preparation. The authors have tried thorium dioxide on fourteen cases with good results. One of them was a large tumor of the liver, which could be seen on the film as a large defect. The preparation, which is called thorotrust, has no direct ill effects, even in large doses. It is very slightly radio-active. From 60 to 90 c.c. are injected. The best concentration in liver and spleen can be seen after from three to five days. However, in some of the cases, as well as in animal experiments, the dye could be found after seven months deposited in the spleen and liver at the same concentration. It is, therefore, to be used with the greatest precaution until further research proves the method to be harmless.

E. A. MAY, M.D.

Intratracheal Injection of Lipiodol Raúl F. Vacarezza. *La Prensa Med. Argentina*, Nov. 20, 1931, XVIII, 798-802.

The author gives a short outline of the methods used for visualization of the bronchial tubes with lipiodol, and his objections to those methods. He then introduces his method, which consists of the suppression of the swallowing reflex by means of anesthesia of the pharynx with 5 per cent cocaine chlorhydrate by spray. The patient is placed in abdominal decubitus and the lipiodol is placed at the base of the tongue. The amount of lipiodol used is usually 20 cubic centimeters. The results obtained have been excellent. Several radiographs are presented.

N. G. GONZALEZ, M.D.

Some Experiments in Rectal Pyelography Knut Wolke. *Acta Radiologica*, 1931, XII, No. 69, 49, 515.

The author compares the absorption efficiency of uroselectan and abrodil (skiodan), the latter being preferred and used in a group of 37 cases. Preparation of the patient and administration of the dye were done in the following manner:

Fluids were withheld for the twelve hours preceding the examination. Two hours after the patient had received an ordinary enema, roentgenograms were made of the urinary tract, after which four suppositories, each containing five grams of skiodan, were inserted into the rectum. The patient was then kept in a sitting position (to prevent ascent of the dye into the upper colon) for forty-five minutes. A roentgenogram of the urinary tract was then made. If there was evidence of dye in the kidney or ureters, compression was applied at the level of the sacroiliacs. The author repeatedly emphasizes the value of compression in all but retrograde pyelographic studies. A film was made about twenty-five minutes later and repeated every fifteen or thirty minutes, until results were satisfactory, or if no dye was noted two and one-half hours after administration, the procedure was stopped and a cleansing enema administered. Of 30 cases receiving 20 grams of skiodan, 18 showed good filling of one or both renal pelvis. The formula of the suppository used by the author was as follows:

| | | |
|----------------|-------|-------|
| Skiodan | 5 | grams |
| Ext belladonna | 0.007 | gram |
| Gelatini pulv | 2 | grams |
| Aq dest. | 1 | gram |
| Glycerini | 0.40 | gram |

DIAPHRAGMATIC HERNIA

Absence of Half of the Diaphragm (Thoracic Stomach, Diaphragmatic Hernia) Edward L. Jenkinson. *Am. Jour. Roentgenol. and Rad. Ther.*, December, 1931, XXVI, 899-903.

A case of thoracic stomach is reported, the diagnosis being first established roentgenoscopically when the patient was 68 years old. He had had more or less gastric complaint in the nature of spitting up of food and difficulty in swallowing since the age of 32. Roentgenoscopically the esophagus was found to be only about three inches long and to enter the stomach at the level of the sternoclavicular articulation. The greater curvature of the stomach was to the right, the pylorus to the left, pointing downward. The duodenal bulb was just about at the level of the normal esophageal opening in the diaphragm, intact on both sides, and the stomach empty at five hours.

Three cases of congenital absence of half of the diaphragm are also reported. Two were seen in the

new-born, one being left-sided absence, with the left chest containing small bowel and a portion of the large intestine, and the other right-sided absence, also containing parts of the large and small intestines. Both cases died a few days after delivery and each showed postmortem findings confirming the roentgenologic diagnosis. The third case occurred in a child, six years of age, who showed absence of the left half of the diaphragm, the stomach and splenic flexure being located in the left chest. This patient was submitted to operation but died. All three cases complained or showed signs of respiratory embarrassment.

EXPERIMENTAL STUDIES

The Significance of Unspecific Immunity in Cancer Therapy W Caspari Strahlentherapie, Dec 12, 1931, XLII, 899-912

The author gives in this paper a summary of his work published in a series of articles during the past 15 years and dealing chiefly with transplantation of tumors in mice and rats. He feels that the so called specific immunity plays an important role in the treatment of carcinoma.

ERNST A POHLE, M D, Ph D

Attempts to Record Alpha-ray Spectra of Very Low Intensity Georg Stetter and Roman Premm. Sitzb Akad Wiss Wien, Math-naturw Klasse, Abt IIa, 1931, CXL, 579-584

The purpose of the experiments was to overcome the difficulties of getting α -ray and H -ray pictures on photographic plates, these difficulties being due to the extreme sensitiveness of the photographic plate to many other influences. First, a suitable chemical process was sought, but nothing was found which would record a single α -particle. Next, a biologic method was tried. Fungus spores were embedded in gelatin on a plate and exposed to α -rays. The germination of the spores was reduced by the rays, but the plates could be used for qualitative observations only, since the proportion of naturally sterile spores varied greatly from plate to plate, and also the time required for germination was very variable. Last, a method was developed with a photographic plate, whereby if the α -rays impinged at nearly grazing incidence, the straight blackened track made by a single α -particle in the film could be observed microscopically and distinguished from blackening due to other causes.

CHEMICAL ABSTRACTS

Effects of Ultra-violet Rays, Radium, and X-rays on Proteins M Spiegel-Adolf Arch Path, 1931, XII, 533-542

Rays of short wave length produce effects on proteins that differ from the effects produced when

the protein solutions are heated to 100°. The reaction due to irradiation is irreversible. This criterion for differentiating between the two types of denaturation cannot be applied to proteins denatured in the presence of alkali, because, under these conditions, the heated protein also undergoes an irreversible change. Differences between alkaline solutions denatured by heat and those denatured by irradiation can, however, be detected easily with the aid of the quartz spectrograph or by determination of the dispersion quotients. Various types of rays, such as ultra-violet rays, X-rays, and Ra, produce effects on proteins that are qualitatively, though not quantitatively, similar. Coagulation of protein results from a few minutes of irradiation with the Hg arc, 3 hours' exposure to X-rays, and 9 hours' exposure to 80 mg of Ra.

The principal absorption bands of the solutions of proteins lie in the ultra-violet region of the spectrum. A conversion of part of the energy of Ra and X-ray radiations into ultra-violet rays should intensify the effect of these radiations on protein. Certain crystals that fluoresce in the ultra-violet region when irradiated by Ra or X-rays were enclosed in quartz tubes and immersed in the protein solution. Whereas proteins irradiated by X-rays and Ra without ultra-violet fluorescence exhibit no changes, the same proteins similarly treated in the presence of the fluorescent material are coagulated. Similar results were obtained with red blood cells and paramecia, and experiments are being carried on with tumor tissue of mice.

CHEMICAL ABSTRACTS

Transmission from Animal to Animal of the Fatal Toxic Disease Caused by the Filtrable Tuberculous Virus in the Guinea Pig Exposed to X-rays M Nasta, I Jovin, and M Blechmann Compt rend Soc de biol, June 30, 1931, CVII, 849-851

The authors were interested in determining whether the fatal toxemia resulting from inoculation of the filtrable tuberculous virus in the guinea pig exposed to X-rays could be transmitted. In order to prove that the transmitted disease was due to the tuberculous virus and not to a toxic property of the filtered products (urine, sputum, etc.), a series of guinea pigs were inoculated with a filtered tuberculous urine. Half the animals were submitted to X-rays. After each irradiation two irradiated animals and two non-irradiated, but all inoculated at the same time, were killed. The liver, spleen, kidneys, and lymph nodes of one of the animals were employed for inoculation to other guinea pigs, whereas the other served for microscopic examinations for tubercle bacilli and histologic survey of the organs.

The result of these experiments was that when transmissions were made with organs of animals inoculated with filtered

mals to which these transmissions were made (afterwards exposed to X-rays), developed fatal toxic accidents, whether or not the animals from which the organs were obtained had been exposed to irradiation. This proves that the toxicity of the filtrated products was due to the presence of a virus and not to toxic properties of the pathologic products (urine, sputum) of the organs injected. In addition, the presence of tubercle bacilli in the inoculated animals was demonstrated.

HENRY BAYON, M.D.

Effects of Cod-liver Oil and Ultra-violet Irradiation, as Influenced by Oyster Shell, in the Diet of Confined Laying Hens Walter A. Hendricks, Alfred R. Lee, and Albert B. Godfrey Jour Agric Research, 1931, XLIII, 517-535

Feeding cod-liver oil or administering ultra-violet irradiation to living hens confined without access to direct sunlight or green feed increased egg production and the thickness of the egg shells and improved the general condition of the birds. Both of these vitamin supplements also indicated a tendency to increase egg weight and improve the hatchability of the eggs. Cod-liver oil was superior to 15 minutes daily administration of the type of ultra-violet irradiation used as a supplement to the basal diet. When no cod-liver oil was included in the diet the addition of oyster shell increased egg production and thickness of egg shell even though mineral supplement was present in the basal diet. Oyster shell thus appears to be a source of easily available mineral or to contain a small amount of some factor which is present in cod-liver oil.

CHEMICAL ABSTRACTS

Microscopic Changes in the Internal Organs of Dogs after the Intravenous Injection of Tetraiodophenolphthalein Vsev Korkhoff and M. Okhowskaya Vestn Rentgenolog i Radiologii, 1931, IX, 105

Having observed that the intravenous injection of tetraiodophenolphthalein for gall-bladder examinations is often followed by various complications, the authors undertook a series of experimental investigations upon dogs. The experiments consisted in the intravenous injection of the dye in dogs and the microscopic examination of the tissues removed from the internal organs at various intervals after the dye injection. It was found that the sections of tissues removed from the animals a day after the injection showed definite abnormal changes, these changes being greater in the liver cells and bile ducts than in any of the other organs examined. Sections of tissues removed at later dates after the injection failed to show any abnormal changes.

The authors are of the opinion that some of the clinical reactions observed in human beings after the intravenous injection of the dye are due to the

abnormal changes which have taken place in the liver. They also believe that the more serious disturbances after the injection of the dye may be due also to impaired tissues in the liver as a result of some previous disease of the liver.

SAMUEL BROWN, M.D.

The Prevention of Experimental Duodenal Ulcer by Feeding Neutral Gastric Mucin M. S. Kim and A. C. Ivey Jour Am Med Assn, Nov 21, 1931, XCVII, 1511-1513

Fogelson found that from the gastric mucosa he could prepare a neutral mucin which had a high combining power for free acid. An ideal antacid, this does not markedly excite gastric secretion, is soothing or protective, and does not alter the body chemistry or disturb the gastro-intestinal tract. Under aseptic procedure a permanent biliary fistula was produced in twenty-seven days. A cholecystectomy was performed in all. The direct etiology of the ulcers following biliary fistula in dogs is unknown, the method having been used because of its simplicity.

Among the ten control dogs which received no mucin, ulcer of the duodenum developed in six, and three of the six had two ulcers. No ulcers developed in the seventeen dogs who received mucin with their food. On mucin, dogs with biliary fistula eat well and maintain their weight, which is not the general rule otherwise. On the basis of these observations, it is concluded that the administration of the mucin prevents ulcer formation in dogs with biliary fistula.

CHARLES G. SUTHERLAND, M.D.

Importance of Duration of Irradiations and Dose of Inoculated Virus for the Production of the Toxic Disease Caused by the Filtrable Tuberculous Virus in the Guinea Pig Irradiated with X-rays M. Nasta, I. Jovin, and M. Blechmann Compt rend Soc. de Biol., June 30, 1931, CVII, 847, 848

Following a previous investigation on the fatal toxic disease caused by the filtrable tuberculous virus in guinea pigs exposed to X-rays, the authors have endeavored to determine the number and minimal duration of the irradiations required to cause toxic phenomena in the experimental animals.

Six guinea pigs inoculated with 5 c.c. of filtered tuberculous urine were given a variable number (3, 2, 1) of exposures, lasting from 8 to 10 minutes each, two other animals were given only one exposure, lasting from 4 to 5 minutes. The interval between exposures was in general 5 days. The conditions of irradiation were identical in all the animals.

Of the two animals receiving 3 irradiations one died after the second irradiation 8 days after inoculation, with a loss in weight of 70 grams, the other died after the third irradiation 12 days after inoculation, with a loss in weight of 120 grams. Of the two receiving two irradiations one died in a

month, losing 120 grams, the other surviving. Of the two receiving only one irradiation, one died in 5 days, 7 days after inoculation, losing 90 grams, the other died more than a month after inoculation, losing 230 grams. Lastly, the two guinea pigs receiving only one irradiation with an exposure of only half the duration survived with a temporary loss of weight.

As demonstrated by these experiments, three exposures of the same intensity and duration were needed to produce fatal toxic results. It is true, however, that often the same results were obtained after one or two irradiations, these results depending evidently on individual differences in the animals (perhaps also on differences in toxicity of the virus employed), but these results are unusual, whereas after three irradiations death has been the uniform outcome.

In these animals, as in a number of others employed in previous experiments, the leukopenia occurring during the height of the toxemia reaches a level of from 5,000 to 6,000 leukocytes per cubic millimeter.

Regarding the importance of the dose of the inoculated virus, the authors have injected three groups of two guinea pigs each with 3, 2, and 1 c.c. of filtered tuberculous urine. The two animals inoculated with 3 c.c. and exposed to three irradiations both died one day after the last irradiation and 13 days after inoculation. The two animals inoculated with 2 and 1 c.c. have both survived after temporary loss of weight.

It follows from these experiments that the quantity of filtrable virus inoculated must not sink below a certain level in order to determine fatal toxemia.

HENRY BAYON, M.D.

Influence of Roentgen Rays on the Power of Fermentation of *Saccharomyces Cerevisiae*. Experimental Contribution to the Biologic Action of Roentgen Rays. Virgilio Gronchi. Bollettino dell'Istituto Sieroterapico Milanese, December, 1931, pp. 759-775.

From the results of numerous tests regarding the effect of roentgen rays on the power of fermentation of *Saccharomyces cerevisiae* in the presence of glucose, the author reached the following conclusions:

(1) Roentgen rays of 0.37 Å and from 0.16 Å, in dosages of approximately 600 to 1,800 r., exert on the *saccharomyces* a functional stimulus, as shown by increased speed in the production of CO₂.

(2) This stimulus of excitation, other conditions being the same, is proportional to the radiant energy involved.

(3) With equality of dosage and under like conditions the stimulative action is greater with hard rays than with soft rays.

W. W. WHITELOCK, Ph.D.

GALL BLADDER (NORMAL AND PATHOLOGIC)

An Effective Gall-bladder Stimulant to Supplant the Fat Meal. Lester Levyn. Am. Jour. Roentgenol and Rad. Ther., December, 1931, XXVI, 904.

Experiments were conducted to determine the effects of the various ingredients of egg-yolk in an effort to find an effective gall-bladder stimulant which would leave the stomach rapidly, thereby allowing the prompt beginning of a gastro-intestinal opaque meal examination. Lecithin was shown to be the most active stimulant to gall-bladder contractions, and it was found that by mixing fresh egg-yolk (45 gm.) with glycerin (55 gm.) and then adding 25 gm. of lecithin dissolved in 3 c.c. absolute alcohol, a mixture is obtained which is not unpleasant to take. In the standard dose of 10 c.c. it serves as an effective gall-bladder stimulant, yet passes rapidly out of the stomach and does not retard gastric peristalsis if a barium meal is given immediately upon completion of the cholecystographic study.

J. E. HABBE, M.D.

GASTRO-INTESTINAL TRACT (DIAGNOSIS)

Gastroscopic Control of the Roentgen Findings in the Contour of the Gastric Mucosa. R. Schindler and H. Sielmann. München med. Wochenschr., Nov. 20, 1931, LXXVIII, 1989-1991.

The articles of Berg, Chaoul, Forssell, and others on the roentgen visualization of the gastric mucosa are of great importance. Small carcinomas and superficial ulcers can be well outlined, but to obtain information on minute details, gastroscopy is far superior.

In three cases the contour of the mucosa was such that a carcinoma of the greater curvature near the cardia was diagnosed by means of the X-ray. Gastroscopy revealed only normal mucosa. The patients are well to-day.

A diagnosis of gastritis is often made by X-ray examination, but cannot be sustained by gastroscopy. Inasmuch as a carcinoma of the other parts of the stomach can be easily demonstrated by the relief method of Berg, the gastroscopic method has differed in only one out of seven cases. The roentgen findings were negative, but the gastroscope detected a secondary carcinoma near the cardia. In ulcer both methods have equal results. However, the authors are convinced that in gastritis the gastroscopic method gives more exact results than the roentgen method.

ERNST A. MAY, M.D.

Thoracic Stomach A Beutel Röntgenpraxis, Jan 1, 1932, IV, 40-46

The author intends to classify the roentgenologic symptomatology of the "thoracic stomach" on the basis of cases reported in the literature and one case of his own. In this case two-thirds of the stomach was in the right chest, and the esophagus was very short. Symptoms which had been present since childhood suggested a congenital anomaly. An ulcer niche complicated the picture. A pneumoperitoneum might, in selected cases, be useful for the differentiation of the hernia contents and the demonstration of empty portions of the hernial sac.

H W HEFKE, M D

A Case of Pancreatic Stones Diagnosed during Life Wilhelm Schöndube Röntgenpraxis, Dec 1, 1931, III, 1095-1099

Only a very few cases of pancreatic stones have been diagnosed before operation. A carefully taken history and several laboratory tests should give the clue to a possible presence of this disease (pain in the upper abdomen, radiating toward the left, & Heid's zone on the left).

The roentgenograms in a case described showed multiple calculi distributed through the upper abdomen in an arch-like fashion, the arch being open on the lower aspect. Barium in the stomach and duodenum showed the position of the stones as typical for the pancreatic region. Calcified mesenteric glands must be differentiated from them.

H W HEFKE, M D

The Mechanism of Gastric Evacuation J Earl Thomas Jour Am Med Assn, Dec 5 1931, XCVII, 1663-1668

There is quite general agreement on the main features of the gastric motor function. The characteristic motility of the stomach is a form of peristalsis, beginning as feeble contractions of the gastric musculature and furnishing the power which drives the chyme through the pylorus into the duodenum. There is definite evidence of opening of the pylorus with each wave of peristalsis.

Cannon found that chyme does not pass the pylorus at the approach of every peristaltic wave but occasionally, at irregular intervals. McCann was convinced that gastric evacuation depends on progressive relaxation of the pars pylorica, which he attributed to a change in irritability brought about by variations in the character of the gastric contents, chiefly digestion of protein. The character of the intragastric stimuli so far found to have an effect on the emptying process indicates that they are mainly concerned with delaying evacuation until a satisfactory degree of digestion has been attained. Available facts indicate that the principal function

of the pyloric sphincter is to furnish this resistance. Gastric evacuation occurs whenever the intragastric pressure near the pylorus exceeds the resistance due to the sphincter. Regulation results from stimuli due to conditions within the stomach and within the small intestine. The tonus of the pyloric sphincter is chiefly determined by stimuli affecting the stomach muscle as a whole. It serves as a constant resistance to the passage of chyme and blocks the exit of solid particles. By maintaining a narrow orifice it "filters" the gastric contents. By contracting when the duodenum contracts, it also limits regurgitation.

CHARLES G SUTHERLAND, M D

Gastro-intestinal Allergy Albert H Rowe Jour Am Med Assn, Nov 14, 1931, XCVII, 1440-1445

Gastro-intestinal symptoms in allergic patients have been noted by many observers. Food allergy probably produces more symptoms in the gastro-intestinal tract than in any other part of the body, because of the contact of foods with the tissues. It occurs most frequently in infancy and childhood and is apt to persist for many years. Edema of the mucous membrane and spasm of the smooth muscle produce disturbances in peristalsis and in function. Hepatic reactions are not infrequent. Allergic reactions in the urogenital tract, including the uterus, may also produce abdominal distress and pain. Symptoms may be immediate, delayed, or cumulative. Mild alimentary symptoms are undoubtedly more frequent than the marked or severe ones. Peptic ulcer in some patients may result from the action of digestive ferments in canker-like lesions in the gastric or duodenal mucosa.

Roentgen studies in 150 patients were negative, except for a spastic colon in twelve and moderate duodenal stasis in five. Roentgen studies with a milk vehicle for the barium are contra-indicated. When mild allergy is present, marked disturbance in function and peristalsis is apt to result.

Treatment consists of elimination of the specific foods productive of allergy. Desensitization to allergy-producing foods may occur in a few weeks or months with their total exclusion from the diet.

C G SUTHERLAND, M D

Common Anomalies of Duodenum and Colon Their Practical Significance Result of Eight Years' Combined Clinical and Roentgen Study John L Kantor Jour Am Med Assn, Dec 12, 1931, XCVII, 1785-1791

This study covers an eight-year period of a consecutive series of private patients complaining of digestive disorders.

Duodenal bands represent anatomically the unabsorbed portion of the free edge of the lesser curvature and are variously called hepatoduodenal, hepatocolic or cystocolic ligaments, depending on the

actual course of the anomalous membranes. When the first portion alone is involved, various deformities of the cap are observed roentgenologically. Bands involving the second portion of the duodenum cause a characteristic roentgen appearance. The most common associated anomaly is a low cecum. Most of the bands in the right upper quadrant are undoubtedly of congenital origin. Acquired adhesions may also occur.

Redundant colon (dolichocolon) is one which is too long to fit into the body of the owner, without undergoing reduplication. The most common variety is an enlarged sigmoid loop. Two subvarieties are encountered often enough to receive the descriptive terms "double splenic flexure, with straight efferent loop" and "pelvic loop to the right." Kinks of the colon, presumably due to adhesions, are rather frequent. In many, the stomach is displaced or deformed, resulting in "cascade" or "retort-shaped" stomach.

High cecum is the result of arrest in embryologic descent, low cecum being the result of embryologic hyperdescent. The chief clinical aspects of each are discussed, and the general significance of digestive anomalies is summarized.

CHARLES G. SUTHERLAND, M.D.

GENITO-URINARY TRACT (DIAGNOSIS)

True Prostatic Calculi. Joseph A. Lazarus and Arthur A. Rosenthal. *Urol and Cutan Rev*, February, 1932, XXXVI, 99-102.

A review of the literature revealed records of 370 cases of prostatic calculi, exclusive of the present series of 15 cases reported by the authors. It is believed, however, that many cases are not reported and that, therefore, this number is not a true index of the incidence of the condition. The introduction of roentgenography in routine urologic studies has shown it to be a rather common condition.

Prostatic calculi may be divided into the endogenous, or those calculi formed in the substance of the gland, and exogenous, which are formed in the urologic system and deposited in the prostate. The authors' series included only endogenous or true prostatic calculi.

The diversity of opinion regarding the etiology of prostatic calculi is an admission of failure in the discovery of the true causative factor. Sir Harry Thompson, in 1861, maintained that the corpora amylacea may under certain conditions lead to inflammatory changes within the prostatic acini, in which there occurs a deposition of calcium salts with the resultant formation of concretions. Trauma is believed to play an important rôle. Judd and Crenshaw are of the opinion that prostatic calculi result from a pre-existing prostatitis complicated by hyper-

trophy. In about 30 per cent of the cases, a positive history of gonorrhea is obtained. A pre-existing or existing infection within the gland in an individual who possesses a tendency to calcium deposits seems to the authors to be the most plausible cause for calculous formation in the majority of cases.

Prostatic calculi vary in size, consistency, and in their chemical constituents. The nucleus usually consists of an albuminoid substance, such as epithelial detritus, blood clot, a clump of bacteria, corpora amylacea, or necrotic tissue as a result of abscess formation. The surrounding laminated layers are made up of calcium phosphate, calcium carbonate, calcium oxalate, and ammonium magnesium phosphate. Most calculi are found in the lateral lobe and occasionally in the median lobe.

The symptoms of this condition in the order of their relative importance are as follows: Frequency, dysuria, perineal, penile, and rectal pain, urgency and tenesmus, hematuria, retention, impotencia, and hematospermia. Many calculi, particularly those deeply embedded in the gland, are asymptomatic and are accidentally discovered in a routine urologic study, with the aid of X-rays and digital examination. On digital examination a sensation of stony-hard substance, with crepitation, is diagnostic of this condition. Radiography, in addition to establishing the diagnosis, also indicates the position, size, and number of calculi present. Cystography will prove of value in cases in which it is difficult to ascertain whether the calculi are in the bladder or prostate.

Chronic prostatitis, with hard nodular inflammatory or malignant infiltrations, may often be mistaken for prostatic calculi, but cystoscopic and X-ray examinations usually suffice to make the differential diagnosis. Tuberculosis, with calcification of the prostate, often simulates prostatic calculi. In the case of tuberculosis, the associated involvement of other organs and the presence of tubercle bacilli in the urine aid in the diagnosis.

The treatment of prostatic calculi depends upon the presence of symptoms. In the symptomless case, surgical interference is contra-indicated and diathermy and massage are recommended. Suprapubic prostatectomy is the procedure of choice when an adenoma is found associated with prostatic calculi.

J. N. ANÉ, M.D.

Fibrin Stones of the Urinary Tract. Report of Two Cases. Neil S. Moore. *Urol and Cutan Rev*, February, 1932, XXXVI, 90-93.

Fibrin stones of the urinary tract are considered by most authors to be a very rare condition. The first case was reported by Marcell, in 1817, and up to 1930, 26 cases, which were found at operation or autopsy, had been reported. The author describes two additional cases of this condition.

Fibrin stones have been thought to result from

blood clots, masses of coagulated inflammatory exudate, clumps of bacteria, and pus, or from true stones which have lost their mineral matter. Infection of the colon bacillus group is a constant finding in these cases. Ikoma considers faulty metabolism of great importance in the etiology.

The consistency of fibrin stones is that of putty. A definite capsule is usually present and the stones may be faceted. While the stones are more commonly found in the kidney pelvis in large numbers, they are occasionally encountered in the bladder, in which case they are fewer in number and larger in size.

Since fibrin stones are almost always accompanied by infection, the symptoms are those of pyelonephritis. Roentgenograms fail to reveal definite shadows of the stones, however, in one of the author's cases, negative shadows resembling gas bubbles were noted, and in Pedroso's case, negative shadows were observed on the pyelogram.

The treatment is limited to either pyelotomy or nephrotomy. In the opinion of the author, nephrectomy is the operation of choice in those cases in which a normal kidney is present on the opposite side.

J. N. ANE, MD

Two Cases of "False Route" Determined by Urethrography Italo Levi Archivio Italiano di Dermatologia, Sifilografia e Venereologia, November, 1931, VII, 501-505

Radiographic examination of the urethra is not only useful in many cases but even indispensable. Such cases include all forms of chronic blennorrhea, in which urethrography brings into evidence lesions not easily subject to diagnosis by other methods, both as regards affections of the urethra itself as well as alterations in the glandular adnexa. Fröhwald was thus able in numerous cases of chronic blennorrhea to demonstrate small abscesses of the prostate which were not observable clinically. Indeed, the prostate appeared even normal under clinical examination.

The most positive indication for roentgenographic examination of the urethra is seen in cases of stricture, especially those resulting from gonorrhoea, less frequently those of syphilitic origin. Urethrography furnishes an exact picture both of the nature and extent of the stricture, and reveals the eventual presence of numerous strictures at different points. In addition, the physician is made aware of the existence of so-called "false routes," into which the sound may penetrate, giving rise to serious disturbance, and even to hemorrhage. Determination of the existence of these "false routes" before employing the sound is of the greatest practical importance, and may lead to a complete change of treatment.

As regards harmlessness of the procedure, despite

the fact that a considerable quantity of lithium iodide entered the blood circulation, the author states that patients suffered no marked disturbance, beyond a pronounced metallic taste noticed immediately after the urethrography and persisting for several hours. Likewise, locally there were no inflammatory symptoms resulting from the lithium iodide.

W. W. WHITELOCK, Ph.D.

Renal Hematuria from the Standpoint of the Roentgenologist Ira H. Lockwood Urol and Cutan Rev., February, 1932, XXXVI, 84-88

The author emphasizes the importance of renal hematuria in the symptomatology of many genito-urinary conditions. Very often a patient complaining of hematuria is referred to a roentgenologist, and when no stone is found, the physician and the patient minimize the importance and gravity of this symptom. Also, because the bleeding is usually intermittent and of transitory nature, both are lulled into a condition of false security, and the opportunity for the early recognition of incipiency is lost, irreparable damage resulting. While blood in the urine does not always mean the presence of organic disease in the genito-urinary tract, hematuria in any case should be considered always of sufficient importance to indicate a careful and thorough examination in an effort to determine the nature of the bleeding.

The sources of the bleeding may be considered as intrinsic and extrinsic lesions of the genito-urinary tract, systemic causes, and essential hematuria. The most common causes of renal hematuria are tuberculosis, calculus, infection, and tumors. The author reports five cases, which illustrate various sources of hematuria, and the diagnostic and therapeutic methods employed.

J. N. ANE, MD

Cholecystitis and Cystic Duct Obstruction Significance in the Formation of Gallstones Rich in Calcium Carbonate and in Calcification of the Gall-bladder Wall Preliminary Report D. B. Phemister, Allan G. Rewbridge, and Hillier Rudisill Jour Am Med Assn., Dec. 19, 1931, XCVII, 1843-1849

This is a review of seven cases showing the significance in the formation of gallstones rich in calcium carbonate and in calcification of the gall-bladder wall. The observation was made that in every case the cystic duct was obstructed by a cholesterol-bile pigment or cholesterol stones, indicating that the duct obstruction was a precursor to and a determining factor in calcium carbonate stone formation in the gall bladder. Following obstruction calcium carbonate was thrown out in large quantities. It appears that the order of development of changes was First, there was cholecystitis and cholesterol or cholesterol-pigment stone formation. Calcium car-

bonate and a trace of calcium phosphate were then excreted by the wall of the gall bladder, forming a semi-solid to soft white stone, incorporating other stones when they were present. The indications are that calcium carbonate stones are formed only when bile is excluded from the gall bladder by the obstructing stone, or when the amount entering is greatly reduced.

No explanation has been found for the selective excretion of calcium carbonate over long periods of time in such cases. The assertion that the calcium carbonate of all gallstones is proved out in connection with the mucus formed by the epithelium of the gall bladder is supported by the fact that calculi are occasionally found in the salivary ducts and pancreas, where there is also mucous secretion.

C G SUTHERLAND, M D

A New Case of Double Ureter Pedro Moreyra Bernan La Prensa Med Argentina, Dec. 20, 1931, XVIII, 939-946

Abnormalities of the kidney and ureter, which are frequently encountered, may be the cause of functional disturbances and may modify the symptoms and diagnosis of renal lesions. For that reason, the author gives a review of the different abnormalities, particularly of the ureter. He then proceeds to present the case of a woman, 25 years of age, who came to him sixteen months after giving birth to a child. She complained of backache and pain after urination. These symptoms had not caused much discomfort until three months prior to admission to the hospital, when they gradually became aggravated. There was blood after urination, which occurred five times nightly. On physical examination, there was found tenderness all over the abdomen but particularly over the right kidney region and the left iliac fossa. Cystoscopy revealed two distinct ureters on the right side of the trigone, one higher than the other, urine was collected from the one on the left. A pyelogram was made and the two ureters were found to be independent in their courses from the kidney to the bladder.

In this case, a correct diagnosis could not possibly be made on the symptoms, which pointed to a chronic pyelitis and cystitis. The pain in the right renal area was probably caused by a mild degree of hydronephrosis in the inferior pelvis. The patient improved rapidly by means of cystoscopies and lavage of the two right kidney pelvis with silver nitrate.

N G GONZALEZ, M D

The Significance of Hematuria, with Special Reference to Early Diagnosis William J Wallace Urol and Cutan Rev, February, 1932, XXXVI, 79-82

Hematuria is often the first evidence of major pathology in the genito-urinary tract and may precede subjective and physical manifestations by many

weeks, months, or years. While the causes of hematuria are numerous, the vast majority can be traced to one of the following: Inflammation, tuberculosis, calculus, newgrowths, and trauma. Blood is also found in the urine in many systemic diseases and as the result of poisoning by certain chemicals.

The discovery of the cause of hematuria and the diagnosis of the primary condition require a careful and complete study of the individual case. The family history is of considerable importance, for conditions such as hemophilia, tuberculosis, blood dyscrasias, purpura, or cancer may be disclosed. The personal history should be complete in regard to previous systemic conditions in general and to genito-urinary inflammatory diseases, trauma, and abnormalities in particular. The age and occupation of the patient should always be recorded. The character of the bleeding is a very significant part of the history, and its mode of onset, duration, frequency, amount, and the presence or absence of associated pain should be carefully considered.

The physical examination should be complete with careful attention to every detail. Rectal examination should be made in every case and the prostate carefully examined in all male patients. Vaginal examination and palpation are of equal importance in females. Pathologic involvement of the tubes, ovaries, or uterus can be thus investigated.

Endoscopic examination should be the next procedure in cases of hematuria. The author believes that this procedure can be rendered practically painless by giving sodium amyta by mouth half an hour previous to commencing. This is followed by urethral instillation of a dependable surface anesthetic. After thorough endoscopic examination, the cystoscope is substituted for the endoscopic instrument. X-ray catheters are passed then to the renal pelvis on either side, and a specimen of urine collected from each side. Functional tests should be made to obtain additional information regarding the state of each kidney. Thereafter, a roentgenogram of the entire urinary tract should be made, and this followed in turn by a pyelographic examination. A third exposure is advised, with the patient in the semi-erect position and the opaque catheters partially withdrawn until their tips are about an inch above the ureteral orifice. In the opinion of the author, intravenous pyelography should not be depended upon alone, but should be employed merely as a check for retrograde pyelography.

J N ANE, M D

GENITO-URINARY TRACT (THERAPY)

The Basis for Management of Ureteral Calculi Based on the Study of Five Hundred and Sixty-five Cases Ralph L Dourmashkin Jour Am Med Assn, Jan 23, 1932, XCIVII, 276-283

This series represents 589 stone problems. A

blood clots, masses of coagulated inflammatory exudate, clumps of bacteria, and pus, or from true stones which have lost their mineral matter. Infection of the colon bacillus group is a constant finding in these cases. Ikoma considers faulty metabolism of great importance in the etiology.

The consistency of fibrin stones is that of putty. A definite capsule is usually present and the stones may be faceted. While the stones are more commonly found in the kidney pelvis in large numbers, they are occasionally encountered in the bladder, in which case they are fewer in number and larger in size.

Since fibrin stones are almost always accompanied by infection, the symptoms are those of pyelonephritis. Roentgenograms fail to reveal definite shadows of the stones, however, in one of the author's cases, negative shadows resembling gas bubbles were noted, and in Pedroso's case, negative shadows were observed on the pyelogram.

The treatment is limited to either pyelotomy or nephrotomy. In the opinion of the author, nephrectomy is the operation of choice in those cases in which a normal kidney is present on the opposite side.

J. N. ANE, M.D.

Two Cases of "False Route" Determined by Urography. Italo Levi. Archivio Italiano di Dermatologia, Sifilografia e Venerologia, November, 1931, VII, 501-505.

Radiographic examination of the urethra is not only useful in many cases but even indispensable. Such cases include all forms of chronic blennorrhea, in which urethrography brings into evidence lesions not easily subject to diagnosis by other methods, both as regards affections of the urethra itself as well as alterations in the glandular adnexa. Fröhwald was thus able in numerous cases of chronic blennorrhea to demonstrate small abscesses of the prostate which were not observable clinically. Indeed, the prostate appeared even normal under clinical examination.

The most positive indication for roentgenographic examination of the urethra is seen in cases of stricture, especially those resulting from gonorrhea, less frequently those of syphilitic origin. Urography furnishes an exact picture both of the nature and extent of the stricture, and reveals the eventual presence of numerous strictures at different points. In addition, the physician is made aware of the existence of so-called "false routes," into which the sound may penetrate, giving rise to serious disturbance, and even to hemorrhage. Determination of the existence of these "false routes" before employing the sound is of the greatest practical importance, and may lead to a complete change of treatment.

As regards harmlessness of the procedure, despite

the fact that a considerable quantity of lithium iodide entered the blood circulation, the author states that patients suffered no marked disturbance, beyond a pronounced metallic taste noticed immediately after the urography and persisting for several hours. Likewise, locally there were no inflammatory symptoms resulting from the lithium iodide.

Cholecystitis and Cystic Duct Obstruction. Significance in the Formation of Gallstones Rich in Calcium Carbonate and in Calcification of the Gall-bladder Wall. Preliminary Report. D. B. Phemister, Allan G. Rewbridge, and Hillier Rudisill. Jour Am Med Assn., Dec. 19, 1931, XCVII, 1843-1849.

This is a review of seven cases showing the significance in the formation of gallstones rich in calcium carbonate and in calcification of the gall-bladder wall. The observation was made that in every case the cystic duct was obstructed by a cholesterol-bile pigment or cholesterol stones, indicating that the duct obstruction was a precursor to and a determining factor in calcium carbonate stone formation in the gall bladder. Following obstruction, calcium carbonate was thrown out in large quantities. It appears that the order of development of changes was first, there was cholecystitis and cholesterol or cholesterol-pigment stone formation. Calcium car-

ing sensation locally and along the course of the vein. This sensation—thought to be due to a local action of the drug on the endothelium—has disappeared when the injection is stopped. The authors do not recommend prolonging the time of the injection because of the rapid elimination of the dye by the kidneys. They report the best results when the films are exposed from 10 to 15 minutes after the end of the injection.

In order to obtain good pyelograms it is necessary that the renal function be good. The intensity of the pyelogram depends directly upon the renal function. When there is a lesion of the kidneys bilaterally, the shadow either is opaque or does not show at all. Naturally the intensity of the shadow depends on the concentration of the dye in the urine, a concentration of at least 5 per cent being necessary for good results. When sodium bromide is used, a concentration of 20 per cent is required. If there is an obstruction to the urine flow, the shadows above this obstruction will be more intense because of the urine concentration. Another point in favor of uroselectan is the fact that when it is used the urinary tract is studied in its normal physiologic condition. This is not true of the catheter method of pyelography. When one compares the intravenous with the catheter method, one cannot fail to favor the former.

By means of the above method the authors have found the following changes to occur:

(1) Obstruction to the urine flow at the level of the innominate line. This they believe to be due to the uterine compression on the ureters as they cross the pelvis.

(2) Dilatation of the ureters above the compression. This they attribute to the retarded flow of urine.

(3) There is a compensatory change between the two ureters. When one is dilated, the other is found to have a smaller diameter in proportion.

JOSEPH MALDONADO, MD

Six Hundred Hysterosalpingographies Diagnostic Errors and Dangers Günter K F Schultze Röntgenpraxis, Dec 15, 1931, III, 1105-1108

Of 600 hysterosalpingographies, 250 were checked by surgery and 200 by repeated examinations. Technical errors were responsible for 90 per cent of all wrong diagnoses; they consisted of too small a filling (too little lipiodol) or too large a filling, the examiner having neglected to watch the injection with the fluoroscope and to take a roentgenogram twenty-four hours afterwards. The percentage of diagnostic errors naturally decreases with the technique and experience of the examiner. A correct diagnosis, as far as the structure and pathology of the tubes is concerned, may be made in over 90 per

cent of cases. The diagnosis of a myoma of the uterus can be made in over 80 per cent of all cases, and of ovarian tumors in only about 50 per cent. In 8,300 hysterosalpingographies, done with iodized oils, and reported in the literature, three deaths and 30 inflammatory complications were reported. The actual percentage of harmful sequences is probably greater. No deaths took place in this series, and inflammatory complications were seen five times, which, however, did not lead to permanent damage.

To avoid complications one should make a careful selection of cases, should examine in the middle menstruation cycle, and should use lipiodol as contrast material. The injecting should be done under the fluoroscope, no intra-uterine instruments being used, and no force being employed. The amount of oil should be as small as possible and the uterus should be emptied. After the examination, bed-rest should be advised. If these points are remembered and followed, this method gives very satisfactory results.

H W HEFKE, MD

Hysterosalpingography as a Help in Gynecology A Roentgenologic and Clinical Study S W Leibow and Dr Goldstein Rontgenpraxis, Jan 1, 1932, IV, 16-31

The authors review 61 hysterosalpingographies which they had performed. This method is very valuable, giving information about anatomy and function of the uterus and tubes. The diagnosis of gynecologic diseases is made clearer by it, and anomalies of the uterus might be graphically demonstrated.

The peristalsis of the tubes seems to take place in three ways, wavelike, pendulum type, and the "ballstring" type. An early pregnancy can be shown, but the method should, at present, be used only in cases in which a therapeutic abortion is indicated. Repeated films, taken at not too long intervals, seem necessary in order to show a spasm of the tubes. If such spasm of the uterine end of the tubes is suspected, only a small amount of lipiodol or iodipin (about 2 c.c.) should be injected under low pressure.

The advantage of lipiodol injection over Rubin's air test is that it shows much more than only the patency or occlusion of the tubes. Surgery seems indicated only when the abdominal end, not other portions, of the tube is occluded. If one irradiates the ovaries without effect, this method can locate the ovary. It can be done without danger very easily, if technically correct and with the right indication, without confining the patient to the hospital. There will probably be many more facts found by its use in anatomy, physiology, and pathology of the uterus and tubes.

H W HEFKE, MD

stone may be lodged in a ureter for a considerable length of time without seriously hampering kidney drainage and without producing pelvic infection or extensive changes, marked by hydronephrosis or a chemical pyelonephritis. The routine injection of opaque solutions into the renal pelvis in the presence of ureteral obstruction should always be regarded as a procedure pregnant with dangerous possibilities. With the advent of intravenous pyelography a new, practically harmless medium for obtaining information, regarding changes taking place above the obstructing stone, immediately has become available. In addition, it determines the all-important fact relative to maintenance of renal function. Temporary cessation of renal function may produce a total absence of the dye shadow in the affected side. These should not be mistaken for cases of serious renal obstruction. An indwelling catheter will, as a rule, quickly restore the *status quo* of renal function.

C G SUTHERLAND, MD

GRENZ RAYS

Grenz-ray Therapy Alfred Reisner Röntgen-praxis, Jan 1, 1932, IV, 7-10

A critical study of the value of the Grenz rays is possible only when one confines oneself to the publications which are based on exact measurement of quality and quantity of the radiation. The author uses 0.02 mm Al half value layer, 10 kilovolts, and 10 ma, the distance is 10 cm in localized, and 15 cm in general, irradiation. A single dose of 5,000 r did not cause epilation.

The question of their separation in biologic action from ultra-violet and roentgen rays is not settled. Treatment of superficial diseases of the skin has been greatly improved by the utilization of these rays. Even if X-rays and Grenz rays lead to the same improvement, the Grenz rays ought to be preferred, because the deeper tissues are not affected by them. Superficial nevi can be made to disappear. Tuberculous diseases of the skin require high doses. Carcinoma of the skin should not be treated by Grenz rays, but by roentgen and radium rays. The general action of Grenz rays on the entire body, used in generalized skin diseases and internal diseases, has not been definitely proven as yet in the author's opinion.

H W HEFFE, MD

Grenz-ray Therapy in Dermatology E Lachmann and L Loewenstein München med Wechschr, Oct 16, 1931, LXXVIII, 1793-1795

The authors give a general view of the physical properties of the Grenz rays and of their indications. The rays are a valuable addition in the therapeutic armamentarium of the dermatologist.

E A MAY, MD

GYNECOLOGY AND OBSTETRICS

Renal Pelvis and Ureteral Changes during Pregnancy F Carreras, F Farxat, and I Figueras Rev Med Cubana, January, 1932, XLIII, 75-81

A previous piece of work on this subject gave the authors the thought that there must be some changes taking place in the kidney pelvis and ureters during pregnancy. These changes, the authors believe, are predisposing factors in the causation of pyelitis, which is reported in the literature to occur in from 40 to 66 per cent of the cases of pregnancy, varying according to the author reporting. Most of the authors report the condition as occurring more frequently on the right side. Kretschmer and Heaney believe it occurs in from 80 to 85 per cent of cases. By means of cystoscopy, ureteral catheterization, and pyelography, Carson reports that the capacity of the right ureter changes from 13 c.c. to 100 c.c., and the left side increases to 80 c.c. during pregnancy. The changes found at examination and at autopsy are Dilatation, change in course, strangulation, and kinking.

The changes in position are due to a compression of these structures by the uterus. With normal fetal position, there is an increase in pressure to the right, which accounts for the more frequent changes on this side. The authors have also noted a change that varies from a constriction to a kink, which is usually found just a few centimeters below the kidney pelvis. This they believe to be due to a compensation, with the dilatation below.

The compression of the ureters against the innominate line is not recognized by the authors, but they are of the same opinion as Beaufond, Porcher, Legueu, and Vaudescal, namely, that it is due to a lack of contractility of this part of the ureters. This is more evident when one considers the changes in texture of the ureteral walls. There is a definite rigidity of the walls produced by an increase in tissue of a non-contractile nature. A hyperplasia of the walls is also observed.

In the technic of this study the authors used uroselectan exclusively, because the drug is excreted entirely by the kidneys. After describing the composition of and mechanics of the action of uroselectan, they describe their technic in detail. In doing uroselectan pyelography the authors recommend the following. The colon must be thoroughly clean, as when exploratory pyelography is done. They use 30 gm of the drug dissolved in 100 c.c. bidistilled water. After this solution is sterilized in the autoclave, it is injected intravenously either by means of a syringe or by the Murphy drip. The drug is injected slowly, but not so slowly as when gallbladder visualization is done. The authors take from 10 to 15 minutes to inject the solution. In this way, they have not experienced much reaction. The only complaint that patients have made is of a burn-

the specialist but also to the general practitioner. Lately, there has been great progress made in osteo-articular surgical pathology, with predilection to the coxofemoral articulation, but this knowledge has been imparted only to the specialist. Sometimes, the diagnosis of an infectious process is made, but the family is restless, a complete clinical and radiologic examination is made and syphilitic osteitis diagnosed, thus changing the whole treatment.

Since this subject is so extensive, the purpose of the author is to present certain fundamental conditions, such as the classification of the diverse syndrome of the hip and the corresponding physiopathologic conclusions. He then presents the teachings of Allison, concerning articular pathology and physiology. He believes that the advent of the X-ray broadens the horizon of medicine, particularly in the pathology of bone. Here, it brought to light new entities or corroborated previous findings. From 1908, when Köhler advanced the matter of epiphysitis, through Perthes, who described osteo-arthritis deformans juvenilis, up to the present, our knowledge has been gradually increasing. The author then discusses the classification of such conditions and concludes that the clinical findings are of no importance in comparison with those of the X-ray.

N G GONZALEZ, M D

Meniscitis of the Knee Joint Extracondylloid Luxation Ricardo Finocchietto and Augusto A. Corvaro La Prensa Méd Argentina, Dec 10, 1931, XVIII, 901-904

Usually a severed meniscus has the tendency to have its free part in the intercondylloid space. The purpose of this paper is to present three observations in which the position adopted by the fractured cartilage was completely the opposite, the free portion of the cut meniscus being outside the surface of the interline, thus forming a true extracondylloid luxation. The first case, a boy 17 years old, fell down in forced left genu valgum. There was great pain in the posterior part of the knee and, later on, tumefaction and other symptoms of meniscal lesion. This type of accident happened three times to the same patient. He was operated on, diagnosis was confirmed, and damage repaired.

The second case, a man 22 years old, while playing football hit his left leg in forced flexion. He felt severe pain which was followed later by tumefaction. The same accident happened twenty days later. The identical condition is above was found on operation.

The third case, a man, 20 years old, while playing football, was hit by the foot of another player on the left popliteal region. He fell down with his leg flexed. There was severe pain in the whole articulation, but within twenty minutes it disappeared.

On examination, there was felt a small posterior tumefaction. He was also operated upon and diagnosis confirmed. The authors conclude their paper by presenting a radiograph of the third case and stating that the two outstanding symptoms are (1) tumefaction of the internal side of the articulation and (2) the "jump sign" of the meniscus (movement of the meniscus when caught between the examining finger and the bone).

N G GONZALEZ, M D

NERVOUS SYSTEM (GENERAL)

Radiotherapy of the Sympathetic System in Certain Cardiovascular Affections L Delherm and Henri Beau Jour d'Rad et d'electrol, July, 1930, XIV, 391-401

Observations on the successful treatment of seven cases of Raynaud's disease were made. In all these cases the cervicodorsal region was irradiated, however, recently peripheral irradiations have been employed with success. Only one case of obliterative arteritis is reported. Considerable improvement occurred after irradiation of Scarpa's triangle and the popliteal space. Successful cases treated by others are noted.

Radiotherapy in Raynaud's disease not only stops the local asphyxia but also causes a cicatrization of the ulcers. Capillary circulation improvement is most marked in recent cases, but not rarely is improvement seen in older ones. When scleroderma accompanies this condition, one can observe the loosening of the derma.

This treatment causes a cessation of the spasm and dilates the collaterals so that the claudications stop, pain is relieved, and the color and temperature return to normal. Positive reaction to a hot foot bath is a good prognostic sign of the efficacy of the treatment. A negative reaction calls for a guarded prognosis.

For the upper extremities, irradiation should include the cervicodorsal region to the second dorsal vertebra for the lower extremities, the region from the tenth dorsal to the second lumbar vertebrae. It is advisable also to irradiate areas all along the vessels of the limb. Two symmetrical fields on each side of the vertebral column FSD 25 cm, filter Al = 5 mm, 400 r at each application, 3 applications a week, from 1,200 to 1,600 r per series a week with at least three weeks' rest after each series. For the irradiation of the extremities it is logical to reduce the filtration (to 2 mm) and the voltage as well. An attempt is made to explain the action of the X-ray and its effect on the sympathetic system and not on a modification of the suprarenal secretion. The action is thought to be due to its inhibitory effect on the intermedio-lateral tract and its

HEART AND VASCULAR SYSTEM (DIAGNOSIS)

Multiple Aneurysms of the Aorta in a Six-year-old Girl M Acuña, P Winocur, and G Orosco P La Prensa Méd Argentina, Nov 20, 1931, XVIII, 788-795

This is undoubtedly a very interesting case because of the age of the patient. The family history was suggestive of syphilis. The patient, a six-year-old girl, was always weak. Three months prior to her visit to the authors, she had edema of both ankles, which disappeared after two weeks in bed. Shortly afterward, it was noticed that she was failing in health, had become pale, and developed edema of the feet and ankles, accompanied by urinary disturbances. Physical examination revealed an enlargement of the mediastinum, heart, and liver, tachycardia, and a flattening of the tips of the fingers. The Wassermann reaction was weakly positive. A radiogram of the chest showed an enlarged globular heart. The patient started suffering with a dyspneic attack and died twenty-seven days later. At autopsy the following conditions were found: Multiple aneurysms of the aorta, dilatation of the heart, sclerosis of the auriculo-ventricular valves and of the parietal endocardium, and syphilis of the aorta and pulmonary arteries.

N G GONZALEZ, MD

Aneurysmatic Persistence of the Arterial Canal and Aneurysmatic Dilatation of the Pulmonary Artery Carlos Rodrigue and Antonio Battro La Prensa Med Argentina, Dec 30, 1931, XVIII, 986-995

The authors present this case because of its rarity, and also to show the successful results obtained by clinical studies aided by the X-ray. The case here given was of a woman, 27 years of age, who since childhood has been seized with nocturnal epileptiform attacks. When three years old, she was examined by a physician who stated that she had a murmur over the heart. At twelve years of age, she was examined again and the murmur was not found. She was in perfect health until four years ago, when she started complaining of shortness of breath either while resting or exercising, hemoptysis, and pain over the right shoulder.

When examined by the authors, she was found markedly short of breath, and there was present cyanosis of the lips and conjunctiva on the slightest exertion. In the heart, the first sound was found to be blurred in character, while the second was accentuated. A radiograph showed a rare and peculiar heart shadow, the right border being formed in its superior part by the vertebral column and at its lower part by a rather pronounced arch, corresponding to the right auricle. On the left side, there

is observed an arch which runs upward and outward and extends from the second to the fourth intercostal space, where it becomes continuous with the heart shadow. The heart seems to have been displaced to the left so that it almost touches the lateral chest wall, being rotated to that side. There is also seen a light shadow which seems to separate the inferior border of the heart (right ventricle) from the superior border of the right diaphragm. Several radiographs were taken in different positions and the same shadow of the middle arch was noticed.

By a process of elimination, the diagnosis rested upon aneurysm of the pulmonary artery. The X-ray findings did not warrant that diagnosis, so the authors concluded that they were dealing with an aneurysmatic dilatation of the pulmonary artery and an aneurysmatic persistence of the arterial canal.

N G GONZALEZ, MD

HODGKIN'S DISEASE (DIAGNOSIS)

A Contribution to the Question of Lymphogranulomatosis of the Lungs (Roentgenologic Diagnosis and Treatment) W N Bobretzka and J B Porchownik Röntgenpraxis, Nov 15, 1931, III, 1034-1045

Ten cases of involvement of the lungs by Hodgkin's disease are described. In five cases a biopsy had been done, in one an autopsy and in the other four the clinical picture was so typical as to exclude other diseases. Invasion of the lungs in this disease is not infrequent.

The pathologic changes consist in (1) Specific granulomatous growths, and (2) non-specific secondary changes (compression of bronchial walls, atelectasis, etc.). The roentgen picture is various and not typical; all the signs usually evidenced by other tumors may be present, such as invasion, compression, metastasis, and chronic inflammatory processes. The roentgen examination alone does not allow a diagnosis in many of these cases, and a roentgen appearance of a malignant tumor of the lungs does not always exclude Hodgkin's disease.

A biopsy is indicated if glands are present, otherwise a trial series of roentgen treatments, which usually leads to a quick positive effect, is recommended. The treatment should be done carefully so as to avoid a general reaction. Lymphogranulomatosis of the lungs in the terminal stage is influenced very little.

cerebral ganglions, also the small perivascular ganglions

There follows a review of the cases of angina pectoris, reported in the literature as treated by irradiation. Three cases are added in which the intensity and frequency of the pain were lessened after irradiation. The same technic as given above was used except that the irradiation was given over the heart and aorta from the back and anteriorly.

RADIATION

Concerning the Question of the Distribution of Roentgen Intensity in the Body during Deep Therapy Part III—Measurements with the Photographic Method M Dorneich Strahlentherapie, March 9, 1932, XLIII, 441-489

The author has continued his studies concerning "isodoses" and presents in this paper the results of investigations dealing with the development of a reliable photographic method (See *Strahlentherapie*, 1930, XXXVIII, 491, 1931, XLII, 56). The apparatus used is described in detail and the possible sources of error are carefully considered. A few examples of the obtained isodose charts are shown, and their general characteristics are discussed. It appeared that the results of Dessauer's and Vierheller's work (1920) could be confirmed, with the exception of minor deviations. In another article which is to follow soon the entire set of "standard isodose charts" will be published.

ERNST A POHLE, M D, Ph D

Radiotherapy of Blood Diseases G Bignami Strahlentherapie, Jan 9, 1932, XLIII, 43-67

This is a translation of a report presented by the author before the Ninth Italian Congress on Medical Radiology, in Turin. He discusses in great detail all phases of a field which offers many puzzling problems to the radiologist. All types of leukemia and aleukemia, erythrocythemia, lymphogranulomatosis, Gaucher's disease, Mikulicz's disease, chloroma, myeloma, lymphosarcoma, and purpura are discussed. Strict individualization must be regarded as the supreme rule in radiation therapy of blood diseases. In leukemia small or moderate doses seem preferable, if the white count has dropped to about 25,000, an interval in the treatment is usually indicated. Higher doses are recommended for both

polycythemia and Hodgkin's disease. It must be admitted, however, that many radiologists obtain excellent results in lymphogranulomatosis with moderate doses. In purpura the irradiation of the spleen with high doses and of the bones with small doses seems indicated. Pernicious anemia does not respond, in the author's opinion, to radiation therapy.

ERNST A POHLE, M D, Ph D

The Treatment of Chronic Leukemia Franz Bardachzi, Richard Epstein, and Ernst Fiedler Med Klinik, Nov 13, 1931, XXVII, 1671-1674

The technical progress in radiology has been so great that difficulties in applying the desired dose and intensity of X-rays do not exist to any extent. A statement, which is often found in the literature, to the effect that the life of a patient with leukemia is not prolonged, must be corrected. Not to advise roentgenotherapy in these cases is a mistake, which, unfortunately, is still made by some physicians. The authors report 26 cases of myelogenous leukemia and 9 of lymphatic leukemia. In myelogenous leukemias the spleen, bones, liver, or the entire body may be exposed to the X-ray. In previously untreated cases irradiation of the spleen alone is usually sufficient. Serial blood examinations give the indication for the type of treatment. Small repeated doses seem to be tolerated better than larger ones. General reaction must be avoided. An initial dose of one-fourth of an erythema dose is often too large (180 KV effective and a filter of 0.5 mm Cu and 1 mm Al were used). The bones should be irradiated only if the response to splenic irradiation is not marked enough. When the white cells reach 20,000, the treatment should be interrupted. The Teschendorf method of irradiating the entire body, with very small doses and from long distances, seems to give good results in otherwise resistant cases. Irradiation is contra-indicated in the terminal stages. The lymphatic leukemias are treated by softer rays and the bones are not exposed. The localized glandular masses are irradiated by comparatively soft rays in order to avoid damage to the blood-forming organs.

The skeptical view taken by many physicians, as far as the radiologic treatment of leukemias is concerned, is not justifiable, but the task of choosing the right technic for each individual case still remains to be settled.
